Graft versus host disease (GvHD) is a potentially life-threatening condition that occurs most commonly after allogeneic transplantation of bone marrow or stem cells, and less frequently after organ/tissue transplantation. GvHD can present as an acute disease, or it can develop more slowly, resulting in a chronic condition affecting multiple tissues and organs. Allogeneic (acute and chronic) and xenogeneic GvHD models have been developed in mice that aim to replicate some of the clinical manifestations seen in human disease. However, endpoints such as GvHD scoring which are commonly used to track disease progression are subjective and difficult to replicate consistently. In addition, terminal sampling as well as longitudinal blood sampling for biomarker analysis often requires the use of satellite groups which is costly and at odds with the principles of 3R animal usage. To overcome these challenges, we describe the novel use of a Vega ultrasound imaging system (Revvity, Waltham, MA, USA), to monitor longitudinal changes in splenic volume, a well-known biomarker associated with GvHD and other diseases. To determine the feasibility of this workflow, a two-phase pilot study was conducted. The first phase of the pilot study utilized N=15 mice split into 3 groups of 5 mice each. Group 1 mice were controls while groups 2-3 were affected by chronic GvHD. Each mouse was imaged with 3-D high-frequency B-mode ultrasound using the Vega on day 100, 106, and 114 post transfer of splenocytes and bone marrow cells into irradiated recipient mice. Spleens were manually segmented from each image to measure spleen volume. The second phase of the pilot study was focused on tracking changes in an acute model of GvHD. For this phase, N=8 mice were split into 4 groups of 2 mice each. Group 1 were controls, while groups 2-4 received 3e6 to 5e6 dose of splenocytes and 1e7 bone marrow cells. Mice were imaged on day 10, 21, and 31 using the Vega, and spleen volumes were again determined via manual segmentation. In the chronic model, spleen volumes in affected animals were significantly reduced (37.9 ± 11.5 mm3) compared to control animals (84.8 ± 15.3 mm3). In the acute model, we observed an initial phase of splenomegaly followed by a drastic shrinkage of the spleens to roughly 50% of the control volumes. In summary, this study suggests the use of 3D non-invasive ultrasound imaging for assessing organ size and structure differences in GvHD model that will facilitate the discovery of new therapies.

#2533 Image-guided surgery with a new optical probe for breast cancer.

Sunam Mander, Duy Binh Tran, Goto Masahide, Konstantin Christov, Albert Green, Tapas K. Das Gupta, **Tohru Yamada**

Surgery, University of Illinois at Chicago, Chicago, IL

Accurate surgical removal of tumors significantly impacts patient outcomes. However, distinguishing between breast tumors and normal tissue during surgery is often challenging or even impossible. Given the lack of visual discrepancy between malignant and surrounding normal tissue, current breast-conserving surgery (BCS) is associated with a high re-excision rate. Due to this clinical challenge, a new method of complete tumor removal at the initial surgery is needed. To address this, we developed a new fluorescent imaging agent, ICG-p28, for intraoperative imaging guidance to better aid surgeons in achieving negative margins in BCS. ICG-p28 consists of the clinically nontoxic tumor-targeting peptide p28 and the FDA-approved near-infrared (NIR) dye indocyanine green. Here, we evaluated our imaging approach with ICG-p28 *in vitro* and in breast cancer animal models. First, we determined the detection limit of the objective size and depth using phantoms incorporating tumor-simulating inclusions. Even with the smallest objective (1 mm), NIR fluorescence imaging of ICG-p28 at nanomolar concentrations was able to detect the specific signals. We estimated the detection limit of the cell number in vitro. NIR-specific signals were detected from breast cancer cells as low as 200 cells in 1 mm size. Next, we evaluated ICG-p28 in multiple animal models. Athymic mice xenografted with MDA-MB-231 and IOWA-1T human breast cancer cells received a single injection of ICG-p28 i.v. at 0.5 mg/kg (=125 nmole/kg). Twenty-four hours after ICG-p28 injection, we observed the preferential uptake of ICG-p28 by tumors and a clear contrast between the tumor and the surrounding tissue. The histological analyses with H&E and Ki-67 staining on the set of tumor margin samples revealed that image-guided surgery with ICG-p28 could result in a clear negative margin at the edges of mammary tissues. Moreover, our imaging approach can also visually detect LN metastases (metastatic breast cancer in lymph nodes) through the preferential uptake of ICG-p28 concentrated over a period of time in small (~1 mm) LN metastases. Overall, this nontoxic, and cost-effective method can offer a new approach that enables surgeons to identify tumor margins intraoperatively and potentially improves overall outcomes for breast cancer patients.

#2534 A multimodal animal cradle inlay system to facilitate optical, PET, µCT, and MRI co-registrations of a metastatic, colorectal cancer syngeneic mouse model.

Andrew D. G. Van Praagh[1], Paul Ballieu[1], Ali Bahadur[1], Kristin Granlund[1], Saaussan Madi[1], Mark Mattingly[1], Dianne Begemann[2], Fallon Noto[2], Todd Sasser[1]

[1]Preclinical Imaging Lab, Bruker BioSpin Corporation, Billerica, MA,[2]Hera BioLabs, Lexington, KY

INTRODUCTION: Multimodal imaging can dramatically enhance the diagnostic capabilities of pre-clinical animal research models. Investigators in the fields of oncology and immuno-oncology have sought to add optical imaging to their PET/µCT/MRI data sets because optical adds a sensitive, low-cost, high-throughput imaging capability that can predict the biodistributions of high-cost, low throughput PET/µCT/MRI data sets. In this poster, we demonstrate a proof-of-concept multimodal animal cradle system for optical/PET/µCT/MRI co-registrations.

METHODS: Mouse Model: A CT26-luc mouse colorectal carcinoma cell line (derived from ATCC CRL-2638), expressing Red Firefly Luciferase, was injected into 12 adult Balb/C female mice, at dose levels of either $1x10^5$ (n=6) or $5x10^5$ (n=6) by tail vein IV injection. Optical/PET Reporters Used to Detect Cancer Cells: CT26-luc cells were detected *in vivo* either by Red Firefly Luciferase bioluminescent signal, and/or by the FDG PET/µCT/MRI at various points over the study time course. Mouse Multimodal Cradle Inlay System: A novel multimodal cradle inlay system was designed to be used in a range of preclinical imagers including the Lago X (optical), SkyScan (µCT), PET/CT Si78 (PET/µCT) and BioSpec (MRI) systems. All optical/PET/µCT/MRI multimodal co-registrations were performed in the PMOD software platform (Bruker BioSpin, Billerica, MA).

RESULTS and DISCUSSION: Early, Predictive Detection of Metastatic Colorectal Cancer in the Mouse Lung by Optical Imaging. Metastatic colorectal cancer engraftment was achieved in the pulmonary cavity of 10 challenged female, Balb/C mice. The presence of CT26-luc cancer cells in mouse lungs was first detected as early as 24-hours post challenge, by Red Firefly Luciferase bioluminescent imaging (BLI). Soon thereafter, CT26-luc cancer cells were also detected by FDG PET. Optical BLI was found to be predictive of FDG PET biodistributions. Additionally, the quantitative tomographic, anatomical details of FDG PET biodistributions were confirmed by PET/µCT/MRI co-registrations.

The ability of optical BLI to provide sensitive, high-throughput, early predictions of FDG PET biodistributions highlighted the value of the novel cradle inlay system tested here. Specifically, this cradle inlay system proved to be a vital hardware component that facilitated the process of acquiring multimodal optical/PET/µCT/MRI imaging data sets that could then be co-registered in PMOD.

CONCLUSIONS:

• *In vivo* Red FireFly BLI of metastatic colorectal cancer cells in a syngeneic mouse model successfully predicted observed *in vivo* FDG PET biodistributions.

• A proof-of-concept cradle inlay system successfully facilitated the process of acquiring diagnostic, multimodal optical/PET/µCT/MRI data sets that were then readily co-registered in PMOD.

#2535 Uncovering bias in AI-based digital pathology analysis.

Erika M. Skaggs[1], Daniel R. Plaugher[1], Sally R. Ellingson[2], Christine F. Brainson[3]

[1]Toxicology and Cancer Biology, University of Kentucky, Lexington, KY,[2]Division of Biomedical Informatics and Markey Cancer Center, University of Kentucky, Lexington, KY,[3]Toxicology and Cancer Biology; Markey Cancer Center, University of Kentucky, Lexington, KY

As the most transformative technology in a generation, Artificial Intelligence (AI) is a tool that brings tremendous promise and significant risks, particularly in regard to healthcare. Our project aims to address two challenges faced by researchers utilizing AI in the analysis of immunohistochemical (IHC) images: the potential for covert bias and the opaque nature of “black box” systems. We have trained an AI-driven model to detect tumor and stromal regions in non-small cell lung cancer (NSCLC) tissues stained with a variety of IHC markers, including the histone methyltransferase EZH2, the histone mark H3K27me3, the antigen presentation components B2M, HLA-DR,DQ,DP, the immune evasion molecular PD-L1 and the enzyme CBS. By measuring stain intensity in each region, we observed that EZH2 and PD-L1 staining are significantly higher in squamous cell carcinoma tumor cells than in adenocarcinoma tumor cells, and that HLA-DR,DQ,DP has an inverse relationship with EZH2. These data implicate a reason why some squamous cell carcinomas fail anti-PD1 immunotherapy. However, to ensure that the system was not creating or perpetuating existing disparities, we next endeavored to assess the algorithm’s accuracy across multiple demographic bounds. Using the Cohen’s Kappa of Inter-Rater Reliability, we were able to determine that our algorithm has near perfect agreement with trained human observers in each of the six stains tested (EZH2, H3K27me3, B2M, HLA-DR,DQ,DP, PD-L1, and CBS). This was true regardless of race (Black vs Caucasian) or geographical origin (Appalachian Kentucky vs Non-Appalachian Kentucky). However, when comparing performance by gender, one category fell below the threshold for near perfect agreement (CBS in males). Next, we sought to explore what factors might drive the AI’s decision-making process by comparing its accuracy in various histologic contexts. We analyzed the size of the nuclei, the number of nuclei per mm^2, the degree of immune infiltration, the width of the stroma, and the degree of randomness in the arrangement of the tumor and stroma. While the size of the nuclei was not found to have a significant impact on accuracy, the other variables did have the potential to “confuse” the AI, which could lead to less reliable results. By tackling these challenges head-on, we hope that our findings will help set a standard for the equitable and transparent application of artificial intelligence in healthcare. #2536 *In vivo* label-free imaging reveals distinct CD8 T cell metabolic changes during effective radio-immunotherapy in cold murine melanoma versus hot colon carcinoma.

Alexa R. Heaton[1], Anna Hoefges[2], Nathaniel J. Burkard[2], Arika S. Feils[2], Noah W. Tsarovsky[2], Garrett M. Lublin[2], Alina A. Hampton[2], Samantha K. Burkard[2], Aurora D'Amato[2], Mildred A. Felder[2], Anqi Gao[2], Huy Q. Dinh[2], Amy K. Erbe-Gurel[2], Alexander L. Rakhmilevich[2], Paul M. Sondel[2], Melissa C. Skala[1]

[1]Morgridge Institute for Research, Madison, WI,[2]University of Wisconsin, Madison, WI

In vivo multiphoton autofluorescence microscopy provides label-free, single-cell imaging of metabolic changes. These metabolic changes are quantified via the metabolic coenzymes NAD(P)H and FAD which are autofluorescent molecules endogenous to all cells. Metabolic reprogramming is a hallmark of cancer. Immune cells also change their metabolism during cancer progression and this metabolic switch correlates to immune cell phenotype and function. Here, we study metabolic changes during administration of a potent radio-immunotherapy regimen in murine melanoma and colon carcinoma. This therapy includes external beam radiation, hu14.18-IL2 immunocytokine (anti-GD2 mAb fused to IL2) or free IL2, and anti-CTLA-4, leading to *in situ* vaccination and cure of established murine tumors. We created a transgenic mCherry-labeled T cell mouse to study the critical T cell response. We implanted syngeneic B78 (GD2+) melanoma or MC38 (GD2-) colon carcinoma cells into the flanks of mCherry-labeled CD8 T cell reporter mice to induce tumors. Under anesthesia, skin flap surgery was performed, and tumors were imaged at multiple timepoints during therapy. Multiphoton imaging was performed to collect NAD(P)H, FAD, and mCherry signal. Fluorescence lifetime images were collected using time correlated single photon counting electronics. Tissues were also harvested and analyzed via flow cytometry, single-cell RNA sequencing, and multiplex immunofluorescence to corroborate imaging findings and characterize the immune infiltrate. Our *in vivo* label-free imaging revealed that CD8 T cells from treated versus control tumors exhibit different metabolic phenotypes including changes in NAD(P)H and FAD protein binding and redox balance across these two solid tumors. In cold B78 melanoma tumors, *in vivo* metabolic imaging revealed that CD8 T cells are activated early but maintain an oxidative metabolic state consistent with exhaustion or a memory phenotype. In hot MC38 colon carcinoma, *in vivo* metabolic imaging revealed that CD8 T cells are activated early and then quickly transition to a glycolytic state that fuels their cytotoxic function. scRNAseq confirmed the metabolic changes we observed within our B78 model and provided additional insight into CD8 T and tumor cell changes during therapy. Flow cytometry illustrated significant changes in the immune infiltrates of both tumor types over time and treatment. These results show that label-free *in vivo* imaging enables single-cell quantification of metabolic changes during therapy - across multiple solid tumors. Combined with other traditional assays, we can elucidate key immune cell populations and the crucial timepoints during therapy where changes are occurring. This imaging platform may be leveraged to help develop new immunotherapy combinations and study other cancer types where cures have not been realized.

#2537 *In vivo* advanced molecular imaging of the probiotic *L. lactis* expressing fluorescent proteins to monitor its transit through the gastrointestinal tract.

Nestor Rubio-Infante[1], Martin Ramos-Gonzalez[1], James Amos-Landgraf[2], Satyanarayana Rachagani[3], Lacey R. McNally[4], Jorge Gomez-Gutierrez[5]

[1]NextGen Precision Health, University of Missouri - Columbia, Columbia, MO,[2]Department of Veterinary Pathobiology, University of Missouri - Columbia, Columbia, MO,[3]Department of Veterinary Medicine and Surgery, University of Missouri - Columbia, Columbia, MO,[4]Department of Surgery, University of Oklahoma, Oklahoma, OK,[5]Department of Pediatrics, School of Medicine, University of Missouri - Columbia, Columbia, MO

Introduction: The real-time imaging of probiotic bacteria expressing a reporter protein represents an important area for gastrointestinal (GI) research. Fluorescent probiotic bacteria could be useful to evaluate the interaction of probiotics with the gut microbiome, either under normal conditions or dysbiosis. Also, they could be employed as diagnostic tools or in treatments preferentially directed to the harsh hypoxic, and/or acidic microenvironment of digestive diseases such as inflammatory bowel diseases (IBD), adenomatous polyps of the colon or colorectal cancer (CRC).

Methods: Recombinant strains of probiotic bacterium *Lactococcus lactis* expressing different fluorescent proteins were orally administered to C57BL/6 and Balb/c mice, their transit through the GI tract was monitored by *in vivo* advanced molecular imaging and multispectral optoacoustic tomography at different time points after oral gavage inoculation. The *L. lactis*-iRFP intensity signal in live animals was quantified using the software Aura 4.0.7.

Results: We found that the green channel to detect *L. lactis*-GFP results in a strong tissue autofluorescence in both C57BL/6 and Balb/c mice and the signal from *L. lactis*-mCherry could not be detected in neither black nor withe mice because the red wavelength lacks enough deep tissue penetrance to pass through the intestines and abdominal wall. In contrast, *L. lactis*-iRFP bacterium produce a strong, specific and well-localized signal, that can be detected in real-time for up to 24 h after oral gavage administration in Balb/c (white) mice, whereas in C57BL6 (black) mice it could be detected as an unspecific signal which suggests that melanin excess may interfere with the detection of *L. lactis*-iRFP. On the other hand, the pilot optoacoustic tomography imaging revealed that biliverdin, the iRFP substrate generated a strong signal which made it difficult to distinguish between the negative controls and *L. lactis*-iRFP. This result suggests that additional optimization of optoacoustic tomography imaging for iRFP is needed.

Conclusions: These results suggest that *L. lactis*-iRFP in Balb/c mice has the desired features to serve as a fluorescent reporter for *in vivo* imaging that can be used to monitoring the bacterial presence, permanence and interactions with the anatomical structures while transiting through the GI tract. Additionally, optoacoustic tomography imaging requires further optimization and improvement.

#2539 Imaging heterogeneity in pre-clinical models of soft-tissue sarcoma with multi-parametric MRI.

Ellen O'Sullivan, Clementine Lesbats, Paul H. Huang, James P. B. O'Connor, Simon P. Robinson

Radiotherapy and Imaging, The Institute of Cancer Research, London, United Kingdom

Soft tissue sarcomas (STS) are highly aggressive and heterogeneous cancers. There is a clinical need for techniques to image inter- and intratumoral heterogeneity of STS for personalized adaptation of treatment and to improve diagnostic accuracy. Multiparametric MRI (mpMRI) quantitatively maps spatial variations of functional and structural features of tumors *in vivo*. mpMRI data was acquired from mice bearing subcutaneous ICR-LMS-1, SK-UT-1 (both leiomyosarcoma, LMS) or HS-SY-II (synovial sarcoma, SS) xenografts. Biomarkers included quantification of the tumor apparent diffusion coefficient (ADC), native T_1 and T_2 relaxation times, magnetisation transfer ratio (MTR), the transverse relaxation rate R_2*, and the complex shear modulus |G*| using MR elastography to assess tumor stiffness. Pathology correlates were sought from MRI-aligned histological sections. Frequency histograms visualized the distribution of values to assess statistical dispersion. Median ADC and T_2 were significantly higher in the two LMS models compared to the more cellular dense HS-SY-II tumors (table 1). Significantly higher MTR in the HS-SY-II tumors suggests greater macromolecule (e.g protein) content. Tumor R_2*, a proxy for blood vessels, was slowest in the SK-UT-1 cohort, consistent with their low CD31 positivity. All three models exhibited a relatively soft biomechanical phenotype. HS-SY-II tumors displayed unimodal histograms, suggesting homogeneously distributed MRI biomarkers, and had little inter-tumor variation. In contrast, both LMS models exhibited bi- or trimodal distributions and higher interquartile range values, particularly for ADC, indicating pronounced intratumor heterogeneity and marked inter-tumour variation. mpMRI can inform on and assess differences in tissue heterogeneity within STS subtypes. Quantification of tumor ADC may provide a sensitive MRI biomarker to assess differential response of LMS and SS to therapy, which has clear translational potential.

Table 1

	ICR-LMS-1 (n=7)	SK-UT-1 (n=8)	HS-SY-II (n=10)
Tumor volume (mm^3)	374 ± 116	343 ± 26	405 ± 52
ADC ($x10^{-6}mm^3/s$)	1303 ± 139	1083 ± 91	629 ± 30 ***
T_1 (ms)	2549 ± 42	2607 ± 49	2496 ± 33
T_2 (ms)	110 ± 14	96 ± 4.6	73 ± 2 ***
MTR (%)	16.5 ± 6	20 ± 0.46	22 ± 0.41 *
R_2* (s^{-1})	31.7 ± 14.5	26 ± 1.5	43.7 ± 3.4 *
G* (kPa)	3.46 ± 0.45	2.87 ± 1.02	4.06 ± 0.22

#2540 Biodistribution and dosimetry of FAPI-46 in mouse model of colorectal carcinoma with PET and SPECT imaging.

Johanna Rokka, Henrik Vaherto, Susanne Back, **Jussi Rytkonen**

Charles River Laboratories, Inc., Kuopio, Finland

Fibroblast Activation Protein (FAP) is overexpressed in cancer-associated fibroblasts of many epithelial cancers. In nonmalignant conditions FAP is overexpressed in wounds healing, inflammatory and fibrotic tissues, whereas in healthy adult tissue FAP expression is low. Radiolabeled FAP Inhibitors (FAPIs) are used in clinic for imaging and/or radiotherapy. FAPIs are usually conjugated to a DOTA chelating site which allows the use of both diagnostic and therapeutic radionuclides. In this study we investigated the radiochemical properties, pharmacokinetics and dosimetry of FAPI-46 in after Lu-177 or Ga-68 labelling in preclinical mouse model of colorectal carcinoma.

FAPI-46 (non-GMP grade) was radiolabeled with Ga-68 and Lu-177 using previous described synthesis with slight modifications (Loktev et al., J Nucl Med 2019). Radiochemical purity was determined with radio-HPLC (LabLogic). A colon cancer mouse model was created by inoculating $5x10^6$ HCT116 cells in 100 µl 50% matrigel subcutaneously (s.c.) in the interscapular area of NMRI-Foxn1^{nu} male mice. Approximately two weeks post inoculation, animals were randomized into groups based on tumor volume (n = 2-4 / timepoint). Animals were dosed with ^{177}Lu-FAPI-46 or ^{68}Ga-FAPI-46, scanned with SPECT (Mediso) or PET (Sedecal) up to 90 minutes. Simultaneously satellite animals were terminated and sampled for gamma counting (Perkin Elmer) at 30-, 60- and 90-minutes post injection. Image analysis was performed with PMOD software. Dosimetry calculations will be performed with OLINDA 2.0.

^{68}Ga- and ^{177}Lu-FAPI-46 were produced with high radiochemical yield and purity. Nuclear imaging of radiolabeled FAPI-46 with both radiolabels shows fast kinetics and excretion via kidney as shown in literature. The dosimetry calculations are still ongoing. FAPI is suitable for multipurpose imaging and there is a great interest towards this molecule in the fields of imaging and oncology. The same precursor structure can be labeled with more than one radionuclide with high radiochemical yield and purity.

#2541 Imaging mass cytometry detects the true dynamic range of low-abundance biomarker expression in human tumors.

Smriti Kala, Qanber Raza, Jyh Yun Chwee, **Thomas D. Pfister**, Liang Lim, David King, Christina Loh

Standard BioTools, Markham, ON, Canada

Detecting clinically relevant biomarkers in cancer tissues provides key insights into the unique tumor characteristics of patients, allowing for more personalized and effective therapies. Immunohistochemistry (IHC) is the gold-standard technique for biomarker detection and is widely used by pathologists to score low-abundance biomarkers (LABs) in tissues. Limitations related to plexity, quantitation and false signal detection are frequently observed using IHC and day-to-day variability due to multiple steps of signal amplification and pigment mistaken for true signal can misinform pathologists about LAB expression.

Imaging Mass Cytometry™ (IMC™) technology is a multiplexed imaging technique that incorporates quantitative assessment of 40-plus biomarkers simultaneously on the same slide. The Hyperion™ XTi Imaging System, in association with an automated slide loader, permits 24/7 data acquisition and provides biological insights critical for assessment of the tumor microenvironment. We strove to determine whether IMC can be used for pathological evaluation of LABs and provides additional key biological insights for clinical evaluation offered through multiplexed analysis.

We performed a comparison of IHC and IMC technology to detect clinically relevant LABs (PD-1, PD-L1, CTLA-4 and LAG-3) on human tumor tissue microarray and whole tissue samples. For IMC technology, we detected single cells using the Human Immuno-Oncology IMC Panel, which offers cell phenotyping of tumor and immune cell subtypes and their functional states. We stained serial sections of tissues using the same antibody clone and generated IHC and IMC data, which was assessed by a board-certified pathologist. We conducted quantitative image analysis to detect LAB expression on single cells.

Our results demonstrate that while IMC and IHC are similar in detecting LABs, IMC technology can accomplish this without signal amplification, offering an opportunity to evaluate LABs in their true dynamic signal ranges. Quantitative analysis of IHC and IMC data further demonstrated the equivalent performance of both platforms. Multiplexed single-cell analysis using IMC data provided insights about LAB expression on specific immune and tumor cells. While IHC is semi-quantitative and cannot reliably determine the high abundance of a target, IMC technology offers the opportunity of signal quantitation as it displays the complete dynamic range of signal. Clinical assessment of tissues using IMC technology offers an advantage over traditional IHC methods by providing true biological context due to multiplexing capabilities. The ability of IMC to provide high-dimensional spatially resolved data makes it a powerful tool for clinical and translational applications and shows that it is poised to significantly contribute to biomarker discovery and drug development.

For Research Use Only. Not for use in diagnostic procedures.

#2542 Artificial Intelligence(AI)-powered delineation of the prostate cancer surfaceome through subcellular-level expression profiling from immunohistochemistry (IHC) images.

Sukjun Kim, **Jimin Moon**, Sanghoon Song, Hosik Kim, Biagio Brattoli, Jeongun Ryu, Donggeun Yoo, Sergio Pereira, Taebum Lee, Soohyun Hwang, Siraj Ali, Chan-Young Ock

Lunit Inc., Seoul, Korea, Republic of

Background: To assess the expressed surfaceome, we developed an AI-powered analyzer capable of scalably measuring for a given immunostained target cellular and subcellular level expression. We applied this analyzer to assess millions of prostate cancer cells.
Methods: A total of 8,464 prostate cancer and normal IHC images for 74 genes from Human Protein Atlas were analyzed. The 74 genes were the most frequently amplified genes (frequency > 7.8%) in prostate cancer, along with known prostate-specific targets, PSMA (*FOLH1*), *KLK2* and *KLK3*. The AI model, trained on pathologist-annotated histology images from 30+ cancer types and 15+ different IHC stainings, took the IHC images as input to predict cell types and subcellular compartments (nucleus, cytoplasm, and membrane) along with respective intensity scores. Immunostained proteins were evaluated by 1)TCS as the ratio of positive tumor cells to the total number of positive cells, normalized by the proportion of tumor cells, 2) membrane intensity score (MIS), and 3) MBS as the ratio of the membrane intensity score to the sum of intensity scores from all three subcellular compartments.
Results: The IHC analyzer detected and assessed 21.5M immunostained cells including 1.6M prostate cancer cells and 19.9M normal cells in non-prostate samples. The 71 amplified prostate targets had a mean TCS of 0.817 (range 0.181-1.415), a MIS of 0.132 (0.090-0.193), and a MBS of 0.271 (0.221-0.349). The three genes with the highest TCS values were the known therapeutic targets *KLK2* or *KLK3* (KLK2/3, 52.3) and PSMA (33.5), as well as the lesser known *NCALD* (3.97).The lower MBS(x0.63, PSMA: 0.40, KLK2/3: 0.25) and MIS (x0.25, PSMA: 0.08, KLK2/3: 0.02) values suggest that KLK2/3 expression may be less specific to the plasma membrane. Importantly, despite *NCALD* having a lower TCS relative to PSMA, it exhibits higher MIS (0.15) and MBS (0.45) values indicating high proportionate and specific membrane expression.
Conclusion: We developed a pipeline leveraging AI-powered and big-data-driven approaches to assess both the expression and membrane localizations of immunostained targets. We identified *NCALD* as having high membrane specificity which could enable the development of highly selective cell surface targeted therapeutics such as ADCs and bispecifics for prostate cancer.

#2543 Dynamic whole-body PET/CT can predict the treatment response to chemoradiotherapy of esophageal cancer patients.

Yoshihiro Kurata[1], Moe Iwata[1], Koichi Hayano[2], Yasunori Matsumoto[1], Ryota Otsuka[1], Akira Nakano[1], Tadashi Shiraishi[1], Nobufumi Sekino[1], Toyozumi Takeshi[1], Masaya Uesato[1], Gaku Ohira[1], Hiisahiro Matsubara[1]

[1]Department of Frontier Surgery, Chiba Univ. School of Medicine, Chiba, Japan,[2]Chiba Univ. School of Medicine, Chiba, Japan

Background: Majority of positron emission tomography-computed tomography (PET/CT) studies are based on static images. However, dynamic whole-body PET-CT (DW-PET/CT) enables quantification of tissue glucose metabolism dynamics. The purpose of this study is to investigate whether DW-PET/CT can predict the treatment response in esophageal squamous cell carcinoma (ESCC) patients treated with chemoradiotherapy (CRT).
Methods: Fifty ESCC patients who underwent pretreatment DW-PET/CT were evaluated. DW-PET/CT parameters of the main tumor including Patlak slope (PS, absolute rate of tracer consumption) and Patlak intercept (PI, degree of tracer perfusion in the tumor) were calculated using 4 whole-body PET/CT image series acquired at every 5 minutes from 60 minute after injection of 18F-fluorodeoxyglucose. The maximum standardized uptake value (SUVmax) of the tumor was also measured at 60 minute of the tracer injection. The relationships of these PET derived parameters with treatment response was analyzed.
Results: Treatment responders were 34 patients, while non-responders were 16 according to the RECIST criteria. Tumors of responders showed significantly higher SUVmax, PS and PI than non-responders (P=0.03, 0.0003, 0.001, respectively). PS and PI showed a good performance to predict the treatment response with AUC of 0.75 and 0.79, whereas SUVmax showed a poor performance with AUC of 0.69. Tumor contraction rate during CRT showed significant positive correlation with PS and PI (P=0.005, 0.03, respectively).
Conclusions: DW-PET/CT might enable pretreatment prediction for the treatment response to CRT in ESCC patients.

TUMOR BIOLOGY: Aging and Senescence in the Tumor Microenvironment
Poster Session

#2547 The impact of aging on YAP activity in melanoma cells: nuclear localization and condensate formation.

Ethan Black, Danfeng Cai, Ashani Weeraratna

BMB, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD

Melanoma is a highly lethal form of skin cancer which disproportionately impacts older patients, leading to increased rates of melanoma diagnosis and worse prognostic outcomes in this population. This is driven, in part, by higher rates of invasion and therapy resistance caused by age-related changes to the tumor microenvironment. One mechanism this occurs through is the increased senescence of fibroblasts which disrupts extracellular matrix (ECM) deposition, resulting in a more aligned and stiffer matrix. The Hippo pathway is known to shut off in response to matrix stiffness which allows for increased YAP nuclear localization. YAP is a known marker for increased invasion in melanoma. While the importance of YAP in melanoma is known, it is understudied in the context of an aging tumor microenvironment. Additionally, YAP's ability to form transcriptionally active condensates and whether this activity is vital to its function has yet to be elucidated in melanoma. Our lab has previously shown that the increased stiffness of cell-derived matrices (CDMs) created with aged fibroblast cell lines when compared to CDMs from young fibroblasts is sufficient to increase YAP nuclear localization in HUVEC cells. We hypothesize that age-associated increases in ECM stiffness will also increase YAP nuclear localization in melanoma cells, resulting in increased YAP target gene activation, YAP condensate formation, and downstream pro-invasive melanoma cell behavior. To investigate this we employed several techniques, including the creation of CDMs from aged/young fibroblasts, immunofluorescence (IF) staining, and Airyscan super-resolution microscopy. Our data suggests that melanoma cells grown on cell-derived matrices (CDMs) created by aged dermal fibroblasts have increased nuclear YAP localization when compared to cells grown on CDMs created with young dermal fibroblasts. However, the downstream effects of this increased YAP activity on invasion and therapy resistance in melanoma cells as well as whether melanoma cells being plated on aged CDMs increases YAP condensate formation are still being examined. Our IF data from these melanoma cells also suggests that YAP condensates assemble endogenously in melanoma when plated on these CDMs, and the importance of their role in YAP target gene activation warrants further study. As we continue this work, it will allow us to better understand how the aging tumor microenvironment changes YAP activity and the downstream effect this has on the invasive behavior that is characteristic of melanoma in older patients.

#2548 Elucidating the significance of senescent tumor microenvironment in progression of pancreatic adenocarcinoma.

Ankita Semwal[1], Anjali Aggarwal[2], Vinit Sharma[2], Mayank Sharma[2], Rajesh Gupta[3], Ritambhra Nadda[4]

[1]Postgraduate Institute of Medical Education & Research (PGIMER), Chandigarh, India,[2]Anatomy, Postgraduate Institute of Medical Education & Research (PGIMER), Chandigarh, India,[3]GI Surgery, HPB and Liver Transplantation, Postgraduate Institute of Medical Education & Research (PGIMER), Chandigarh, India,[4]Histopathology, Postgraduate Institute of Medical Education & Research (PGIMER), Chandigarh, India

Background: Oncogenes, oxidative stress, DNA damage response are typical stimulators for cellular senescence in tumor microenvironment (TME). The recent literature emphasizes on the dual nature of senescence where its tumor-promoting effects can outweigh the initial tumor-suppressive effects, especially when senescent cells accumulate and are not efficiently cleared. This study aims to see whether senescence in TME plays any role as contributing factor for the progression and relapse in pancreatic adenocarcinoma.
Methodology: In 30 pancreatic adenocarcinoma tissue specimens, senescence was assessed by lysosomal mass quantification, immuno-staining of DNA damage foci, gene expression of cell cycle arrest markers and SASP factors profiling by ELISA. The relevant transcripts of metastasis, stemness and Wnt signaling were evaluated by gene and protein expression. In-vitro Doxorubicin induced senescence model (Panc-1 cells) was created and evaluated for validation of results.
Results: The senescence was markedly elevated in tumor tissue, demonstrated by increased positivity of SA-β-gal, ɣ-H2AX foci, cell cycle arrest markers (p16, p53, p21), pro-inflammatory cytokine (IL-10>0.0547*). The accumulated senescence was found significantly correlated with increased expression of invasiveness markers (Vimentin, and N-cadherin) stemness (Sox2, Oct4, Nanog). The co-localization of ɣ-H2AX and Sox2 as seen in immunofluorescence microscopy concludes the presence of senescence along with stemness. Genes of Wnt signaling cascade (Wnt2<0.0039**; c-Myc< 0.0039**) which are involved in both senescence and stemness were significantly raised in pancreatic adenocarcinoma.
Conclusion: Our findings highlight the critical role of metabolically active senescent cells in remodeling tumor microenvironment through secretory factors and presence of active stemness within. The senescence has positive influence on tumor promoting features like invasion, metastasis and tumor proliferation. Selective elimination of senescence can be a promising therapeutic implication considering the balance between beneficial and harmful effects of senescence in cancer treatment.

#2549 The aged tumor microenvironment limits T cell control of breast cancer.

Jia Meng[1], Denise Goh[1], Kai Soon Ng[1], Xinru Lim[1], Jeffrey Lim[1], Lee Hong Song[2], Jabed Iqbal[2], Darren Wan-Teck Lim[3], Elaine Hsuen Lim[3], Joe Yeong[1]

[1]A*STAR - Inst of Molecular and Cell Biology (IMCB), Singapore, Singapore,[2]Department of Anatomical Pathology, Division of Pathology, Singapore General Hospital, Singapore, Singapore,[3]Division of Medical Oncology, National Cancer Centre Singapore, Singapore, Singapore

Introduction: Breast cancer is the leading cause of cancer-related death among women worldwide and the most commonly diagnosed invasive cancer. Given that the risk of developing cancer increases dramatically with age and is often paralleled with a progressive decline in immune function, breast cancer presents unique challenges for understanding how aging influences tumor development. Amid a globally aging population, the etiology and effect of age-related immune dysfunction in cancer remains unclear.
Methods: To address this, we investigated the major cellular determinants of aging in an orthotopic mouse model using EO771 breast carcinoma cells on young (2-month-old) and old (27-month-old) BALB/c mice separately. 21 days post inoculation, tumors were immuno-profiled with extensive flow cytometry and multiplex immunohistochemistry. Young and aged human breast biopsies were processed to generate tumor-infiltrating lymphocytes, which were subsequently analyzed using single-cell RNA sequencing.
Results: We observed that tumor size increased with mice age, while the frequencies infiltrating CD4 and CD8 T cell decreased. Specifically, CD8 T cell exhaustion is significantly induced in aged breast tumors: quantification by flow cytometry and multiplex immunohistochemistry shows a consistent upward trend in $CD39^{+}$CD8 T, $PD\text{-}1^{+}$CD8 T, and TOX^{+}CD8 T cells in 27-month-old mice. Complemented with a detailed single-cell RNA sequencing analysis of over 5,000 T cells from young and aged human breast biopsies, we verified the presence of exhausted CD8 T cell subsets in the aged tumor microenvironment, characterized by *Pdcd1*, *Havcr2* and *Entpd1* high expression.
Conclusions: Our findings demonstrate that limited priming of $CD8^{+}$T cells in the aged tumor microenvironment within breast cancer, primarily restricts tumor control in aging. Further studies are ongoing to expand the cohort and investigate age-related responses to immunotherapy in immunopathological context with advance single-cell spatial technologies.

#2550 Chemotherapy-induced senescence of cancer-associated fibroblasts promotes gastric cancer progression and resistance to chemotherapy.

In-Hye Ham, Yulim Lee, Hur Hoon

Ajou University School of Medicine, Suwon, Korea, Republic of

Purpose: Chemotherapies for patients with gastric cancers (GCs) has been shown disappointing results in the clinics. The cancer-associated fibroblasts (CAFs) could be considered one cause of the resistance to chemotherapy in GCs. However, the chemotherapy-induced reprogramming of CAFs and its effects on GC progression and the resistance to chemotherapy has not been elucidated.
Methods: IncuCyte and transcriptome were used to identify chemotherapy-induced senescence of CAFs. Screening for drugs to inhibit senescence of CAFs was performed. The cell proliferation and migration assays and phospho-protein array were performed to investigate the effects of senescent CAFs on GC cells. Inhibitory effects of screened drugs on CAFs were also evaluated in experimental models. Senescent CAFs and their clinical meanings were also investigated in the human GC tissues undergoing preoperative chemotherapies.
Results: Chemotherapy could alleviate proliferation and widen cytoplasm of CAFs. Some secretory molecules like *TNF-α* were upregulated in the CAFs with chemotherapy. Chemotherapy-treated CAFs increased the resistance to chemotherapy and the migratory potentials of GC cells. The COX2 inhibitor, one of the screened drugs, has inhibitory effect on chemotherapy-induced senescence CAFs. Consequently, it could suppress GC progression and resistance to chemotherapy. The GC patients with senescent CAFs were significantly correlated with poor histologic response to chemotherapy.
Conclusions: In this study, we are convinced that the chemotherapy-induced senescence of CAFs could have a significant effect on progression and resistance to chemotherapy in GC. Inhibitory drugs for chemotherapy-induced senescence of CAFs could be used to overcome the CAF-induced resistance to the chemotherapy in GCs.

#2551 Aged microenvironments promote liver metastasis in pancreatic ductal adenocarcinoma.

Emma Kartalia, James M. Leatherman, Jae W. Lee, Sara E. Young, Elizabeth M. Jaffee, Won Jin Ho, **Daniel J. Zabransky**

Johns Hopkins University, Baltimore, MD

Advancing age is the strongest independent risk factor for developing pancreatic ductal adenocarcinoma (PDAC). Older patients are more likely to present with advanced stage disease and have inferior overall survival when liver metastases are present. There is a critical need to understand the molecular factors that promote PDAC metastasis in order to guide development of more effective therapies. Despite the strong association of PDAC incidence and liver metastasis with aging, mechanisms through which aging impacts this process are not understood.

Our prior work identified age-related changes in the PDAC tumor microenvironment (TME) that promote orthotopic PDAC tumor growth in aged (>12-month-old) compared to young (8-week-old) mice. GDF-15, a divergent TGFβ superfamily member, is a critical factor released by aged fibroblasts in the TME that promotes PDAC growth in an age-dependent fashion. We have recently identified that liver metastases are significantly more frequent in aged hosts, consistent with clinical observations.

To determine how aging promotes PDAC metastases, we performed studies using novel human and mouse models that incorporate age as a variable. Primary tumors from aged mice have increased angiogenesis and decreased CD8+ T cell infiltration, findings associated with metastasis. To determine if GDF-15, released at high levels by aged but not young pancreatic fibroblasts, is involved in priming tumors for metastasis, we performed recombinant GDF-15 treatment of young mice harboring orthotopic KPC tumors. We found that GDF-15 significantly increases angiogenesis and decreases CD8+ T cell infiltration, changes associated with increased likelihood of metastasis. Tumors in aged GDF-15 knock out mice give rise to fewer metastases and have decreased angiogenesis and CD8+ T cell infiltration compared to aged wild type mice. Treatment of both human and mouse pancreatic cancer cells *in vitro* with aged fibroblast conditioned media or recombinant GDF-15 results in increased migration and invasion driven by GDF-15 specific activation of AKT signaling relative to controls.

We next tested if the aged liver, independently of effects in a primary tumor, contributes to metastasis. Portal vein injection of KPC and KPCY clones into aged mice resulted in increased and larger metastases compared to young mice. Using imaging mass cytometry, we identified that liver metastases in aged mice were immune excluded with low CD8+ T cell infiltration and increased spatial interactions between immune cells and fibroblast populations with immunosuppressive phenotypes.

Together, these data show that aging alters the primary tumor and metastatic liver microenvironments to promote more efficient metastatic spread of PDAC cells. We will present this and other ongoing work targeting the aging-driven GDF-15 signaling for the treatment and prevention of PDAC metastasis.

#2552 *TET2*-mutant clonal hematopoiesis enrichment in the tumor microenvironment is an actionable driver of treatment resistance in solid tumors: Thyroid cancer as a paradigm.

P. Sanchez Vela[1], V. Tiedje[1], J. L. Yang[1], B. R. Untch[1], L. Boucai[1], A. J. Stonestrom[1], A. Bueno Costa[2], S. Franch Exposito[1], S. Franch Exposito[1], A. Srivastava[3], M. Kerpelev[1], J. Greenberg[1], M. Wereski[1], A. Kulick[1], K. Chen[1], T. Qin[1], S.-Y. Im[1], A. R. Martinez Benitez[1], R. Pluvinet[2], M. Sahin[1], K. Menghrajani[1], G. P. Krishnamoorthy[1], E. de Stanchina[1], A. Zehir[1], R. Satija[4], J. Knauf[1], R. L. Bowman[1], M. Esteller[2], S. Devlin[1], M. F. Berger[1], R. P. Koche[1], R. L. Levine[1], J. A. Fagin[1];

[1]Memorial Sloan Kettering Cancer Center, New York, NY, [2]Josep Carreras Leukaemia Research Institute, Barcelona, Spain, [3]The Wistar Institute, Philadelphia, PA, [4]New York University, New York, NY

Recurrent mosaic somatic mutations in circulating leukocytes can be frequently found in the aging population. These mutations frequently arise in epigenetic modifier genes like *TET2.* In the absence of signs of hematologic malignancies this condition is termed clonal hematopoiesis (CH). Although CH has been associated with increased incidence and adverse outcomes in patients with solid tumors, the disease-specific effects and mechanisms by which CH alters solid tumor biology have not been delineated. To develop insights into the interplay between mutant CH clones and epithelial tumor cells we analyzed a cohort of over forty-seven thousand patients who underwent paired blood and tumor sequencing. After correcting for age, sex, ancestry, stage, smoking, and previous treatment history, we identify unique patterns of poor survival associated with specific CH genotypes and solid tumor histologies. Given that the detection of tumor-infiltrating *TET2*-CH clones is especially associated with poorer outcomes in thyroid cancer patients (HR 2.18, 95%CI 1.18-4.05, p=0.013), we focused on studying the role of CH in thyroid cancer biology. Compared to other CH alleles, *TET2*-mutant CH is enriched in the tumor microenvironment (TME) across solid tumors and is associated with adverse prognosis specifically in Anaplastic thyroid cancer (ATC) patients. ATC is a clinically aggressive malignancy with a dismal prognosis. Combined BRAF/MEK inhibition offers significant therapeutic benefit in patients with $BRAF^{V600E}$-mutant ATCs. However, relapses are common and overall survival remains poor. A hallmark of ATC is significant infiltration with myeloid cells, particularly macrophages. ATCs are most common in the aging population, which also has an increased incidence of *TET2*-mutant CH. These mutant macrophages have been shown to accelerate CH-associated pathophysiology including atherosclerosis. However, the clinical and mechanistic contribution of *TET2*-mutant clones to the prognosis and/or treatment response in solid tumors has not been elucidated. Using subclonal murine models of *Tet2*-mutant CH we confirm that mutant macrophages selectively infiltrate mouse $Braf^{V600E}$-mutant ATC models (58% higher enrichment of $Tet2^{-/-}$ cells in the TME compared to the WT counterparts) and confer resistance to BRAF/MEK inhibition (68-days median survival compared to no mortality after 147 days). Using single-cell CITEseq, we identify that the overexpression of Tgfβ-family ligands by CH macrophages is the driver of this resistance. Importantly, inhibition of Tgfβ signaling or the depletion of mutant-macrophages completely restored the sensitivity to MAPK pathway inhibition. In summary, this work identified a novel actionable resistance mechanism mediated by a clonally driven process within the tumor-immune microenvironment.

#2553 Hypoxia-associated lncRNA-induced glycolysis and lactylation-driven senescence-associated secretory phenotype in cancer-associated fibroblasts enhances peritoneal dissemination.

J. Zhang;
Liaoning Cancer Hospital & Institute, Shenyang, China

Peritoneal Dissemination is the main site of diffuse gastric cancer (DGC) distant metastasis and indicates an extremely poor prognosis and survival. Our previous research revealed that HIF-1a can initiate the expression of LINC01355, promoting the progression of DGC. Here, in DGC orthotopic transplantation model, we observed that overexpression of LINC01355 could accelerate peritoneal dissemination. We found that LINC01355 could directly bind to Pyruvate Kinase M1/2 (PKM), inhibiting its degradation, thereby facilitating glycolysis in GC and creating a microenvironment with accumulated lactate. Single-cell analysis reveals the presence of a hypoxia-associated subtype of cancer-associated fibroblasts (hypoxiaCAF) within TME of DGC. This distinct subtype is independent of myoCAF, iCAF, and apCAF, representing a novel CAF population. HypoxiaCAFs exhibit a slow proliferation rate and display a senescence-associated secretory phenotype (SASP). Mass spectrometry and related experimental data suggest that lactate accumulation in the TME downregulates the specific histone lysine delactylase HDAC3, promoting histone H4 lysine 12 lactylation (H4K12la). H4K12la is enriched in the promoters of SASP-related genes, driving SASP transcription and exacerbating the senescence of CAFs. Inhibition of HDAC3 blocks the increased viability of DGC cells induced by senescent CAFs and peritoneal tumor formation. Single-cell mass cytometry reveals the presence of fibroblasts in the ascites of patients with peritoneally disseminated DGC, with fibroblast populations displaying high levels of p16 expression and SASP factors. These findings provide insights into the role of histone lactylation in sustaining inflammation-related SASP and the involvement of senescent CAFs in DGC peritoneal dissemination.

#2554 Caloric restriction ameliorates aging and tumor progression via tumor immunity in syngeneic mice model.

T. Horino, H. Horiguchi, Y. Miyamoto, M. Iwatsuki, Y. Oike;
Kumamoto University, Kumamoto City, Japan

Background: Caloric restriction (CR) without malnutrition reportedly improves life span and ameliorates aging in preclinical models. Decreased expressions of aging-related genes and inflammation-related genes have been observed in CR mice. Moreover, CR decreases cancer risk and inhibits tumor progression, but the underlying mechanisms are not fully understood.
Methods: In this study, we developed a syngeneic model using C57BL/6N male mice, and verified the tumor-suppressing mechanisms of CR. Mice were randomized into 2 groups: normal diet (ND) group fed with ad lib diet, and CR group with 30% reduced feeding compared with the ND group, started from 2 months age. MC38, murine colorectal adenocarcinoma cells, were implanted subcutaneously. We compared tumor growth and survival between the CR group and the ND group. Moreover, to verify the contribution of tumor immunity, we compared the tumor-suppressing effects of anti-PD-1 antibody between the CR group and the ND group. To clarify the impacts of CD8+ cytotoxic T cells, we also conducted CD8 depletion by anti-CD8 antibody.
Results: Firstly, we observed significantly restricted tumor progression of the CR group in aged mice, but it was relatively modest in young mice. Secondly, the tumor-suppressing effect of anti-PD-1 was equivalent between the CR group and the ND group in aged mice, which suggests tumor immunity is essential to demonstrate anti-tumor effects in CR mice. However, CD8 depletion in CR mice showed only partial tumor-promoting effects, which suggests immune function excluding CD8+ T cells contributes to suppressing tumor progression in the CR group.
Conclusion: Our findings suggest that CR ameliorates aging and tumor progression. Promoted immune function, especially immune cells excluding CD8+ T cells, might play a role in the tumor-suppressing effects of CR. CD4 depletion and comprehensive analyses of intratumoral T cells are currently underway to elucidate the underlying mechanisms of tumor suppression induced by CR.

#2555 Multimodal atlas of cellular senescence in human bone marrow reveals insights into aging and multiple myeloma.

Wen-hung Chou[1], Julia T. Wang[1], Xiang Li[1], Kapur B. Dhami[1], Daniel Rapp[2], Andre Luiz N. Targino da Costa[1], Andrew Houston[1], Xiyi Wei[1], Yuting Zhao[1], Maede Shahin[1], Yizhe Song[1], Xiangwei Fang[1], Julie Fortier[1], Yuwei Zhang[1], Matthew Wyczalkowski[1], Reyka G. Jayasinghe[1], Kelsey Gallant[1], Michael Slade[1], Karolyn A. Oetjen[1], Kiran Vij[1], Daniel C. Link[1], Ryan Nunley[3], Ravi Vij[1], Feng Chen[4], Ryan C. Fields[2], Li Ding[1]

[1]Department of Medicine, Division of Oncology, Washington University School of Medicine in St. Louis, St. Louis, MO,[2]Department of Surgery, Surgical Oncology, Washington University School of Medicine in St. Louis, St. Louis, MO,[3]Department of Orthopedic Surgery, Washington University School of Medicine in St. Louis, St. Louis, MO,[4]Department of Medicine, Division of Nephrology, Washington University School of Medicine in St. Louis, St. Louis, MO

Hematologic malignancies, such as multiple myeloma, exhibit a markedly increased incidence with age and are profoundly influenced by the bone marrow microenvironment. The aged microenvironment can lead to the accumulation of senescent cells, characterized by permanent cell cycle arrest and a pro-inflammatory secretory phenotype. Despite its significance in age-related diseases, the role of senescent cells in the bone marrow microenvironment and their impact on aging and hematologic malignancies remain poorly understood.As part of the Cellular Senescence Network (SenNet), we created a multimodal atlas to characterize senescent cells in the human bone marrow using single-cell RNA sequencing (scRNA-seq) and spatial transcriptomics. Analysis of 55 scRNA-seq samples from healthy donors (aged 25-84) revealed that mesenchymal cells exhibited the strongest senescence signatures, which were elevated in aged individuals. While monocytes also displayed senescence signatures, they did not show an age-associated increase. Hematopoietic stem cell (HSC) subpopulations showed senescent profiles, suggesting that senescence spans multiple cell types in the bone marrow.Using the Xenium spatial transcriptomics platform, we profiled the bone marrow microenvironment in 17 samples from 15 healthy donors across a similar age range. We identified 32 distinct cell types and uncovered putative senescent subpopulations in plasma cells and vascular smooth muscle cells. Our analysis revealed 9 unique cellular neighborhoods, some anchored around established niches like the endosteum and arteriole, while others suggested novel niche candidates such as adipocytes, early myeloid progenitors, and megakaryocytes. Aging was associated with significant microenvironment remodeling, including increased mature myeloid cell types and lymphoid aggregates, along with a decline in lymphoid and progenitor populations.In 22 multiple myeloma samples from 15 untreated and 4 relapsed patients, we found significant microenvironment changes, such as the formation of plasma cell-rich pockets. These neighborhoods were enriched with monocytes and CD8 T cells, the latter showing elevated expression of exhaustion markers. In agreement with our neighborhood analysis, monocytes and CD8 T cells were found in closer proximity to plasma cells in samples with high tumor burden. Mesenchymal stem cells near plasma cells also showed increased senescence signatures compared to age-matched controls.Overall, our findings illuminate the senescent landscape of the bone marrow and provide a resource for understanding its role in aging and multiple myeloma.

#2556 Therapy-induced senescent cancer cells facilitate immune evasion in cancer by promoting PD-L1 upregulation through a ribophorin 1-dependent pathway.

H. Hwang[1], D. Kang[1], **J. Shin**[1], J. Jung[1], S. Ko[1], K. Jung[1], S.-S. Hong[1], J. Park[2], M. Oh[2], H. An[2], W.-H. Yang[3], Y.-G. Ko[4], M. Choi[1], J.-H. Cha[1], J.-S. Lee[1];

[1]Inha University, Incheon, Korea, Republic of, [2]Chungnam National University, Daejeon, Korea, Republic of, [3]China Medical University, Taiwan, Taiwan, [4]Korea University, Seoul, Korea, Republic of

Cancer senescence induced by conventional chemotherapy and radiotherapy, characterized by limited proliferation, drug resistance, and a senescence-associated secretory phenotype, is increasingly recognized as a contributor to cancer relapse and the development of an immunosuppressive tumor microenvironment. However, the relationship between cancer senescence and anti-tumor immunity remains poorly understood. In this study, we demonstrate that senescent cancer cells upregulate PD-L1 expression by enhancing its transcription and glycosylation. We identify ribophorin 1 as a key regulator of PD-L1 glycosylation during cancer senescence. Ribophorin 1 depletion significantly reduces PD-L1 levels through the ER-lysosome-associated degradation pathway, rendering senescent cancer cells more susceptible to T-cell-mediated killing. Furthermore, ribophorin 1 depletion suppresses tumor growth by decreasing PD-L1 levels and enhancing cytotoxic T lymphocyte (CTL) activity. Additionally, targeting ribophorin 1 or using anti-PD-1 therapy effectively reduces the number of senescent cancer cells in irradiated tumors and suppresses cancer recurrence by activating CTLs. These findings clarify how senescent cancer cells evade T-cell immunity following treatment, contributing to cancer recurrence. Our results highlight the therapeutic potential of targeting senescent cancer cells as a strategy in cancer treatment.

#2557 Age of host and its impact on progression and treatment response in tumors derived from early or late onset Hispanic colorectal cancer patients.

Lesly Torres-Gonzalez[1], Shivani Soni[1], Goar Symbatyan[1], Jae Ho Lo[1], Pooja Mittal[1], Unnati Hemant Shah[1], Francesca Battaglin[1], Karam Ashouri[1], Sandra Algaze[1], Priya Jayachandran[1], Wu Zhang[1], David W. Craig[2], Julie Culver[1], Mariana C. Stren[3], John D. Carpten[2], Bodour Salhia[1], Heinz-Josef Lenz[1]

[1]Norris Comprehensive Cancer Center, Keck School of Medicine, University of Southern California, Los Angeles, CA,[2]Beckman Research Institute, City of Hope, Duarte, CA,[3]Department of Population and Public Health Sciences, Keck School of Medicine, University of Southern California, Los Angeles, CA

Background: Colorectal cancer (CRC) is one of the most commonly diagnosed cancers and causes of cancer-related death in the Hispanic/Latino (H&L) population. Rates of early onset (<50, EO) CRC have increased more rapidly in H&L than other ethnic and racial groups. EO CRCs are often diagnosed at advanced stages, suggesting a more aggressive tumor biology. Investigations on the effect of age within both the tumor and host environments could provide insight into key differences between EO and late onset (>50, LO) CRCs. Our study (Cancer Moonshot Program), explores how both age of the host and tumor intrinsic factors influence growth, progression, and treatment response.

Methods: CRC patient derived xenograft (PDX) models were selected from our biorepository based on race and age. Tumor samples from an EO 36 year old (young patient, YP) and a LO 66 year old (old patient, OP) H&L male were expanded using 2 month old NSG mice. Following expansion, each tumor was then implanted into both young (2 months, YM) and old male NSG mice (13-14 months, OM) to establish four PDX models: YP in YM, OP in YM, YP in OM, and OP in OM. Each model was treated with oxaliplatin (6mg/kg), 5-fluorouracil (5-FU, 50mg/kg), or vehicle (control) twice a week for four weeks and monitored for survival. Tumor volume was measured twice per week until an endpoint of 15mm at any diameter was reached. Tumor tissue and blood samples were collected and used for metabolomic and epigenomic analysis.

Results: Initial patient tumor expansion showed differing tumor growth rates between YP and OP tumors, with each being ready for mouse implantation at 63 and 90 days respectively. In all models, control mice had significantly higher tumor growth rates compared to treatment groups ($p<0.01$), except in the 5-FU treated OP in OM. Survival analysis showed significantly increased survival in treatment groups for YP in YM and YP in OM ($p<0.05$). Within each treatment group, YP in YM showed significantly increased tumor growth when compared to other models ($p<0.01$). Additionally, OP in YM also showed significantly reduced growth in the 5-FU treatment group compared to other groups ($p<0.05$).

Conclusion: Our current findings showed that all patient tumor-mouse host age combinations showed significant tumor growth reduction when treated with oxaliplatin or 5-FU, except in 5-FU treated OP in OM. The YP in YM model displays significantly more aggressive tumor growth regardless of the treatment given. However, comparison of treatments to control in YP in YM show significant tumor growth reduction and increased survival, suggesting a more effective response to treatments. The similarity in growth rates of the three other models, regardless of treatment, may suggest that the aggressive characteristics of YP in YM are influenced by both the host and tumor. Further studies are warranted to understand the modifications that influence the observed differences.

#2558 Ferroptosis modulates melanoma progression in an age-specific manner through changes in the tumor microenvironment.

Murilo Ramos Rocha[1], Yash Chhabra[2], Alexis E. Carey[1], Cheyenne Palm[1], Kevin Zhang[3], Edwin Kumah[1], Vania Wang[1], Laura Huser[1], Elizabeth I. Harper[1], Fan Huang[1], Ashani Weeraratna[1]

[1]Biochemistry and Molecular Biology, Johns Hopkins Bloomberg Sch. of Public Health, Baltimore, MD,[2]Fox Chase Cancer Center, Philadelphia, PA,[3]Department of Pathology, Johns Hopkins University, Baltimore, MD

Aging is an independent prognostic factor for melanoma, the most aggressive form of skin cancer. Although immune therapy has shown a dramatic improvement in melanoma treatment, resistance to it still occurs in some patients. Higher oxidative damage in tumor cells and lipid and iron accumulation are singular characteristics of the aged tumor microenvironment (TME). Here, we investigate the impact of these characteristics of the aged TME in promoting ferroptosis, a caspase-independent iron-mediated type of cell death, and as a possible therapeutic opportunity for older patients. Lipid peroxidation levels, resistance to ferroptosis inducers, and the impact of the aged TME secretome were assessed through in vitro and in vivo modeling. Initially, correlation analysis between transcriptomic data (TCGA-SKCM) and ferroptosis sensitivity (CTD^2) was performed to identify common denominators among transcripts associated with the aged TME and ferroptosis pathway. Phenotype-switching markers, such as AXL and Wnt5a, showed a strong correlation with several ferroptosis-related transcripts and an inverse correlation with ferroptosis resistance. Using a panel of melanoma cell lines with distinct Wnt5a levels, we confirmed this association and observed that three critical regulators of lipid peroxidation are downregulated in Wnt5a high lines: GPX4, AIFM2, and GCH1. The comparison through IHC of young and aged mouse skin samples highlighted a pro-ferroptosis signature increasing with age. Senescence markers such as p16 and p21 could be modulated in dermal fibroblasts through induction or inhibition of lipid peroxidation. When associating conditioned media (CM) derived from these dermal fibroblasts (capable of inducing phenotype switching), RSL-3, a GPX4 inhibitor, induced a higher lipid peroxidation and cell death in melanoma cells exposed to aged CM. To understand how ferroptosis impacts tumor growth in young and aged mice, we used a syngeneic tumor model injecting Yumm1.7 cells intra-dermally and the treatment with a lipid peroxidation inducer (imidazole ketone erastin, IKE) or an inhibitor (Liproxstatin-1). Tumors from aged mice showed stronger staining with 4-HNE antibody when compared to young, correlating with AXL and Wnt5a staining. Interestingly, both IKE and Liproxstatin-1 lead to age-specific reduced tumor growth, followed by changes in immune cell populations such as monocytes, macrophages and NK cells. We are currently exploring how these treatments impacted metastatic dissemination, stromal architecture and sensitivity in BRAF/MEK-resistant tumors. These results indicate that ferroptosis modulation is a promising avenue for combined treatment with existing clinical strategies.

#2559 The impact of aging on the brain microenvironment and melanoma brain metastasis: Vasculature dysfunction, inflammation, and tumor colonization.

Cheyenne M. Palm[1], Alexis Carey[2], Murilo Ramos Rocha[1], Kevin Zhang[1], Ashani Weeraratna[1]

[1]Biochemistry and Molecular Biology, Johns Hopkins Bloomberg Sch. of Public Health, Baltimore, MD,[2]Cellular and Molecular Biology, Johns Hopkins School of Medicine, Baltimore, MD

Melanoma is the third most common source of brain metastases after lung and breast cancer; however, melanoma has the highest risk of spreading to the central nervous system (CNS). Previous studies have shown that age is an independent negative prognostic factor for early-stage and metastatic melanoma. Our lab has shown differences in the skin, lung, and pancreatic aging microenvironment that affect older patients' prognosis and response to therapy and emphasizes the need to uncover other molecular mechanisms of cancer progression in older patients. Currently, the role of the aged brain microenvironment in the development of melanoma brain metastases (MBM) is poorly understood due to limited data available. We hypothesize that changes in the aged brain microenvironment create a more tumor-permissive environment for melanoma metastasis to the brain. Previous studies have shown that the native brain environment, particularly glial cells such as astrocytes and microglia, can directly interact with melanoma in both a pro- and anti-tumorigenic manner. Additionally, melanoma cells have been shown to disrupt the blood-brain barrier (BBB) during migration; however, whether the aging microenvironment makes the BBB more susceptible to this disruption is not clearly understood. To understand these factors, we employed various techniques, including in vitro primary culture of brain cells from young and aged mice, ex vivo brain co-cultures with melanoma, and in vivo mouse models to characterize the aging brain microenvironment. We have shown that the young and aged brain endothelium impacts melanoma migration and have observed differences in vascular integrity and vasculature changes with aging and tumor presence. Additionally, aged mice that are more prone to vasculature dysfunction have a higher rate of melanoma colonization in the brain and higher activation of pro-inflammatory factors from the native brain microenvironment. These results give insight into differences in melanoma migration and colonization in the brain between aged and young mice. However, whether this results from astrocyte involvement in melanoma recruitment or disruption of the blood-brain barrier remains to be elucidated. The knowledge from this study will be pivotal to shaping future work by analyzing molecular changes in young and aged patients with malignant melanoma. It may provide new therapeutic targets for effectively preventing and treating this disease.

#2560 Age-dependent differences in breast tumor microenvironment: Challenges and opportunities for efficacy studies in preclinical models.

Paolo Falvo[1], Stephan Gruener[2], Stefania Orecchioni[1], Giovanna Talarico[1], Giulia Mitola[1], Giulia Bravetti[1], Federica Pisati[3], Juliane Winkler[2], Iros Barozzi[2], **Francesco Bertolini**[1]

[1]IEO - European Institute of Oncology, Milan, Italy,[2]Medical University of Vienna, Vienna, Austria,[3]Cogentech, Milan, Italy

Immunity declines with age, leading to functional deficits and an increased incidence of cancer in the elderly. Despite this, most cancer models utilize young (6-8 week old) mice, which are not representative of adult cancer patients. Triple negative breast cancer (TNBC) typically occurs around 30-50 years of age, which can be approximated to 12 months in mice. We previously demonstrated that a Triple-Therapy (TT) including APC activation via vinorelbine and the generation of TCF1+ stem-cell-like T cells (scTs) by cyclophosphamide (CTX), significantly enhances anti-PD-1 efficacy in TNBC and lymphoma models resistant to anti-PD1 treatment by promoting T-cell-mediated tumor abrogation. In this study, we examine TT effects on TNBC growth and the tumor microenvironment (TME) in young (6-8 weeks) vs adult (12 months) mice. We investigated two models, one (4T1) with predominantly lymphoid TME and the other (EMT6) with a predominant myeloid TME. Regular-dose-TT efficacy was similar across age groups, as - notably - CD8+ scTs were only slightly reduced in adults. At variance, low-dose TT and/or metronomic CTX were significantly less effective in adult mice. This might explain why encouraging preclinical results of metronomic CTX where sometimes difficult to replicate with adult cancer patients. Single-cell analyses revealed substantial differences in the TME: adults exhibited fewer CD4+ scTs, naïve B cells, and NK cells, but more memory B cells. Cancer-associated fibroblasts (CAFs) with an extracellular matrix (ECM) deposition signature (Matrix-CAFs) were more prevalent in young mice, whereas pro-inflammatory stromal populations and myofibroblasts were more frequent in adults. In adult mice, Matrix-CAFs displayed reduced ECM-remodeling capacity, decreased collagen deposition, and distinct interaction patterns with other cells in the TME. To gain further insight, non-epithelial cells from the mammary gland and scRNA data of Tabula Muris Senis were contextualised with the TME age-related signature. Age-related transcriptional differences observed in the TME already show an age-related trend in the stroma of the normal mammary gland, including a reduction of T cells, and an increase in the ECM remodeling ability of fibroblasts. Nevertheless, the extent of these differences is larger in the TME as compared to normal ageing breast, suggesting the tumor cells can leverage and exacerbate these differences, potentially to the tumor’s advantage. These findings underscore the importance of considering age-dependent TME variations when designing preclinical studies.

#2561 Immune mediated expansion of p53 mutant clonal hematopoiesis following carboplatin treatment.

Priyanka Khanna, Dexin Yang, Muharrem Muftuoglu, Lauren Ostermann, Shayaun Khazaei, Ran Zhao, Mahesh Basyal, Michael Andreeff, Mihai Gagea, Ruoyan Li, Koichi Takahashi, **Rasoul Pourebrahim**

UT MD Anderson Cancer Center, Houston, TX

Therapy-related myeloid neoplasms (t-MNs) are devastating complications arising from cancer chemotherapy, particularly affecting patients treated with agents like alkylating agents and platinum compounds. *TP53* mutations are the most frequent genetic alterations in t-MNs, present in 25-40% of cases. While the selective expansion of p53-mutant HSCs under chemotherapeutic pressure, known as clonal hematopoiesis (CH), has been implicated in t-MN development, the transition from clonal expansion to malignant transformation remains poorly understood.

To elucidate the mechanisms driving the transformation of p53 mutant HSCs following chemotherapy, we established a mouse model of p53-mutated CH. Using a chimeric bone marrow transplantation approach, we co-transplanted GFP-labeled *Trp53*^{R172H} mutant BM cells and RFP-labeled wild-type BM cells into irradiated recipients. Six weeks post-transplantation, mice were treated with weekly intraperitoneal injections of carboplatin or no treatment for four weeks. Flow cytometry revealed a significant expansion of p53 mutant cells in the carboplatin-treated group compared to both baseline and controls. All carboplatin-treated mice developed t-MNs within four months, while none of the control group did. Bone marrow analysis using CyTOF identified a distinct population of proliferative erythroid progenitors expressing c-Kit, Ki-67, mutant p53, and CD71 exclusively in the carboplatin group. Whole exome sequencing of sorted GFP-positive p53 mutant cells revealed recurrent deletions in chromosomal regions 1q, 4q, and chromosome 10. Frequent mutations in RAS pathway genes were also identified, with *Ptpn11* mutations in six out of eight mice and *Kras* and *Nf1* mutations in the remaining two. Single-cell RNA sequencing of GFP+c-Kit+ cells from t-MN mice uncovered proliferative progenitor clusters with upregulated DNA damage response and repair pathways. Importantly, a recurrent deletion on chromosome 4 included genes encoding the interferon alpha (Ifn-α) family was identified. In NSG mice lacking functional immune cells, p53 mutant clones did not expand or progress to AML following carboplatin, suggesting a non-cell-autonomous immune role in clonal expansion.

Our findings reveal a critical role of immune-mediated mechanisms, particularly through IFN-α signaling, in driving the expansion and transformation of p53 mutant HSCs. Modulating immune interactions may offer a strategy to prevent t-MNs. Future studies should explore combining chemotherapy with immunosuppressive therapies to mitigate the risk of t-MNs and improve patient outcomes.

#2562 Cell populations in human breast cancers are molecularly and biologically distinct with age.

Adrienne Parsons[1], Esther Sauras Colon[2], Milos Spasic[1], Busem Binboga Kurt[3], Beyza Koca[4], Meghana Manjunath[1], Dimitry Lineker[1], Ashka Patel[4], Craig Snow[4], Alexander Swarbrick[5], Rachel Freedman[4], Elizabeth Mittendorf[4], Peter van Galen[1], Sandra McAllister[1]

[1]Hematology, Brigham and Women's Hospital, Boston, MA,[2]Universitat Rovira i Virgili, Tortosa, Tarragona, Spain,[3]Massachusetts General Hospital, Boston, MA,[4]Dana-Farber Cancer Institute, Boston, MA,[5]Garvan Institute of Medical Research, Darlinghurst, Australia

Aging is associated with increased breast cancer risk and outcomes are worse for the oldest and youngest patients, yet it is unknown how cells in the breast tumor microenvironment (TME) are impacted by age or how age contributes to disease pathology. Here, we discover age-associated differences in cell states and interactions in human estrogen receptor-positive (ER+) and triple-negative breast cancers (TNBC) using computational analyses of existing bulk and single-cell gene expression data.

We developed the age-specific program enrichment (ASPEN) pipeline, revealing age associations by correlating gene expression and pathway enrichment to age using single cell RNA sequencing (scRNAseq) data. Using the scRNAseq and spatially resolved breast cancer atlas (Wu et al., *Nature Genetics*, 2021), we identified cell-specific, age-related transcriptional programs in TNBC and ER+ breast cancer. ASPEN revealed increased tumor cell epithelial-mesenchymal transition (EMT), cancer-associated fibroblast (CAF) inflammatory responses, and T cell stress responses with age in TNBC. ER+ breast cancer is dominated by increased luminal cell activity and reduced immune cell metabolism with age.

Analysis of differential gene expression between younger and older patients followed by GSEA using the METABRIC bulk gene expression dataset (n = 63 TNBC >65 years, n= 50 TNBC <45 years, n = 386 ER+ >65 years, n = 86 ER+ <45 years) confirmed enrichment of immune pathways (e.g., antigen processing and presentation, immune response) with increased age in TNBC, and pathways related to oncogenic signaling (e.g., TP53 and RB1 targets) and breast biology (e.g., mammary stem cell, luminal v basal) enriched in younger donors in ER+ breast cancer.

Cell interactome analysis revealed candidate signaling pathways that could drive these cell states. Expression of the immune-inhibitory protein, Galectin-9 (*LGALS9),* was observed in both age cohorts in TNBC, yet interactions with the receptor TIM-3 (*HAVCR2*) were elevated in the younger cohort and those with the receptor prolyl 4-hydroxylase beta (*P4HB*) were exclusive to the older cohort. Interactions between the EMT-inducing factor, *PLAU*, expressed by myCAFs and monocyte/macrophages, and its receptor, *PLAUR,* on cancer cells, were increased with age in TNBC, supporting the finding of increased EMT signatures with age. In ER+ breast cancer, adhesion proteins and extracellular matrix (ECM) engagement comprised most signaling interactions in both age cohorts. Nearly all adhesion/ECM signaling involving either cancer luminal A cells, differentiated perivascular-like cells, or macrophages were enriched in the older cohort; those involving iCAFs, myCAFs, and ACKR1+ endothelial cells were enriched in the younger cohort.

This work reveals key biological differences with age at cell type resolution and lays a foundation for discovery of new, age-adapted therapeutic interventions for breast cancer.

TUMOR BIOLOGY: CAFs and Beyond: A Central Role for the Tumor Microenvironment in Cancer

#2566 Dissecting PDAC cell-microenvironment interplay in liver metastasis by single cell analysis.

Claudia Fioravanti[1], Arianna Vallerga[2], Giulia Garattini[1], Ilaria Craparotta[2], Federica Di Leva[1], Chiara Grasselli[2], Fabio Sangalli[1], Andrea Resovi[1], Raffaella Giavazzi[2], Marco Bolis[2], Giulia Taraboletti[1], **Dorina Belotti**[1]

[1]Mario Negri Institute for Pharmacological Research, Bergamo, Italy,[2]Mario Negri Institute for Pharmacological Research, Milano, Italy

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal tumors. Because most PDAC patients are diagnosed with an already advanced and metastatic stage of the disease, only 15% are suitable for surgical intervention. Thus, an improved understanding of the metastatic mechanism is critical to improve the outcome of these patients. The most common target for PDAC metastasis is the liver. Outgrowth of metastases requires acquisition of tumor genetic alterations in conjunction with alterations in the pancreas and liver microenvironment. The aim of the study was to investigate the role of the tumor microenvironment and the molecular alterations in tumor and stroma cells leading to PDAC liver metastasis formation. To this purpose a metastatic cell variant was established from the FC1199 pancreatic cancer cell line, derived from tumors arisen in LSL-Kras$^{G12D/+}$;LSL-Trp53$^{R172H/+}$;Pdx-1-Cre mice and growing orthotopically in C57BL/6 mice. The FC199LV metastatic variant was obtained by successive rounds of *in vivo* selection of cells implanted in the pancreas, isolated from liver metastases and re-implanted in the pancreas for a total of 5 rounds. IHC and *in vivo* MicroCT analysis of livers at different time points after tumor cell injection highlighted the presence of metastases only in mice transplanted with FC1199LV. Single cell RNA-sequencing analysis of dissociated primary tumors and livers of mice transplanted with FC1199 and FC1199LV highlighted differences in the microenvironmental transcription profile between the two tumor variants. The spontaneous metastatic model of PDAC is an important tool to study the interplay between tumor and stroma in PDAC metastatic process and to identify a tumor and tumor microenvironment gene expression signature associated with PDAC liver metastasis.

#2567 CX3CR1 surface expression on metastatic prostate cancer cells is increased by the target organs and is associated with a distinct metabolic phenotype.

Ruxu Zhai, Jieyi Zhang, Olimpia Meucci, Alessandro Fatatis

Pharmacology & Physiology, Drexel University College of Medicine, Philadelphia, PA

Studies from us and others have shown that the chemokine receptor CX3CR1 drives cancer cells to the skeleton, activates pro-survival signaling pathways and bears unique therapeutic potential. We have recently reported that the small subsets of prostate cancer cells that expose CX3CR1 on their surface ($CX3CR1^{Surf+}$) are endowed with stemness features and behave as metastasis-initiating cells (MICs). Interestingly, their $CX3CR1^{Surf-}$ counterparts can re-express CX3CR1 on the cell surface while undergoing partial EMT, thus re-acquiring MIC features. This phenotypic plasticity can be temporally monitored *in vitro*, with cultures of 100% $CX3CR1^{Surf-}$ cells reaching a phenotypic equilibrium (5-7% of $CX3CR1^{Surf+}$) in ~ 8 days. However, when cells at phenotypic equilibrium are grafted in mice via systemic blood circulation, the resulting tumors in the skeleton and soft tissues show a dramatic increase in the $CX3CR1^{Surf+}$ fraction. This suggests that the stroma of target organs promotes CX3CR1 plasticity, an effect not observed when the same cells are grafted subcutaneously. We also show that FX-68, a potent and specific antagonist of CX3CR1, dramatically reduces the number of disseminated tumors and total tumor burden in mice. FX-68 does not alter the percentage of $CX3CR1^{Surf+}$ cancer cells in disseminated tumors, suggesting that its anti-tumor effects are exerted by functional inactivation of CX3CR1. Notably, we found a strong association between the $CX3CR1^{Surf+}$ status and a metabolic shift away from the OXPHOS pathway and towards glycolysis. Based on these findings, we conducted further studies by assessing the short- and long-term effects of CX3CR1 activation on the metabolic profile of prostate cancer cells. Furthermore, *in vivo* studies with tumor-bearing mice treated with FX-68 revealed the effects of this compound on the metabolic profiles of cancer cells harvested from tumors in the skeleton and soft tissues. Our work reports for the first time the association of CX3CR1 with the metabolic status of prostate cancer cells. We also provide evidence that interfering with CX3CR1 signaling could impede a metabolic switch promoted by target organs and sustaining metastatic progression.

#2568 Cancer-associated fibroblasts-derived periostin promotes lymph node metastasis of cholangiocarcinoma through lymphatic endothelial reprogramming.

Z. Song, X. Li, H. Zhang, C. Liu;
Sun Yat-sen Memorial Hospital, Sun Yat-sen University, Guangzhou, China

Purpose: Cholangiocarcinoma (CCA) is a bile duct malignancy with poor outcomes, especially in patients with lymph node metastasis (LNM). However, the mechanism of LNM in CCA as well as its therapeutic options remain undefined. Understanding crosstalk between the cellular components in the complex tumor microenvironment (TME) of CCA, and how it influence LNM, may help identifying novel therapeutic targets in LNM of CCA.
Method: Freshly resected tumors from 10 CCA patients were collected for single-cell RNA sequencing (scRNA-seq), aiming to identify the differences between CCA with or without LNM. Immunohistochemistry (IHC) and enzyme-linked immune sorbent assay (ELISA) were applied to validate the identified targets. In vivo study was conducted using foot pad-popliteal LNM mouse model to find out main factors affect LNM. Co-culture system was established to interrogate cellular crosstalk between human lymphatic endothelial cells (HLECs) and patient-derived CAFs in TME of CCA. Other phenotypic and mechanistic experiments include tube formation assay, trans-endothelial migration assay, cell adhesion assay, pull down assay, etc.
Results: Our scRNA-seq revealed the enrichment of a distinguish subtype of CAFs that express periostin (POSTN) in CCA tumors with LNM. IHC and immunofluorescence staining in CCA sections validated that the CAF-specific expressing protein, POSTN, expresses significantly higher in CCA with LNM, which is also associated with higher circulating tumor cells (CTCs), and worse prognosis. In vivo study shows that CAFs highly expressing POSTN (POSTN+CAFs) lead to higher incidence of LNM. In vitro study indicates that either with co-culture of POSTN+CAFs or treatment of recombinant human POSTN (rhPOSTN), HLECs developed increased capacity of tube formation and migration, while CCA cells also show increased capacity of migration in trans-endothelial assay but not traditional migration assay. Meanwhile, POSTN also impairs integrity of lymphatic vessels, providing routes for CCA cells to disseminate. Pull down assay identifies the binding of POSTN to its receptor, αVβ3 integrin, on HLECs. We demonstrate that the effects of POSTN aforementioned can be abrogated by knockdown of ITGB3 in HLECs, suggesting that POSTN exerts its effects in an αVβ3-dependent manner. We further show that POSTN's effects are attributed to the activation of integrin-FAK/Src pathway. Moreover, in vivo application of Cilengitide, an αVβ3/5 inhibitor, decreases the incidence of LNM in CCA, indicating its therapeutic efficacy in mitigating LNM burden in CCA patients with higher expression of POSTN.
Conclusion: This study uncovers the novel role of CAF-derived POSTN in promoting LNM of CCA, presenting the potential therapeutic promise of the FDA-approved αVβ3/5 inhibitor, Cilengitide, in inhibiting LNM in CCA.

#2569 Cancer associated fibroblast dependency in a model of muscle invasive bladder cancer.

Henkel Valentine, Uttam Satyal, Alexander Metz, Rhea Arya, Tahmina Hague, Laura Bukavina, Philip H. Abbosh

Fox Chase Cancer Center, Philadelphia, PA

Introduction: The relationship between genotype and phenotype in targeted therapy is crucial, especially in diseases like bladder cancer where the PI3K/AKT/mTOR pathway is widely activated but untargeted. We have developed an immunocompetent, CRISPR-edited bladder cancer mouse model that recapitulates common PI3K/AKT/mTOR mutations. Through targeting generated PI3K/AKT/mTOR mutations, we hope to establish rationale for clinical investigation of PI3K/AKT/mTOR-directed therapy. Our mouse model displays a dependency on Cancer Associated Fibroblasts (CAFs) to create a pro-tumorigenic environment *in vivo*, facilitating engraftment and tumor progression. Given the observed *in vivo* CAF dependency, we aim to understand the mechanisms of immune modulation between CAFs and the tumor microenvironment.

Methods and Results: Urothelial cells were isolated from the bladder of Rosa26 LSL-Cas9/GFP transgenic mice to develop organoids. These organoids were co-edited for *Trp53* knockout and either *Rb1 knockout* or *9p21* (homologous to mouse 4q) large deletion. Further editing of the *Pten* gene resulted in a nine-fold increase in sensitivity to the kinase inhibitor ipatasertib, while a Pikc3a H1047R hotspot mutation sensitized organoids up to 2000-fold to the Pik3 inhibitor pictilisib. Despite successful engraftment into mouse bladder, these edited cells regressed before tumor formation. We have since demonstrated that co-injecting edited organoids with skin cancer or bladder cancer derived-CAFs yielded palpable subcutaneous and orthotopic tumors. To further understand the mechanisms of immune suppression *in vivo*, we performed a medium throughput cytokine array with a panel of 16 mouse adaptive immune markers. Cytokine analysis revealed that CAFs secreted interlukin-6 in the presence of organoids which themselves secreted GM-CSF. This combination is well-known to be pro-tumorigenic, facilitating recruitment of M2 macrophages which we also observe in *in vivo* tumors. Further, CAFs activate TGF-β pathway as demonstrated by phosphorylation of SMAD2/3. Taken together we believe that CAFs, through GM-CSF/IL-6 secretion along with TGF Beta pathway activation, regulate the TME to create a suitable environment for tumor engraftment.

Conclusions: Our research demonstrates the importance of CAFs in bladder cancer progression. Through further examining the mechanistic interplays between CAFs and immunoregulation, we can gain a better understanding of the main drivers and potential targets in bladder tumorigenesis.

#2570 Deciphering local immunosuppression in pancreatic cancer: targeting CAF-myeloid cell crosstalk to enhance immune response.

Marie C. Hasselluhn[1], Lukas Vlahos[1], Yuanqing Xue[1], Dafydd Thomas[2], Quin T. Waterbury[1], Allison C. Hess[1], Tanner C. Dalton[1], Amanda R. Decker-Farrell[3], Alvaro Curiel Garcia[1], Stephen A. Sastra[1], Carmine F. Palermo[1], Timothy C. Wang[1], Andrea Califano[1], Kenneth P. Olive[1]

[1]Columbia University Irving Medical Center, New York, NY,[2]PMV Pharmaceuticals, Inc., Princeton, NJ,[3]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY

Immunotherapy has revolutionized cancer treatment but remains largely ineffective in pancreatic ductal adenocarcinoma (PDAC). A hallmark of PDAC is local immunosuppression, driving cytotoxic T cell exclusion and deactivation, undermining immune-mediated tumor control. Better understanding of the cellular crosstalk in the tumor microenvironment (TME) and identifying stromal and immune populations shaping this immunosuppressive landscape is critically needed. Oncogenic KRAS activation in PDAC cells promotes recruitment and proliferation of tumor-supporting stromal cells while excluding cancer-targeted cytotoxic T cells. Local immunosuppression is driven by interactions between subtypes of cancer-associated fibroblasts (CAFs) and resident myeloid cells. Previous efforts to reverse immunosuppression by targeting individual stromal populations have largely failed, highlighting the complexity of stromal interactions in the TME. The stromal diversity of PDAC complicates investigating paracrine signaling involving multiple cell types. To address this, we use in vivo mouse models that recapitulate human disease, alongside a novel tumor explant system enabling short-term culture of intact human or murine PDAC tissue. These explants retain histopathological architecture and cellular diversity, providing a medium-throughput platform for testing drugs and mechanistic hypotheses in the native TME. Preliminary data show that Smoothened inhibition (SMOi) reduces myCAF proliferation and activity but drives CD11b-positive myeloid cell expansion in vivo. We hypothesize local immunosuppression in PDAC is sustained by a delicate balance between myCAFs and myeloid cells, collectively hindering T cell infiltration. Single-cell RNA sequencing of control vs. SMOi-treated murine PDAC identified stromal subpopulations maintaining immunosuppression and revealed specific myeloid subtypes emerging after SMOi. Strikingly, combining SMOi with anti-Gr1 or CCR1 inhibition (CCR1i) markedly increased cytotoxic T cell numbers—up to 20-fold—within the TME. We are now exploring whether these T cells' activity can be further enhanced using additional immunomodulatory agents. Testing therapeutic combinations in the same TME allows us to identify synergistic effects that may inform future PDAC immunotherapy. Our work elucidates complex immunosuppressive mechanisms in PDAC, leveraging a novel tumor explant system and in vivo models. Our ultimate goal is to develop translatable regimens that neutralize local immunosuppression, enabling cytotoxic T cells to infiltrate, proliferate, and effectively attack cancer cells.

#2571 Effects of patient-derived ovarian cancer-associated fibroblasts and tumor progression and metastasis.

Ji-Young Lee, Sung Wan Kang, Min-Seo Lee, Ok-Ju Kang, Yong-Man Kim, Shin-Wha Lee

Obstetrics and Gynecology, Asan Medical Center, University of Ulsan, Seoul, Korea, Republic of

Background: Ovarian cancer (OC) is a highly treatment-resistant malignancy, often diagnosed late due to minimal symptoms and extensive metastasis. Despite platinum-based chemotherapy, recurrence and chemoresistance highlight the need for new therapies. This study focuses on cancer-associated fibroblasts (CAFs), key TME components, to explore their impact on OC progression and identify novel CAF subtypes. Methods: CAFs were isolated from OC patient tumors via enzymatic dissociation and flow cytometry. Their markers, FAP and α-SMA, were analyzed using immunofluorescence and flow cytometry. Conditioned media from CAF cultures were tested on OC cell lines (A2780, A2780-cp, SKOV3, OVCAR3) to assess proliferation and migration via cell viability and scratch assays. Cytokines in CAF-conditioned media were quantified using ELISA.
Results: CAFs were identified within OC tumors, with their expression of FAP validated in high-grade serous ovarian cancer (HGSOC) samples via immunohistochemistry and flow cytometry. CAFs were successfully isolated and cultured from patient-derived OC tumors. Flow cytometry revealed that CAFs represent a minor subset of the total tumor cell population. Morphologically, CAFs exhibited plump spindle or stellate forms. CAFs derived from HGSOC displayed elevated levels of FAP and α-SMA expression compared to those derived from non-HGSOC tumors. Exposure of four OC cell lines (A2780, A2780-cp, SKOV3, OVCAR3) to CAF-conditioned media significantly promoted their growth. Scratch assays revealed enhanced motility in two OC cell lines (SKOV3 and OVCAR3) following treatment with CAF-conditioned media. Notably, the HGSOC-derived CAF subtype, W-OVCAF7, exhibited significantly greater growth- and motility-enhancing effects compared to non-HGSOC-derived CAFs. Scratch assays further confirmed that W-OVCAF7 markedly increased the migratory capacity of both SKOV3 and OVCAR3 cells, suggesting that CAF activity may vary depending on the tumor cell type. These findings underscore the pivotal role of CAFs in modulating the proliferation and migration of OC cells.
Conclusion: Tumor-derived CAFs significantly enhance OC cell proliferation and migration, underscoring their critical role in the TME. This study highlights the importance of patient-derived CAFs for precise analysis of OC dynamics and lays a foundation for therapeutic strategies targeting the CAF-TME interplay.

#2572 Association of cancer-associated fibroblast composition with CD4 T cells in pancreatic ductal adenocarcinoma.

Jessica Hung, Michel DuPage

Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Understanding interactions between cancer-associated fibroblasts (CAFs) and immune components in the tumor microenvironment (TME) is crucial for engineering antitumor immunity in pancreatic ductal adenocarcinoma (PDAC). While most studies have focused on CAF-mediated immunomodulation, the impacts of immune cells on CAF heterogeneity and function remain underexplored. In this study, we used flow cytometry and microscopy to profile three major CAF subsets—myofibroblasts (myCAFs), inflammatory CAFs (iCAFs), and antigen-presenting CAFs (apCAFs)—in two orthotopic mouse models of PDAC presenting “immune-hot” (6421c2) and “immune-cold” (FC1245) TMEs. Consistent with subcutaneous models, orthotopic 6421c2 tumors exhibited smaller tumor size, elevated T cell infiltration, and reduced suppressive neutrophils compared to FC1245, highlighting distinct immune microenvironments. Although the overall frequency of $PDPN^+$CAFs in the non-immune compartments was similar, CAF composition differed significantly between the two tumors. FC1245 was predominantly composed of myCAFs (80% of $PDPN^+$CAFs), with low iCAF and apCAF proportions. In contrast, 6421c2 tumors displayed increased iCAFs (30%) and apCAFs (20%) alongside a reduced myCAF frequency (50%). Immunofluorescence and Trichrome staining revealed elevated αSMA^+myCAFs and increased collagen deposition in FC1245, suggesting unique CAF composition and function in immunologically distinct TMEs. To examine whether intratumoral T cells modulate CAF heterogeneity in vivo, we examined CAF compositions in tumor-bearing mice administrated with $CD8^+$ or $CD4^+$ T cell depleting antibodies or in the $Foxp3^{DTR}$ mice given diphtheria toxin (DT) to deplete regulatory T cells (T_{regs}). Unlike CD8 or CD4 depletion, T_{reg} depletion significantly improved primary tumor control in 6421c2, reduced metastasis, and prolonged survival in FC1245. CAF subset analysis also revealed T_{reg}’s unique roles in regulating the myCAF and apCAF subsets in PDAC. Specifically, T_{reg} depletion significantly reduced myCAFs, supporting prior findings that T_{regs} are essential for myCAF development during PDAC precursor lesion formation. Furthermore, T_{reg}-mediated support of myCAF was $CD4^+$ conventional T cell (T_{conv})-dependent, as myCAF level was restored upon CD4 depletion in DT-treated mice. Conversely, apCAFs increased following T_{reg} depletion but were completely abolished with CD4 depletion, suggesting that effector CD4 T cells are required for recruiting or maintaining MHC II-expressing CAFs within the TME. In summary, our study reveals distinct CAF compositions in immunologically diverse TMEs and uncovers the unique roles of T_{regs} and T_{conv} in regulating CAF subsets. These findings provide novel insights into CAF-CD4 T cell interactions in vivo and support further investigation of molecular mechanisms underlying stromal functions in PDAC.

#2573 Single-cell multi-omics analysis identifies a novel GPRC5B-marked endothelial cell subset and its mechanistic role in tumor stemness in colorectal cancer.

Mengying Suo, Hongyu Huang, Tianyou Li, Ziqi Meng, Xueqian Zhang, Shanshan Jiang, Na Li

Nankai University School of Medicine, Tianjin, China

Introduction: Tumor endothelial cells (ECs) support the tumor microenvironment and regulate the status of tumor cells. GPRC5B, enriched in ECs, is linked to poor prognosis in colorectal cancer (CRC). Yet, the influence of GPRC5B on ECs and its regulatory mechanism on CRC stemness are still elusive. Therefore, this study aims to clarify the impact of GPRC5B on ECs states, the specific role of GPRC5B-marked ECs (GPRC5B$^+$ ECs) in tumor/stromal interactions and the mechanisms regulating CRC stemness.

Methods: We analyzed scRNA-seq data from 18 CRC samples to decode the endothelial heterogeneity. We used an original SVM-based algorithm to find EC subsets linked to CRC stemness, ultimately identifying the GPRC5B$^+$ ECs. By deconvoluted bulk RNA-seq data, we evaluated stemness level in GPRC5B$^+$ EC-enriched samples. Cellular interactions and spatial omics analyses were employed to examine the signaling axis between GPRC5B$^+$ECs and CRC stem cells. ChIP-seq and hdWGCNA algorithm pinpointed upstream regulators in the axis.

We also developed a GPRC5B-overexpressing EC line and co-cultured it with CRC cells, whose stemness was then assessed by spheroid formation assays and western blot. Inhibitors targeting this signaling axis were administered, and changes in stemness phenotype and key signaling molecules were measured in co-cultured CRC cells. Finally, we constructed a CT26 subcutaneous tumor mouse model and treated the mice with siRNA targeting GPRC5B (siGPRC5B) to monitor tumor growth. Tumor tissues were collected to detect the expression of stemness markers using IHC and western blot.

Results: GPRC5B$^+$ ECs exhibited high angiogenic potential, with significant ERK pathway activation. ScRNA and bulk analyses showed GPRC5B$^+$ ECs enhance CRC stemness, which was further confirmed by the increased spheroid formation ability and enhanced expression of KLF4 and SOX2 in CRC cells after co-culturing with GPRC5B-high ECs. Mouse models showed that high GPRC5B expression in ECs fosters tumor stemness and progression.

Mechanistically, multi-omics and in vitro analyses revealed that GPRC5B in ECs activated the ERK-SP1 axis to promote the expression of ADAM17, which cleaved and activated JAG1, ultimately enhancing stemness of CRC cells via JAG1/NOTCH1 interaction. Application of ERK pathway or ADAM17 inhibitors to ECs decreased tumor stemness, respectively. Besides, application of siGPRC5B effectively inhibited tumor growth *in vivo*.

Conclusion: Through single-cell multi-omics analyses, we identified a novel GPRC5B-marked EC subset, promoting angiogenesis and CRC progression, and revealed that GPRC5B$^+$ ECs enhance tumor stemness via the ERK/SP1/ADAM17/JAG1-NOTCH1 axis. The study offers insights into CRC endothelial heterogeneity and tumor/stromal interactions, and future targeted therapy will be conducted to elucidate its clinical application potential.

#2574 Cancer associated fibroblasts with high expression of immunoglobulin superfamily containing leucine-rich repeat show tumor inhibitory capabilities in brain metastasis.

Thomas Simon[1], Aspiara Roosmin[1], David N. Buckley[1], Ben Y. Tew[1], Gerald C. Gooden[1], Gabriel Zada[2], Bodour Salhia[1]

[1]Department of Translational Genomics, USC - University of Southern California, Los Angeles, CA,[2]Department of Neurosurgery, USC - University of Southern California - Keck School of Medicine, Los Angeles, CA

Brain metastasis (BM) remains mostly incurable with a dismal mean 2-year survival of less than 2%. The tumor microenvironment (TME) of BM is complex and includes cancer associated fibroblasts (CAFs), which we have shown can either support or inhibit tumor growth, pointing to their heterogeneity. To examine the CAF heterogeneity in the BM TME, we performed a cell multiome sequencing analysis (scMultiome-seq) of BM patient tissues and identified 4 diverse CAF subpopulations in the TME. Among these was a subpopulation of CAFs that expressed high levels of tumor inhibitory CAF marker immunoglobulin superfamily containing leucine-rich repeat (ISLR). High expression of ISLR was also observed in CAFs we have previously reported as tumor inhibitory in an *in vivo* model of BM. We thus hypothesized that ISLR-CAFs could be tumor inhibitory in the BM TME. Further analysis of our scMultiome-seq data to infer cell-cell communication revealed the anti-proliferative IGFBP3-TMEM219 pathway as a potential communication mechanism between ISLR-CAFs and BM tumor cells. In the present study, we thus aimed to investigate the role of ISLR in BM CAFs and to study the significance of the IGFBP3-TMEM219 pathway in the tumor-inhibitory effects of ISLR-CAFs *in vitro.* To do so, patient-derived BM tumor (CM04) and CAF (CM01, CM02, CM03 and CM08) cell lines previously established in our lab were used. BM tumor cells were treated with CAF-derived conditioned media (CM) and cell viability was assessed using the CellTiter-Glo assay. The expression of ISLR, IGFBP3 and TMEM219, along with the activation of caspase-8 signaling linked to the anti-proliferative effects of the IGFBP3-TMEM219 pathway, was analyzed via western blotting. We observed high expression of ISLR in CM03 and CM08 CAFs, as compared to CM01 and CM02 CAFs, which expressed low to no ISLR. CM04 tumor cells showed high expression of TMEM219 compared to CAFs, while CM03 and CM08 CAFs expressed the highest levels of IGFBP3. Both ISLR and IGFBP3 were also detected in CM derived from CM03 and CM08 CAFs. We observed that CM03 and CM08 CAF-derived CM significantly inhibited CM04 tumor cell viability *in vitro*. In addition, activation of the caspase 8 signaling was detected in CM04 tumor cells treated with CM08 CAF-derived CM. Next, ISLR knock-down was performed in CAFs using lentiviral shRNA particles to confirm a role for ISLR in CAF-mediated tumor inhibition. ISLR knock-down in CM08 CAFs decreased expression of IGFBP3, suggesting a role for ISLR in regulating IGFBP3 expression in CAFs. Altogether the present data revealed that CAFs with high ISLR expression could inhibit tumor growth *via* the IGFBP3-TMEM219 pathway in the BM TME. Further in-depth understanding of the roles of ISLR-CAFs in the BM TME could help develop strategies that selectively target tumor supportive CAFs while protecting tumor inhibitory ones.

#2575 Tumor microenvironmental metabolites regulate cancer-associated fibroblast heterogeneity.

Chufan Cai[1], Marta Storl-Desmond[1], Kristof Turan[1], Axel R. Concepcion[2], Jing Chen[1], **Simon Schwoerer**[1]

[1]Medicine, University of Chicago, Chicago, IL,[2]Biochemistry, University of Chicago, Chicago, IL

Pancreatic ductal adenocarcinoma (PDAC) is characterized by a prominent desmoplastic response with a high abundance of cancer-associated fibroblasts (CAFs). CAFs are a functionally and transcriptionally heterogeneous population of cells and include inflammatory CAFs (iCAFs), thought to promote tumor growth via the secretion of cytokines and chemokines, as well as myofibroblasts CAFs (myCAFs), thought to restrain tumor growth via the secretion of extracellular matrix. The iCAF and myCAF states are highly plastic. Preventing the interconversion of CAF populations could have significant clinical benefits, but how this plasticity is regulated is largely unknown. Cytokines like IL1α and growth factors like TGFβ are required but not sufficient to induce changes in the CAF state. Instead, their effect is dependent on the presence of other environmental factors. We recently demonstrated that cancer cell-derived cytokines synergize with hypoxia to induce a transition from a myCAF- towards and an iCAF state, indicating that metabolic factors in the TME can modulate the CAF state in combination with signaling molecules. To identify other extracellular metabolic factors that synergize with cytokines in regulating CAF plasticity, we performed a high-content screen using a human blood chemical library in combination with our recently developed fibroblast reporter (FIRE) system incorporating iCAF (*IL6*-EGFP) and myCAF (*Acta2*-DsRed) transcriptional reporters. Out of hundreds of compounds, we identified and validated one metabolite that synergizes with the cytokines IL1α and TNFα to promote *IL6* expression in a time- and dose-dependent manner. Intriguingly, previous studies have reported that this metabolite accumulates in the PDAC TME to a high micromolar range. Metabolite and cytokine treatment together induce pancreatic stellate cells (PSCs) to upregulate production and secretion of pro-inflammatory cytokines including IL6, CXCL1 and LIF. Pretreatment of PSCs with physiological concentrations of this metabolite is sufficient to alter the fibroblast state and to promote tumor growth when co-injected with PDAC cells *in vivo*. Mechanistically, we find that this metabolite acts in part through the JAK-STAT pathway, a major regulator of the iCAF state. These findings support the idea that TME metabolites can alter PDAC progression by regulating CAF heterogeneity through synergy with cancer cell-derived signaling molecules.

#2576 Crosstalk between cancer-associated fibroblasts and sympathetic nerves promotes pancreatic ductal adenocarcinoma progression.

Ariana Sattler[1], Parham Diba[1], Tetiana Korzun[1], Marigold Kuykendall[1], Kevin MacPherson-Hawthorne[1], Mara Sherman[2], Teresa A. Zimmers[1], Sebnem E. Eksi[1]

[1]Oregon Health & Science University, Portland, OR,[2]Memorial Sloan Kettering Cancer Center, New York, NY

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal cancers, with a 5-year survival rate of 12.8%. This aggressive malignancy is composed of a heterogenous tumor microenvironment (TME), including cancer-associated fibroblasts (CAFs) and sympathetic neurons. The abundance of CAFs and sympathetic neurons correlates with tumor progression and is often associated with poor prognosis of PDAC patients. However, the precise role of CAF-nerve interactions in cancer progression and metastasis remains unclear. To explore our hypothesis that these bidirectional interactions can be tumor-supportive, we used advanced imaging and sequencing techniques, an *in vivo* tumor denervation murine model, and *in vitro* CAF-sympathetic neuron coculture systems. Compared to human PDAC tumors, we affirmed that sympathetic innervation is recapitulated in murine PDAC tumors, and these intratumor nerves are similarly surrounded by an abundance of CAFs. To focus on the interaction between CAFs and sympathetic nerves, we developed and optimized *in vitro* coculture systems. These cocultures initially revealed that CAFs consistently interact with nerve fibers and significantly increase sympathetic nerve outgrowth. Transcriptional analysis of these co-cultures further identified genes upregulated in CAFs that promote adhesion, ECM deposition, and neuroactive ligand-receptor interactions, while sympathetic nerves upregulated pathways associated with nerve injury response. To further interrogate the impact of sympathetic innervation in the PDAC TME, we specifically and locally ablated sympathetic nerves in murine orthotopic PDAC tumors and spatially evaluated the cellular and molecular changes in response. Collectively, our findings suggest that the crosstalk between sympathetic nerves and CAFs may modulate CAF behavior, enhance tumor innervation, and drive tumor-promoting phenotypes in PDAC progression.

#2577 Antigen-presenting CAFs in PDAC differentially regulate Treg phenotype and function via CXCL9 and CCL22.

S. Y. Maru, J. T. Mitchell, M. Wetzel, N. E. Gross, L. Andaloori, K. Howe, E. Kartalia, G. Mo, J. Leatherman, W. Ho, E. Fertig, L. T. Kagohara, E. J. Pearce, E. M. Jaffee;
Johns Hopkins University School of Medicine, Baltimore, MD

Pancreatic ductal adenocarcinoma (PDAC) is characterized by a complex tumor microenvironment (TME) including stromal cells that influence resistance to therapy. Recent studies have revealed that stromal cancer-associated fibroblasts (CAFs) are heterogeneous in origin, gene expression, and function. One such population, antigen-presenting CAFs (apCAFs), is defined by MHC-II and can induce both $CD4^+$ T cell activation and regulatory T cell (Treg) differentiation. Understanding apCAF biology could uncover mechanisms that can be targeted to promote CAF differentiation and enhance T cell activity.

Methods: Two clones differing in sensitivity to immune checkpoint blockade (ICB), derived from the autochthonous KPC murine PDAC model, were implanted orthotopically into the pancreas of syngeneic C57BL/6 mice. apCAF KO mice were generated by crossing $PDGFR\alpha^{Cre}$ and MHC-II^{flx} mice. All mouse strains were untreated, treated with ICB or anti-mesothelin antibody, or immunized with a KRAS peptide vaccine. Tumors were harvested for TME characterization, functional assays, single-cell RNA sequencing (scRNAseq), and imaging mass cytometry (IMC). apCAFs, DCs, and $CD4^+$ T cells were isolated and peptide-pulsed apCAFs and DCs were cultured with naïve OT-II $CD4^+$ T cells or tumor-infiltrating $CD4^+$ T cells. Cell to cell communication inference using dominoSignal was performed to assess signaling between apCAFs and $CD4^+$ T cells.

Results: Immunosensitive (sKPC) tumors were characterized by higher immune cell and apCAF infiltration than resistant (rKPC) tumors. IMC analysis showed proximity of apCAFs and $CD4^+$ T cells in both sKPC and rKPC tumors implicating interaction within the TME. apCAF-depleted sKPC tumor-bearing mice have diminished sensitivity to ICB. apCAFs activate tumor-infiltrating $CD4^+$ T cells and induce Treg differentiation, but not production of immunosuppressive cytokines in sKPC tumors. scRNAseq revealed greater Th1-like Treg differentiation in CD4s cultured with sKPC apCAFs, and differential chemokine signaling from apCAFs based on TME of origin, such that sKPC apCAFs induce Th1-like Tregs via CXCL9 and rKPC apCAFs induce classical Tregs via CCL22.

Conclusions: apCAFs are more abundant in immunosensitive PDAC tumors, spatially involved with $CD4^+$ T cells, and are functionally relevant for response to ICB as shown by two depletion models. Notably, chemokine signaling from apCAFs varies with tumor of origin and modulates Treg function. Together these data implicate apCAFs as important mediators of the antitumor immune response. Although a small proportion of the TME, modulating apCAF number or function may provide a solution to the currently unmet need of new and more effective treatments for PDAC patients.

#2578 GDF15 reprograms the microenvironment to drive the development of uveal melanoma liver metastases.

Sathya Neelature Sriramareddy[1], Navya Siddarajappa[1], Thanh Nguyen[2], Jeffim Kunetsov[3], Stefan Kurtenbach[3], James Jarad Dollar[3], Jonathan D. Licht[4], Ann Y. Chen[2], William J. Harbour[5], Keiran S. M. Smalley[1]

[1]Department of Tumor Microenvironment & Metastasis, H. Lee Moffitt Cancer Center, Tampa, FL,[2]Department of Biostatistics,, University of Utah, Salt Lake City, UT,[3]Sylvester Cancer Center, University of Miami, Miami, FL,[4]University of Florida Health Sciences Center, Gainesville, FL,[5]Department of Ophthalmology, University of Texas Southwestern, Dallas, TX

Little is known about how interactions between the uveal melanoma (UM) and host cells in the tumor microenvironment (TME) drive the progression of liver metastases. Single cell RNA-seq analysis of UM samples identified marked differences in cell-cell communication between primary and metastatic UM characterized by increased signaling strength and numbers of interactions emanating from the hepatic stellate cells (HSCs) and endothelial cells in the metastatic samples. In co-culture, HSCs modulated the transcriptional heterogeneity of the UM cells, enriching for cell states that expressed genes implicated in cell survival, metabolic reprogramming and the angiogenic response. Co-culture of HSCs and UM cells also led to increased expression of growth factors and receptors implicated in angiogenesis including IL-8, VCAM1, VEGF and ICAM1. One candidate driver of HSC reprogramming was the TGF-beta family member GDF15. Increased expression of GDF15 was associated with a Class 2 metastatic UM phenotype in clinical UM samples and UM cell lines, with silencing of BAP1 in UM cells increasing both GDF15 expression and H3K27ac marks at the GDF15 promoter. Treatment of HSCs with GDF15 led to increased expression of multiple ECM proteins, inflammatory cytokines and angiogenic factors, including IL- 8. Both exogenous GDF15, IL-8 and conditioned media from UM-HSC co-cultures increased endothelial cell network formation in vitro, an effect that could be blocked by anti-GDF15 antibodies. In an eye->liver metastasis model of UM, silencing of GDF15 did not prevent the seeding of UM cells to the liver, but did inhibit the outgrowth of metastatic lesions. Although the GDF15-silenced UM cells were proliferative they did not recruit endothelial cells, leading to a significant reduction in metastatic burden. In sum, we provide the first evidence that UM liver metastasis development is dependent upon GDF15-mediated remodeling of the liver microenvironment leading to an angiogenic response that supports tumor growth.

#2579 Integrated sequencing analysis reveals prognostic thyroid cancer-associated fibroblast subpopulations.

Matthew A. Loberg[1], George J. Xu[1], Claudia C. Wahoski[1], Kailey P. Caroland[1], Megan L. Tigue[1], Sheau-Chiann Chen[2], Hua-Chang Chen[2], Quanhu Sheng[2], Eric C. Huang[3], Fei Ye[2], Ryan H. Belcher[2], Ethan Lee[1], Vivian L. Weiss[2]

[1]Vanderbilt University, Nashville, TN,[2]Vanderbilt University Medical Center, Nashville, TN,[3]University of Washington School of Medicine, Seattle, WA

Thyroid cancers exist on a continuum of differentiation. Our group recently defined dynamic changes in the tumor microenvironment co-occurring with tumor histotypes and de-differentiation. Here, we integrate 423,733 cells from seven distinct single-cell RNA-sequencing cohorts to define unique thyroid cancer- specific fibroblast subtypes occurring across the histologic and mutational spectrum of thyroid cancer. We identify distinct inflammatory, perivascular-like, and myofibroblastic cancer-associated (myCAF) populations. The myCAF population, specifically, is only found in malignant samples, and mapping myCAFs to three thyroid cancer bulk RNA-sequencing cohorts reveals an association with disease progression, with hazard ratio of 3.0 (95% CI, 1.7-5.3). Within this myCAF population, we identify subpopulations with immune-regulating phenotypes that are specifically associated with de-differentiated tumors. Additionally, we identify an invasive tumor cell phenotype in both differentiated and de-differentiated tumors marked by TNC and LAMB3. Ligand-receptor interaction analysis indicates robust interaction of myCAFs and invasive tumor cells through TGF-beta, tenascin, and collagen signaling pathways. Multiplex immunofluorescence, immunohistochemistry, and spatial transcriptomics analysis of 28 tumors (13 differentiated, 8 de-differentiated, 7 with areas of differentiated and de-differentiated histopathology) confirms robust upregulation of myCAFs in de-differentiated tumors. Further, myCAFs spatially localize next to the leading edge of de-differentiated tumors and near invasive cells from differentiated tumors, supporting a tumor-promoting role for myCAFs in aggressive thyroid carcinomas. In summary, our study provides an integrated atlas of thyroid cancer fibroblast subtypes, spatial analysis on patient samples, and an association of fibroblasts with disease progression.

#2580 Direct interaction between cancer cells and fibroblasts drives epithelial-to-mesenchymal plasticity (EMP) and contribute to chemotherapy resistance.

Nilu Dhungel, Ana- Maria Dragoi

Department of Molecular and Cellular Physiology, LSU Health Sciences Center, Shreveport, LA

The tumor microenvironment (TME), composed of immune cells and fibroblasts, blood vessels, signaling molecules and extracellular matrix, provides important cues that govern epithelial-to-mesenchymal transition (EMT) and facilitate the acquisition of aggressive traits such as chemotherapy resistance by cancer cells. Cancer cells exist in multiple hybrid epithelial/mesenchymal (E/M) states responsible for the ever-changing environment during tumor development and metastasis. How are these hybrid states generated and maintained is not fully understood. Using small cell lung carcinoma (SCLC) and normal lung fibroblasts model we show that direct interaction between SCLC and lung fibroblasts induces a hybrid EMT phenotype in cancer cells in which several mesenchymal genes involved in receptor interaction with the extracellular matrix (ECM) and ECM remodeling are upregulated while epithelial genes such as E-cadherin remain unchanged. We also demonstrate that several core EMT-regulating transcription factors (EMT-TFs) are upregulated in cancer cells during direct contact with fibroblasts, including Yes-associated protein (YAP1), a major regulator of the Hippo pathway. Furthermore, we demonstrate that this upregulation of YAP1 in cancer cells which occurs significantly only during the direct interaction with fibroblast makes the cancer cells more resistant to chemotherapeutic agents resulting in more aggressive phenotypes. The cells become sensitive to chemotherapeutic agents when YAP1 is inhibited. Altogether, our results provide evidence that tumor cells' direct contact with the fibroblasts in the TME initiates a signaling cascade responsible for hybrid E/M states of cancer cells. These hybrid states are maintained during the interaction and contribute to therapy resistance via YAP1 pathway, while interference with direct contact will result in slow recovery and a switch to the initial states.

#2581 Establishing a multi-omic spatial ECM proteome and N-glycome of pancreatic ductal adenocarcinoma tissues.

Caroline G. Kittrell[1], Jade Macdonald[1], Blake Sells[2], Lyndsay E. A. Young[1], David DeNardo[2], Peggi M. Angel[1], Richard R. Drake[1]

[1]The Medical University of South Carolina (MUSC), Charleston, SC,[2]Washinton University in St. Louis, St. Louis, MO

Pancreatic Ductal Adenocarcinoma (PDAC), one of the leading causes of cancer related mortality nationwide, is characterized by an extensive desmoplastic stromal reaction and an altered N-glycome. Stromal collagens serve to modulate the immune microenvironment, limit nutrient and oxygen diffusion, influence chemotherapy resistance, and promote tumor progression and metastasis. Dysregulated cancer cell N-glycosylation also promotes immune evasion and neoplastic spread. Despite their important roles in cancer pathogenesis, little is known about the spatial localization and organization of the various stromal collagens, other extracellular matrix proteins, and N-glycans within the PDAC tumor microenvironment. This study utilized Matrix Assisted Laser Desorption Ionization-Mass Spectrometry Imaging (MALDI-MSI) with Liquid Chromatography Tandem Mass Spectrometry (LC-MS/MS) to characterize the extracellular matrix proteome and glycome of 10 primary PDAC patient tumors in collaboration with the Washington University SPORE in Pancreatic Cancer at the Siteman Cancer Center. Following PNGaseF glycosidase digestion of PDAC tissues, 214 released N-glycans and their spatial distributions were detected by MALDI-MSI. These tissues were then digested with Collagenase III for detection and localization via peptide MALDI-MSI. Tissues were scraped from the slide and further digested with Collagenase III in solution for peptide ID analysis by LC-MS/MS, with 31 identified peptides confirmed and matched to MALDI peaks. Spatially, both ECM peptides and N-glycans uniquely colocalize with various histopathologic features according to multiplex immunohistochemistry. N-glycans with bisecting N-acetylglucosamine structures associated specifically with the invasive tumor front and clusters of immune cell infiltrate, while distinct collagen species encased tumor cell regions and formed stromal nests surrounding immune cells. The degree of proline hydroxylation and other post translational modifications also varied across confirmed ECM peptides and may impact stability and deposition. From this analysis we may begin to link the N-glycome and ECM proteome of PDAC with patient survival, treatment response and other clinical variables.

#2583 A T cell engager targeting cancer associated fibroblasts inhibits tumor growth and modulates the tumor microenvironment.

Joshua R. Tagore[1], **Robert Joseph Norgard**[1], Pratha Budhani[1], Sai Charan Penikalapati[1], Jessica N. Egan[1], Di Feng[1], Leticia Corrales-Pecino[2], Anna Bachmayr-Heyda[2], Claudia Reichel-Voda[2], Abhishek Kashyap[1], Youli Xia[1], Sarah A. O'Brien[1]

[1]Boehringer Ingelheim, Ridgefield, CT,[2]Boehringer Ingelheim, Vienna, Austria

Fibroblast activating protein (FAP) is an attractive target for therapeutic intervention being mainly expressed in malignant tissues. Previous studies have targeted FAP using a variety of methods yet failed in clinics. Here, we utilize FAP-targeted T cell engager (TcE) in KPCY tumor models to recapitulate a pre-clinical environment. The use of FAP- TcE efficiently depleted FAP+ fibroblasts *in vitro* and *in vivo* from tumors. This resulted in bystander killing of tumor cells and tumor growth control *in vivo*. This therapeutic effect was not dependent on priming via lymph node activation as shown in other publications. To understand the complex interactions with FAP expression, we perform comprehensive single cell RNA-sequencing profiling before and after FAP-TcE depletion to understand the pivotal genetic roles of FAP depletion in all cell types. This analysis initially revealed a T cell exhaustion phenotype with upregulated of PD-1 on T cells after FAP-TcE treatment. However, while addition of anti-PD-1 therapy significantly enhanced tumor efficacy, complete control was absent. RNA sequencing of the fibroblasts identified depletion of a myCAF-like fibroblast and an outgrowth of a mixed CAF population with phenotypes of both myCAF and iCAF. This population correlated with tumor growth, and cell cycle gene signatures. Future work will investigate the implications of this fibroblast population's role in subverting immune suppression.

#2584 *In situ* hybridization-based validation of transcriptionally-defined stromal clusters in the prostate cancer microenvironment.

Filippo Pederzoli, Hubert Pakula, Wikum Dinalankara, Jeanne Jiang, Mohamed Omar, Silvia Rodrigues, Pier Vitale Nuzzo, Fabio Socciarelli, Giuseppe Nicolo Fanelli, Luigi Marchionni, Massimo Loda

Pathology and Laboratory Medicine, Weill Cornell Medicine, New York, NY

Introduction: Stromal cells in the prostate tumor microenvironment (TME) affect tumor progression and exhibit both a universal response to tumorigenesis and specific ones determined by the genotype that drives the tumor (*Pakula et al., Nat Commun 2024*). As a result, stromal clusters associated with murine and human prostate cancer identified by single cell RNA sequencing (scRNA-seq) fall into a) common subtypes: myofibroblasts/pericytes and innate immunity-associated; as well as b) two additional ones specific to either AR positive adenocarcinomas or neuroendocrine tumors (NEPC). Here, we defined their spatial localization leveraging spatial transcriptomics and multiplex *in situ* RNA hybridization.

Methods & Results: We computationally identify the most discriminative genes able to distinguish the four stromal groups. Specifically, we first identified highly discriminatory genes representative of each cluster. We then used integer programming-based optimization to obtain small sets of genes ($n \leq 4$) that are differentially expressed in each group compared to the remaining three. For instance, group 0, encompassing myofibroblasts and pericytes, was characterized by the expression of Rgs5 and Myh11, while group 2, whose stromal cells are characterized by the expression of Ar and Wnt signaling genes, was characterized by the expression of Wif1 and Coch. A decision-tree analysis was able to discriminate all the different stromal groups. These were validated using 1) *in situ* RNA hybridization + multiplex immunofluorescence panels and 2) spatial transcriptomics. Myofibroblasts/pericytes were found to be distant to tumor cells, common clusters were associated with all tumors of diverse phenotype (Tmprss2-ERG, cMYC, $Pten^{-/-}$, $Pten^{-/-}$/ $Rb1^{-/-}$ $NMYC^{+/+}$), while periostin high/AR low clusters were immediately adjacent to NEPC foci in mouse models.

Conclusions: Our integrated computational and experimental approach establishes a robust pipeline for validating stromal markers identified through scRNA-seq, enabling spatial mapping of stromal heterogeneity in prostate cancer.

#2585 GABA shunt pathway promotes peri-synaptic brain metastasis by hijacking synaptic signaling.

Shih-Ying Wu[1], Kerui Wu[2], Abhishek Tyagi[1], Ravindra Pramod Deshpande[1], Eleanor Cecile Smith[1], Jee Won Kim[1], Kounosuke Watabe[1]

[1]Wake Forest University School of Medicine, Winston-Salem, NC,[2]University of North Carolina at Greensboro, Greensboro, NC

Metastatic brain tumors are the most common intracranial neoplasms in adults. Among all subtypes of breast cancer, triple-negative breast cancer (TNBC) has a significantly poorer prognosis compared to other subtypes. Pre-menopause and estrogen replacement therapy after menopause have been shown to increase the risk of brain metastases in TNBC patients. Estrogen blockade using tamoxifen demonstrates some efficacy in TNBC, suggesting that estrogen promotes brain metastases by modulating the tumor microenvironment in estrogen receptor (ER)-negative tumors. Neurons, as highly specialized cells responsible for cell-to-cell signal transmission, are among the most critical and abundant cell types in the brain. However, the role of tumor-associated neurons and their contributions to TNBC remain poorly understood. We hypothesize that estrogen promotes brain metastasis in hormone receptor-negative breast cancer by increasing the release of gamma-aminobutyric acid (GABA), which serves as a metabolic substrate to fuel tumor cell growth. We further hypothesize that blocking GABA transporter function will suppress brain metastases in hormone receptor-negative breast cancer. Our findings show that pre-menopausal TNBC patients exhibit higher synaptic formation and increased expression of GABA transporters in brain metastases, suggesting that neurons may contribute to tumor growth. To investigate the effect of estrogen on brain metastasis in ER-negative breast cancer aCnd to understand how estrogen depletion modulates metastatic growth in the brain, we performed bilateral ovariectomy in female mice and intracardially implanted luciferase-labeled human ER-negative brain metastatic breast cancer cells (231BrM). Our results demonstrate that estrogen increases synaptic formation and upregulates the expression of GABA and GABA transporter 1 (GAT1) in brain metastases more prominently than other neurotransmitter receptors. To examine the effect of GABA on tumor progression, 231BrM cells were treated with 0.5 mM GABA, mimicking physiological brain concentrations, or recombinant GABA. We found that GABA treatment upregulated GAT1 expression and enhanced colony formation and migration abilities, strongly suggesting that GABA promotes brain metastasis. Furthermore, treating 231BrM cells with conditioned medium (CM) obtained from GABAergic neurons exposed to estrogen led to increased tumor growth through activation of the GABA shunt pathway in tumor cells. Blocking GAT1 using CRISPR/Cas9 or a small-molecule GAT1 inhibitor effectively suppressed GABAergic neuron-induced tumor progression. Our results suggest that estrogen enhances GABA release from neurons, subsequently promoting activation of the GABA shunt pathway in tumor cells. This study highlights GAT1 inhibitors as promising therapeutic tools for treating TNBC patients with brain metastases.

#2586 PAI-1 promotes tumor angiogenesis and metastasis via crosstalk between NSCLC cells and CAFs.

Kazuhiro Okada, Ken Suzawa, Yin Min Thu, Ryunosuke Fujii, Kousei Ishimura, Ryota Fujiwara, Kazuya Hisamatsu, Ryo Yoshichika, Tomoaki Higashihara, Naohiro Hayashi, Fumiaki Mukohara, Mao Yoshikawa, Yuma Fukumoto, Keiichi Date, Hidejiro Torigoe, Kazuhiko Shien, Shinichi Toyooka

General Thoracic Surgery, Okayama Univ. Graduate School of Med., Okayama, Japan

Plasminogen activator inhibitor -1 (PAI-1) plays a multifaceted role in the tumor microenvironment, with its high expression correlated with poor prognosis in multiple cancers, including non-small cell lung cancer (NSCLC). Our group's previous studies have shown that cancer-associated fibroblasts (CAFs) induced PAI-1 in lung cancer cells and that PAI-1 mediated the MET-targeted therapy resistance in NSCLC. In this study, we discovered that CAFs promoted PAI-1 as a secretory protein and its expression in cancer cells themselves and into the conditioned medium by the stimulation of CAF-derived stimulatory factors of transforming growth factor beta-1 (TGFb-1) and -3. Next, we used several lung cancer cell lines with different mutational profiles to assess the effect of PAI-1 in the tumor microenvironment. We investigated the phenotypic changes of lung cancer cells by recombinant human PAI-1 administration and the PAI-1 overexpressed lung cancer cell lines. PAI-1 increased the migratory ability of cancer cells and promoted epithelial to mesenchymal transition (EMT). PAI-1 contributed to tumor progression via the enrichment of EMT, extracellular matrix signaling, and inflammatory and immune responses according to gene set enrichment analysis (GSEA) revealed by the PAI-1 overexpressed lung cancer cells. Moreover, PAI-1 also promoted angiogenesis via the vascular endothelial growth factor (VEGF) pathway supported by the tube formation assay, western blot pathway analysis, and the GSEA. This impact is further validated through vivo study, in which the inhibition of PAI-1 improves the anti-cancer targeted therapy in vivo, where the tumor growth is inhibited by the combination of target therapy and the PAI-1 inhibitor, tiplaxtinin. The tumors from PAI-1 overexpressed lung cancer cells xenograft models also showed high expression of CD31 compared to control, confirming that angiogenesis is being promoted in these tumors. These findings underscore the clinical importance of PAI-1 as an important target for personalized anti-cancer drug therapy.

#2587 Transcription factor ZEB1 controls lineage specificity of African ancestry-enriched breast stromal multilineage cells.

M. Shukla[1], M. Krishnan[2], M. Niese[2], J. Ji[2], H. Gao[2], Y. Liu[2], M. H. Kaplan[2], H. Nakshatri[2];
[1]IU Simon Comprehensive Cancer Center, Indianapolis, IN, [2]IU School of Medicine, Indianapolis, IN

Although disparity in breast cancer outcomes in women of African Ancestry (AA) as compared to European Ancestry (EA) has been thought to derive from socioeconomic factors, emerging evidence demonstrating genetic ancestry-dependent differences in normal and cancer genome, cancer-associated mutation patterns and immunosuppressed tumor microenvironment suggests the involvement of biological factors. To investigate breast cancer outcome-associated biologic factors, we analyzed breast tissues of healthy donors of distinct genetic ancestry and found that PROCR$^+$/ ZEB1$^+$/ PDGFRα$^+$ stromal cells (hence, called PZP) are more abundant in normal breast tissues of women of AA as compared to EA. PZP cells display the properties of multi-lineage fibroadipogenic mesenchymal stromal cells and can differentiate into adipogenic and osteogenic lineages. Whether and how PZP cells contribute to breast cancer progression is unknown. Using a combination of gene knockout, RNA-sequencing, co-culture and immunophenotyping studies, we investigated the role of PZP cell-enriched Zinc finger E-box-binding homeobox 1 (ZEB1) transcription factor in PZP cell function. ZEB1 knockout in PZP cells resulted in altered lineage specificity. The expression of epithelial markers KRT 7, 8, 18 and adipogenic markers PPARG and PPARGC1B were upregulated upon ZEB1 knockout suggesting that ZEB1 maintains PZP cells in an undifferentiated state. ZEB1 also controlled the expression of several genes that encode extracellular matrix (ECM) associated proteins including Tenascin-C (TNC), an ECM factor linked to aggressive tumors and immunosuppressive microenvironment. Furthermore, the expression of matrix metallopeptidase 1 (MMP1) and a Leucine-rich repeat-containing protein 15 (LRRC15), both of which are markers of myofibroblasts, was downregulated in ZEB1 knockout cells suggesting the role of ZEB1 in trans-differentiation of PZP cells into cancer-promoting myofibroblast lineage. In addition, ZEB1 controlled the expression of prostaglandin-endoperoxide synthase 1 (PTGS1), which synthesizes immunosuppressive prostaglandin E2 (PGE2), in PZP cells. In support of immunosuppressive role of PZP cells, PZP cell secreted factors decreased the expression of Interferon γ and Granzyme B in CD8$^+$ T cells, which are critical for effector function of T cells. Ongoing studies are investigating the potential contributions of ZEB1, PGE2, and TNC in PZP cell-mediated decrease in effector function of CD8$^+$ T cells. Collectively, our results suggest that PZP cells are enriched in breast tissues of AA women and contribute to breast cancer progression through the breast stroma-enriched therapeutic target ZEB1.

#2588 Stromal remodeling promotes immune triad formation in the tumor microenvironment (TME).

Daniel Lagal[1], Duncan Hong[1], Athanasios Papadas[2], Alicia Gibbons[1], Yun Huang[1], Yaling Dou[1], Alexander Cicala[3], Elsa Molina[4], Kristina Matkowskyj[5], Dustin Deming[6], Fotis Asimakopoulos[1]

[1]UC San Diego, La Jolla, CA,[2]Ohio State University, Columbus, OH,[3]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY,[4]Salk Institute for Biological Studies, La Jolla, CA,[5]Mayo Clinic, Rochester, MN,[6]UW-Madison, Madison, WI

Recent evidence has highlighted the critical requirement for “immune triads” of CD8+ T cells, CD4+ T cells and dendritic cells (DC) for tumor elimination in response to checkpoint inhibition (CPI) immunotherapy. However, the mechanistic underpinnings of this cross-talk are poorly understood. Immune triads are often located in peripherally-distributed DC-rich niches within the tumor stroma. We have hypothesized that stromal remodeling in response to tumor expansion generates homeostatic signals that trigger an adaptive immune response that may ultimately fail through effector exhaustion or apoptosis. In particular, stromal proteolysis of the large matrix proteoglycan versican (VCAN) has been associated with T-cell infiltration across multiple tumor types. The objective of this study was to interrogate a mechanistic link between stromal remodeling, immune triad formation and response to CPI. We used HALO image analysis to determine the spatial relationship of CD4+ and CD8+ T cells in a panel of 95 human non-small cell lung cancers. Each tumor was VCAN proteolysis-scored based on a binning system measuring staining intensity for a neoepitope exposed through site-specific VCAN proteolysis. Tumors displaying VCAN proteolysis intensity of zero (0) had an average of 0.122 CD8+ T cells located with 10um of a CD4+ T cell vs. 0.216 in tumors with any VCAN proteolysis (intensity 1,2,3 combined); p=0.04. Similar results were obtained when measuring proximity of CD4+ to CD8+ T cells (0.124 vs 0.223, p=0.02). These data demonstrate that remodeling stroma promotes CD4+:CD8+ crosstalk. Site-specific VCAN proteolysis releases a 441 N-terminal bioactive fragment, versikine. Versikine constitutes a classical “matrikine”, i.e., a bioactive matrix fragment possessing novel functions compared to its parent macromolecule. To determine the mechanisms by which versikine may promote immune triad niches, we generated several transplantable syngeneic tumor cell lines engineered to stably secrete versikine into the TME. One CPI-refractory tumor cell line (Lewis Lung Carcinoma, LLC) and two partially CPI-responsive transplantable tumor lines (CT26 and MC38 colorectal carcinoma) were extensively characterized through flow cytometry, spatial immunofluorescence and scRNAseq. Our results demonstrate that in all contexts, versikine results in expansion of Tfh-like CD4+ T cells expressing Cd40lg and Icos. This expansion is associated with specific patterns of CD8+ T cell exhaustion that will be discussed. Therapeutically, versikine reversed anti-PD-1 pathway refractoriness in the poorly-immunogenic LLC model and demonstrated superior synergy with CPI in the more immunogenic CT26 and MC38 models, leading to tumor eradication with resistance to tumor rechallenge. Our data bolster the mechanistic rationale for exploitation of stromal remodeling signals to promote CD4+T:CD8+T:DC cross-talk for enhanced CPI efficacy.

#2589 Folate receptor α confers colonization advantage of cholangiocarcinoma in peritoneal microenvironment with therapeutic vulnerability.

H. Zhang[1], L. Guo[2], S. Lin[1], X. Li[1], Z. Song[1], L. Xu[1], C. Liu[1];

[1]Sun Yat-Sen Memorial Hospital of Sun Yat-Sen University, Guangzhou, China, [2]Fudan University Shanghai Cancer Center, Shanghai, China

Purpose: Peritoneal metastasis/recurrence results in poor prognosis and failure of radical resection in cholangiocarcinoma (CCA) patients, but the molecular mechanisms and potential therapy strategies remain an enigma.

Methods: Freshly resected primary lesions and peritoneal metastases from CCA patients were collected for single-cell RNA sequencing (scRNA-seq) and spatial transcriptomics to identify the crucial target during peritoneal colonization of CCA cells. Tumor-adipocytes *in vitro* co-culture model and tumor peritoneal implantation mouse model were utilized to investigate the role and therapeutic promises of the identified target in peritoneal metastasis of CCA. Metabolomics, metabolic flux, and flow cytometry assays were employed to delve into the underlying molecular mechanisms.

Results: The scRNA-seq analysis of CCA tumors (N=5 pairs) revealed an up-regulated expression of FOLR1, encoding folate receptor alpha (FRα), in CCA cells after colonization in the peritoneal microenvironment, which was validated by spatial transcriptomics (N=2 pairs). The specifical overexpression of FRα in CCA cells in the peritoneal metastases was validated by immunohistochemistry and multiplex immunofluorescence staining, and it was associated with a poorer prognosis, larger metastases size, and increased ascites volume in CCA patients (N=68). Despite no significant impact on the proliferative and invasive capacities of CCA cells in conventional culturing, overexpression of FRα enhanced their proliferation in the tumor-adipocytes co-culture model and tumor peritoneal implantation mouse model. Mechanistically, utilization of enriched fatty acids from adipocytes for fatty acid oxidation fuels CCA cells outgrowth and colonization in peritoneal metastases, but it also leads to excessive oxidative stress. FRα-dependent folate metabolism and one-carbon metabolism contribute to production of NADPH and GSH, the essential substrates for cellular anti-oxidative stress, thus leading to growth advantage of CCA cells in the peritoneal microenvironment. Herein, the utilization of Mirvetuximab Soravtansine, the antibody-drug conjugate targeting FRα, demonstrated an encouraging therapeutic efficacy in CCA peritoneal implantation mouse models, including reduced tumor size, decreased number of disseminated lesions, lowered ascites volume and ascites CTCs, prolonged mouse survival, and delayed recurrence of peritoneal metastases after peritoneal metastasectomy.

Conclusions: Hence, FRα plays a pivotal role in facilitating the colonization of CCA in the peritoneal microenvironment, rendering it a promising therapeutic target for alleviating peritoneal metastases burden in advanced CCA patients. The potential therapeutic advantages of Mirvetuximab Soravtansine warrant preliminary investigation in our planned clinical trial.

#2590 Characterization of tumor-neuron communication in lung adenocarcinoma brain metastasis.

Sampada Chande[1], Don Nguyen[1], Atsushi Yamasaki[2], Veronica Chiang[1], Declan McGuone[1]

[1]Yale School of Medicine, New Haven, CT,[2]Daiichi Sankyo, New Haven, CT

30-40% of cancer patients with lung cancer develop brain metastasis with poor prognosis. The incidence of brain metastasis has increased in patients that have received standard of care treatment, including targeted therapies. The mechanisms which promote lung cancer cell dissemination and colonization of the central nervous system (CNS) remain understudied and identifying novel drug targets to treat brain metastasis is an unmet clinical need. By using a variety of animal models of lung cancer metastasis, we previously identified shifts in epithelial and neuronal like lineage gene expression programs in malignant cells as they adapt to the brain tumor microenvironment (TME) *in vivo*. Gene set enrichment analysis (GSEA) revealed that most of genes are involved in neuronal guidance and cell adhesion pathways (L2FC > 0.5, padj < 0.05, Log2RPKM > 1 compared to 2D culture). We also examined tumor-neuron interactions in patient derived surgical biopsies and found active areas of interaction between tumors and neurons in human lung adenocarcinoma (LUAD) brain metastasis. Spatial transcriptomics of human brain metastasis also revealed differential profiles for areas of active interaction. *In vitro*, we established co-culture conditions which demonstrate that primary neurons can directly interact with brain metastatic LUAD cells and improve their fitness. Based on these observations, we performed a custom Clustered regularly interspaced palindromic repeats (CRISPR)-Cas9 loss of function screen targeting 470 neuronal and cell adhesion genes that are up-regulated in LUAD cells that seed the brain *in vivo*. Moreover, we performed our screens under different conditions which recapitulate tumor cell-tumor cell clustering in 3-dimensional culture conditions (3D) or tumor-neuron co-clustering in 3D. Results from this differential screening approach suggests that LUAD cells are increasingly, but not exclusively, dependent on several neuronal genes as they are co-cultured with neurons. In conclusion, we have modelled direct tumor-neuronal cell interaction *in vitro*, shown that it is an important component of brain metastasis, and identified putative targets that can be inhibited to disrupt tumor-neuron interactions and potentially limit brain metastatic progression.

#2591 The interaction of pericytes and brain metastasizing cancer cells in the *in vitro* co-culture system.

Shoko Noda-Narita, Atsu Aiba

The University of Tokyo, Tokyo, Japan

Introduction: Brain metastasis significantly reduces the patients' quality of life and survival, but there are only a few choices of treatment for brain metastasis. The research for brain metastasis is difficult because of its complex and unique microenvironment, including blood-brain barrier (BBB). As the role of pericytes in maintaining the BBB function has become clearer, the reconstituted models of the BBB in which endothelial cells (ECs), pericytes, and astrocytes are seeded on the front and back of the insert membrane have gotten our attention. We previously applied a reconstituted BBB model (Ito R, et al. *Mol Pharm* 2019) to develop a co-culture system for the evaluation of brain metastatic cells. This *in vitro* brain metastasis model mimics the brain vascular microenvironment, and successfully reproduces the invasive ability of brain metastatic cell lines. In this study, we figured out the role of pericytes in promoting cancer invasion and elucidated the interaction between pericytes and metastasizing cancer cells.

Methods: Using our *in vitro* co-culture system, we compared the migration ability of MDA231 and Ex3LL in several BBB models: EPA model (ECs, pericytes, and astrocytes), E0A model (ECs and astrocytes), EP0 model (ECs and pericytes), and E00 model (ECs only). To figure out how pericytes promote the migration of Ex3LL, we analyzed the morphology, transcriptome and migration ability of the parental and brain metastatic (BrM) cell lines of Ex3LL with and without pericytes.

Results: Though the migration of MDA231 was inhibited when co-cultured with pericytes or astrocytes, the migration of Ex3LL was promoted by the co-culture with pericytes. BrM cells of Ex3LL showed further increased migration ability when co-cultured with pericytes, compared to the parental cells. The transcriptome analysis of BrM cells of Ex3LL showed upregulated signaling pathway of the cell-cell and cell-matrix interactions, which implied the direct interaction between pericytes and cancer cells. The migration analysis using EP0 model (pericytes were seeded on the back of the insert membrane and had a direct interaction with cancer cells) and E0P model (pericytes were seeded on the bottom surface of the well and only secreted factors affected the cancer cells), also suggested the direct interaction of pericytes promoting the migration of Ex3LL.

Conclusion: Using our BBB reconstituted model, we showed that the role of pericytes in promoting cancer invasion depended on cancer cell types. Our results suggested that the direct interaction between pericytes and cancer cells, and assumedly ECs, was indispensable for the mechanism in which pericytes promote the Ex3LL migration. We need further investigation to elucidate the molecular mechanism underlying the interaction between pericytes and brain metastasizing cancer cells.

#2592 The osteoblastic microenvironment determines the fate of breast cancer cells disseminated in the bone marrow.

Hong-Li Wang, Xiao-Min Yue, Rui Zhang, Yu-Fan Huang, Rong Meng, **Xiao-Qing Li**

Tianjin Medical University Cancer Institute & Hospital, Tianjin, China

Bone is the most common destination for metastatic breast cancer cells. When cancer cells disseminate to the bone, they may either colonize or settle into a quiescent state, depending on their interaction with the bone microenvironment. In this study, we elucidated how the differentiation status of the osteoblastic microenvironment determines the fate of cancer cells disseminated in the bone marrow. We analyzed clinical survival data and demonstrated that luminal-like cancer cells with high Runt-related transcription factor 2 (RUNX2) expression exhibited an increased risk of bone metastases in breast patients. By using RUNX2-overexpressing cancer cells as bone-tropic seeds and establishing various osteoblastic microenvironments with different differentiation statuses in vitro and in vivo, we observed that both luminal-like and basal-like cancer cells remained quiescent as disseminated tumor cells (DTCs) or micrometastases within an inactive osteoblastic microenvironment. In contrast, luminal-like cancer cells colonize the bone within both nonmineralized and mineralized active osteoblastic (osteogenic) microenvironments. Basal-like cancer cells, however, remained quiescent within highly mineralized osteogenic microenvironment but colonized bone in a nonmineralized osteogenic niche rich in nonmineralized bone matrix (osteoid). In the active microenvironments, well-differentiated osteoblasts were observed to be responsible for recruiting cancer cells, whereas the nonmineralized bone matrix supported the proliferation of both luminal-like and basal-like cancer cells, with luminal-like cells gaining additional growth advantages from well-differentiated osteoblasts. Furthermore, we explored the possibility that activation of the osteoblastic microenvironment due to abnormal bone metabolism and fluctuating estrogen levels reactivate quiescent DTCs or micrometastases, leading to increased risk of bone metastasis. Additionally, in a supportive osteogenic microenvironment, both cancer cells and well-differentiated osteoblasts were found to contribute to the activation of osteoclasts, resulting in the development of osteolytic lesions. Thus, this study provides a comprehensive explanation for the divergent outcomes of disseminated cancer cells in the bone, whether they colonize the bone or become dormant, and suggests promising therapeutic strategies to block the reactivation of quiescent tumor cells.

#2593 Caspase-1 dependent pyroptosis converts αSMA^{+} CAFs into collagen-III high iCAFs to fuel chemoresistant cancer stem cells.

Hongbo (Beth) Gao[1], Stephen Q.R. Wong[1], Ethan Subel[1], Mustafa Karabicici[2], Winston Huang[1], Mark Ellie Alonzo[2], Keith Syson Chan[1]

[1]Houston Methodist Research Institute, Houston, TX,[2]Cedars-Sinai Medical Center, Los Angeles, CA

Chemotherapy-induced pyroptotic tumor cells potentially impact on cancer-associated fibroblasts (CAFs), which serve as key cellular components in stroma to construct a favorable tumor microenvironment (TME). Our study identifies three CAFs subtypes: αSMA^{+}IL-6^{-} myofibroblastic CAFs (myCAFs), αSMA^{-}IL-6^{+} inflammatory CAFs (iCAFs), and hybrid i/myCAFs. Caspase-1 activation in tumor cells release inflammatory chemokines/cytokines, promoting iCAFs formation in a CCR6-dependent manner. Interestingly, the reactive iCAFs, instead of myCAFs, contribute to collagen III expression upon chemotherapy-induced cancer cell pyroptosis. Collagen III-enriched microenvironment preferentially harbors CD44^{high} cancer stem cells (CSCs). Consistently, chemoresistant bladder cancers enhance iCAFs markers and collagen III after neoadjuvant chemotherapy. Thus, chemotherapy-caused pyroptotic cancer cells initiates an iCAFs-CSCs feedforward loop to drive the formation of chemoresistant TME.

#2594 Estrogen-regulated cytokine and growth factor secretion from breast cancers of women of diverse ancestry and effects on myelopoiesis.

Marisol Chavez[1], Mario Morales Martinez[1], Eduardo Mauricio Gonzalez[1], Gang Deng[2], Julia Aguade Gorgorio[3], Madhuri Wadehra[4], Nalo Hamilton[5], Michael E. Jung[2], Evelyn Jiagge[6], Sofia Merajver[6], Hannah Mikkola[3], Richard J. Pietras[1], Diana Marquez-Garban[1]

[1]Department of Medicine, UCLA Jonsson Comprehensive Cancer Center, Los Angeles, CA,[2]Department of Chemistry and Biochemistry, UCLA Jonsson Comprehensive Cancer Center, Los Angeles, CA,[3]Molecular Cell and Developmental Biology. Broad and Stem Cell Research Center, UCLA Jonsson Comprehensive Cancer Center, Los Angeles, CA,[4]Department of Pathology and Laboratory Medicine, UCLA Jonsson Comprehensive Cancer Center, Los Angeles, CA,[5]UCLA Jonsson Comprehensive Cancer Center, UCLA School of Nursing, Los Angeles, CA,[6]University of Michigan School of Medicine, Ann Arbor, MI

Breast cancer (BC) is the most common cancer among women in the U.S. It disproportionately affects African American (AA) women who have earlier disease onset, more aggressive subtypes, and lower survival rates compared to European American (EA) women. AA tumors show distinct gene variants linked to poor BC outcomes and immune signatures with differential expression of cytokines/chemokines potentially driving a more immunosuppressive tumor microenvironment (TME). Of note, cancer-related inflammation promotes aberrant myelopoiesis in bone marrow mediated distantly by tumor secretion of specific factors that stimulate accumulation of immunosuppressive myeloid cells. We have previously reported that estrogen signaling induces the expansion of myeloid derived suppressor cells (MDSCs), an action that can be blocked by selective estrogen receptor degraders (SERD), such as fulvestrant and our newly-designed oral SERD, JD128. To explore potential differences in cytokine/chemokine/growth factor secretion patterns in BC cells from EA and AA women, we used a Luminex multiplex assay to detect 38 cytokines/growth factors. Findings indicate different patterns of secretion occur, with AA cells showing significantly higher extracellular levels of CXCL9, MCP1, IL-8, PDGF-AB/BB, VEGF, TNFα and G-CSF under basal conditions as compared to EA cells ($P<0.05$). Further, treatment with estradiol-17β stimulated secretion of TNFα, IL8, IL13, IL18,MCP1, G-CSF and PDGF-AA, an action that was significantly inhibited by use of SERDs fulvestrant or JD128 ($P<0.05$). TNFα and G-CSF are known to promote myelopoiesis and a greater ratio of MDSC/CD8 T-cells, thereby potentially contributing to an immunosuppressive state in the TME. Further, estrogen stimulated proliferation of CD34+ bone marrow stem cells and MDSCs derived from normal female donors, an effect inhibited by fulvestrant and JD128 indicating that hematopoietic stem cells express estrogen receptors and respond to estrogen. Notably, using ELISA and qRT/PCR, SERDs fulvestrant and JD-128 decreased expression of transcript and protein levels of estrogen receptor alpha ($P<0.05$). Our preliminary data provides further evidence of a biologically distinct immunosuppressive profile that may drive more aggressive BC outcomes in AA women. Estrogen-mediated effects on hematopoietic cells may have implications for use of SERDs for estrogen receptor positive or negative BC. Ewing sarcoma (EwS) is an aggressive pediatric bone tumor with an enigmatic cell-of-origin. The fusion oncogene EWS::FLI1 is pathognomonic for EwS and the primary driver in 85% of EwS patients. Human mesenchymal stem cells (hMSCs) are considered to be the likely cell of origin of EwS for two reasons: their ability to tolerate ectopic EWS::FLI1 expression and the resemblance in the transcriptomes of EWS::FLI1 expressing hMSCs to primary Ewing tumors. However, to date a cellular differentiation-based model of EwS does not exist. To obtain insights into EwS etiology and histogenesis, this study has established the first comprehensive single-cell differentiation atlas of juvenile bone marrow-derived hMSCs with and without EWS::FLI1 expression. A pool of bone-marrow derived hMSCs from nineteen healthy juvenile donors was engineered to conditionally express EWS::FLI1. We used physiology mimicking conditions (hypoxia, spheroid cultures, serum-free growth and differentiation media) and induced EWS::FLI1 oncogene expression for 24h or 72h at daily time points of hMSC differentiation into adipo-, chondro-, osteo- and neuro-genic lineages. This highly resolved atlas of 252 samples representing normal and perturbed differentiation allowed us to map single cell tumor data from EwS patients to multiple lineages and time-points across stages of lineage commitment. Single-cell RNA-seq analysis of ~488,000 transcriptomes revealed loss of lineage identity in the presence of EWS::FLI1 across all four lineages. However, the analysis of genes detected in the EWS::FLI1 high cluster uncovered a specific time and lineage preference towards treated adipogenic cells that shared the transcriptomic signature with tumor cells, indicating the potential cell/stage of tumor-origin. Longer EWS::FLI1 induction led to enhanced loss of lineage identity and higher mapping with patient data. Soft agar colony formation assay confirmed stronger transformation potential of EWS::FLI1 expressing adipogenic cells. Our results offer novel insights into the elusive cellular origins of Ewing sarcoma, thereby establishing a foundation for the development of indispensable preclinical models to inform tailored therapeutic approaches. This study is supported by a generous grant (#20-17258) of the Alex’s Lemonade Stand Foundation (ALSF) Crazy8 Program.

#2599 Biological consequences and mechanisms of neural signatures in fusion-positive rhabdomyosarcoma.

Jack Kucinski, Alexi Tallan, Matthew Kent, Cenny Taslim, Meng Wang, Matthew V. Cannon, Katherine M. Silvius, Benjamin Z. Stanton, Genevieve C. Kendall

The chimeric transcription factor PAX3::FOXO1 is a core dependency and monogenic driver of fusion-positive rhabdomyosarcoma, an aggressive pediatric soft-tissue sarcoma. *PAX3::FOXO1* consists *of* the *PAX3* DNA binding domains (paired and homeobox) and the *FOXO1* transactivation domain. Despite the identification of the fusion-oncogene over thirty years ago, there are no targeted therapies for children suffering from this disease. The current therapeutic regimen consists of surgery, radiation, and general chemotherapy, which has been largely unsuccessful in improving patient outcomes. This lack of targeted therapies is partly due to unclear in vivo regulatory mechanisms of PAX3::FOXO1 across cellular contexts and tumorigenic stages. Previously, we found that PAX3::FOXO1 has pioneer-like activity and is transforming in zebrafish models, which generate tumors that recapitulate the human disease. To understand initial PAX3::FOXO1 activities, we developed a zebrafish mRNA injection model that broadly expresses the human fusion oncoprotein during early vertebrate development. We find in vivo evidence to characterize PAX3::FOXO1 as a pioneer transcription factor and demonstrate its ability to bind to inaccessible chromatin. We identified partial homeobox motif recognition as a new mode for PAX3::FOXO1 pioneering activity that diverges from in vitro models. PAX3::FOXO1 binding sites and motif selection preference correlated with DNA methylation. Together, these findings highlight that context, specifically underlying DNA methylation, can impact how pioneer factors interact with chromatin. PAX3::FOXO1 subsequently induced chromatin accessibility and activated enhancers upon binding. This was observed at sites where PAX3::FOXO1 was bound to its full composite motif, showing that motif preferences drive different functional roles. This neomorphic chromatin landscape supports the transcriptional activation of known rhabdomyosarcoma gene signatures and neural-related pathways. Even though rhabdomyosarcoma is characterized by incomplete skeletal muscle differentiation, neural signatures specifically exist within this aggressive subtype and are further enriched upon chemotherapeutic treatment in patient-derived xenografts. One critical target of PAX3::FOXO1 in our zebrafish model is the neural transcription factor Her3, zebrafish ortholog to HES3. PAX3::FOXO1 mRNA injection into *her3/HES3* knockout zebrafish embryos suppresses neural transcriptional programs. Altogether, this work highlights neural pathway activation as an initial activity of PAX3::FOXO1 and that these programs could play a critical role across multiple stages of tumorigenesis. Our long-term goal is to further elucidate and delineate how PAX3::FOXO1 cooperates with neural factors across cellular contexts to identify and assess novel therapeutic vulnerabilities to improve the lives of patients.

#2600 A human stem cell model of neuroblastoma reveals candidate drivers of tumorigenesis on chromosome 17q.

W. Fang[1], B. Cheng[2], S. J. Pastor[3], I. Barbaric[4], A. Tsakiridis[4], T. Porras[2], H.-W. Wu[2], C. Parekh[5], S. Asgharzadeh[1], J. M. Maris[3], M. Huang[1];

[1]University of Southern California, Los Angeles, CA, [2]Children's Hospital Los Angeles, Los Angeles, CA, [3]Children's Hospital of Philadelphia, Philadelphia, PA, [4]University of Sheffield, Sheffield, United Kingdom, [5]City of Hope, Duarte, CA

Background: In neuroblastoma (NB), the most common pediatric extracranial solid tumor, the most frequent genetic abnormality is gain of chromosome 17q (17q+), occurring in >80% of all patient tumors. 17q+, similar to amplification of the oncogene *MYCN*, is one of the hallmarks of high-risk NB, which has a 5-year survival rate of less than 50% and is associated with a high relapse rate. Although *MYCN*-driven mouse models of NB exist, mouse models incorporating human 17q+ cannot be established due to the misalignment of genes on mouse and human chromosomes. Thus, the mechanism by which 17q+ contributes to poor prognosis remains largely unknown.

Methods: Here, we used a human stem cell model of NB to investigate the effects of 17q+. Two human embryonic stem cell lines (H7 and H9), either wild-type (WT) or with spontaneous 17q+, were transduced with doxycycline-inducible *MYCN*, differentiated into sympathoadrenal cells (NB cell of origin), and implanted orthotopically into the renal capsule of immunocompromised mice fed doxycycline chow. RNA sequencing was performed on the resulting *MYCN*/17q+ and *MYCN*-driven NBs. *In vitro* proliferation of the tumor cells was assessed by Incucyte live-cell imaging and EdU incorporation assays.

Results: Although 17q+ alone was insufficient to generate NB tumors, *MYCN*/17q+ tumors compared to *MYCN*-only tumors exhibited higher penetrance (H7: 100% vs 60%; H9: 100% vs 50% at day 104 post-implantation) and shorter latency (median survival H7: 70 vs 90 days, p=0.0186; H9: 69 vs 114 days, p=0.0001, n=10 per arm), suggesting that *MYCN* and 17q+ cooperate in tumorigenesis. *MYCN*/17q+ tumor cells also showed increased proliferation and S-phase occupancy relative to *MYCN*-only tumor cells *in vitro*. Bulk RNA sequencing revealed an enrichment in the activation of ribosome biogenesis, cell cycle transition, and DNA replication pathways in *MYCN*/17q+ tumors. Additionally, 16 genes located on 17q were upregulated in *MYCN*/17q+ tumors compared to *MYCN*-only tumors, as well as in NB patients with 17q+ compared to 17q WT. We confirmed the protein-level overexpression of 6 of these 16 genes in *MYCN*/17q+ tumors: *BRIP1* (helicase), *TK1* (thymidine kinase), *BIRC5* (survivin), and *CDC6* (pre-replication complex subunit) directly regulate the cell cycle, while *IGF2BP1* (mRNA binding protein) stabilizes the *MYCN* transcript, and *CBX2* (polycomb repressive complex subunit) blocks neural differentiation. Indeed, individual knockdown of these 6 genes in *MYCN*/17q+ tumor cells reduced proliferation, and individual overexpression in *MYCN*-only tumor cells enhanced proliferation, implicating these genes in tumorigenesis.

Conclusion: A newly established human stem cell model of NB identified *BRIP1*, *TK1*, *BIRC5*, *CDC6*, *IGF2BP1*, and *CBX2* as candidate genes on chromosome 17q that cooperate in NB tumorigenesis.

#2601 KAT6A and B inhibition increases efficacy of differentiation and GD2 targeting immunotherapy in neuroblastoma.

Nina Weichert-Leahey[1], Alla Berezovskaya[1], Mark W. Zimmerman[1], Francesca Alvarez-Calderon[1], Ulrike Gerdemann[1], Silvi Salhotra[1], Nathaniel Mabe[1], Adam D. Durbin[2], Kimberly Stegmaier[1], Brian J. Abraham[2], A. Thomas Look[1]

[1]Dana-Farber Cancer Institute, Boston, MA,[2]St. Jude Research Hospital, Memphis, TN

Neuroblastoma is a malignancy of the peripheral sympathetic nervous system, accounting for 15% of childhood cancer deaths. Despite multi-modal treatment regimens and post-consolidation therapy, including anti-GD2 antibody treatment combined with retinoic acid, overall survival for patients with high-risk disease is only ~50%, and treatment-associated toxicity is immense. Thus, less toxic and more effective treatment options are desperately needed. Retinoic acid is clinically used to induce growth arrest of neuroblastoma cells and epigenetic rewiring of the enhancer landscape, leading to suppression of oncogenic MYCN expression. However, the epigenetic and growth-suppressing effects of retinoic acid are completely reversible, leading to tumor re-growth. Here, we sought to identify epigenetic modifiers that enhance the antiproliferative effects of retinoids in neuroblastoma. In a drug screen with 452 compounds targeting epigenetic modifiers, we identified PF-9363, an inhibitor of the histone H3K23 acetyltransferases KAT6A and B, as synergistically inhibiting neuroblastoma growth in combination with retinoic acid. Importantly, this growth suppression was durable and persisted beyond retinoid withdrawal in *in vitro* models, in contrast to retinoid treatment alone. Durable growth suppression was due to sustained downregulation of MYCN and the essential transcription factors PHOX2B and GATA3, caused by gene expression silencing through PRC2-dependent deposition of H3K27me3 across their regulatory enhancers. In NSG xenograft models of neuroblastoma, the KAT6A/B inhibitor PF-9363 alone demonstrated significant anti-tumor activity when given at 5 mg/kg daily by oral gavage and tumor volumes were significantly different compared to vehicle treated mice starting at day 4 through the end of treatment on day 28. Moreover, the combination treatment with retinoic acid and PF-9363 exhibited profound and sustained growth suppression compared to vehicle treated mice and exhibited the most sustained growth suppressing effect among all treatment conditions, persisting even after retinoic acid was withdrawn. This outcome was significantly different from retinoid treatment alone, where drug withdrawal resulted in rapid tumor proliferation in NSG mice. Reflecting the epigenetic reprogramming of these tumor cells, we observed that expression of GD2, a cell surface glycosphingolipid that is a target of antibody-based and CAR T cell therapies in neuroblastoma, was induced on $GD2^{low}$ neuroblastoma cells by treatment with retinoic acid plus PF-9363 both *in vitro* and *in vivo*, leading to increased effectiveness of anti-GD2 CAR T cell therapy in neuroblastoma. These studies nominate KAT6A/B inhibition as a novel approach to enhance the effectiveness of differentiation and GD2-immunotherapy in neuroblastoma and may be relevant for other tumors of neuro-ectodermal origin.

#2603 Targeting METTL3 as a novel therapeutic strategy for H3 G34-mutant gliomas.

Maria Eleftheriou[1], Eliza Yankova[1], Rebecca D. Haase[2], Antonella De Cola[1], Michael McNicholas[1], Sian Evans[1], Joao M. L. Dias[1], Natalie Webster[3], Georgia Tsagkogeorga[3], James Russell[1], Manav Pathania[1], Oliver Rausch[3], Mariella G. Filbin[2], Konstantinos Tzelepis[1]

[1]University of Cambridge, Cambridge, United Kingdom,[2]Dana-Farber Boston Children's Cancer and Blood Disorders Centre, Boston, MA,[3]Storm Therapeutics, Cambridge, United Kingdom

Background: Diffuse hemispheric glioma, H3 G34-mutant, is a pediatric-type high-grade glioma with limited treatment options and a poor prognosis. RNA-modifying enzymes, including METTL3, are critical for the initiation and maintenance of various cancers, including brain tumors. We previously presented STM2457, a first-in-class RNA-modifying enzyme inhibitor targeting the catalytic activity of METTL3, preventing m^6A deposition on mRNA. Here, we show small-molecule inhibition of METTL3 as a novel therapeutic strategy for H3 G34-mutant gliomas.

Aims: To study the therapeutic potential of pharmacological inhibition of METTL3 in preclinical models of H3 G34-mutant diffuse hemispheric gliomas (DHG).

Results: Using genome-wide CRISPR/Cas9 screening, we identified METTL3 as a genetic vulnerability in H3.3-G34-mutant primary murine glioma models. We confirmed that METTL3 is essential for the maintenance of glioma through genetic and pharmacological approaches in primary mouse and human glioma models, harboring H3.3-G34 mutations. Notably, METTL3 inhibition did not affect the proliferation of normal murine neuronal stem cells or isogenic primary murine glioma models with H3.3-K27M mutations. m^6A-immunoprecipitation-sequencing revealed downregulation of several stemness-related m^6A substrates, including *Nestin* and *Sox2*, upon pharmacological inhibition of METTL3. In H3.3-G34-mutant human and mouse glioma models, METTL3 inhibition disrupted key glioma pathways, suppressing translation of stem cell-related markers, like Nestin and Sox2, while upregulating glioma differentiation markers, such as Tubb3. In parallel, the transcriptional levels of these markers remained unaltered, highlighting that the effects are primarily on the mRNA translation of glioma-associated m^6A substrates. Notably, pharmacological inhibition in patient-derived samples with H3.3-G34 mutations impaired growth and suppressed the same molecular pathways consistent with our epitranscriptomic and proteomic analyses. Orthotopic transplantation of primary murine H3.3-G34R glioma cells with CRISPR/Cas9-mediated *METTL3* knockout into NSG mice significantly extended survival compared to controls. Importantly, pharmacological inhibition of METTL3 in an H3.3-G34V patient-derived xenograft model recapitulated this effect, significantly prolonging mouse lifespan and validating METTL3 as a therapeutic target in these gliomas.

Conclusions: In summary, here we demonstrate that pharmacological inhibition of METTL3 is a potent therapeutic strategy for H3 G34-mutant gliomas. To our knowledge, this is the first study that reveals that the catalytic function of METTL3 is a critical epitranscriptomic factor in H3 G34-mutant gliomagenesis. Our findings provide strong proof-of-concept that targeting RNA-modifying enzymes offers a promising therapeutic approach for this aggressive glioma subtype.

#2606 In vivo screening reveals therapeutic vulnerabilities in a patient-derived xenograft established from an intraosseous TFCP2-rearranged rhabdomyosarcoma.

Erika Dobrota[1], M. Reza Saadatzadeh[1], Barbara Bailey[1], Keiko Kreklau[1], Kathy Coy[2], Felicia Kennedy[2], Melissa Trowbridge[2], Anthony Sinn[2], Chris Davis[1], Michael Ferguson[3], Steve Angus[1], Pankita Pandya[3], Karen Pollok[3]

[1]Herman B. Wells Center for Pediatric Research, Indiana University School of Medicine, Indianapolis, IN,[2]Indiana University Simon Comprehensive Cancer Center Preclinical Modeling and Therapeutics Core, Indiana University School of Medicine, Indianapolis, IN,[3]Indiana University Melvin and Bren Simon Comprehensive Cancer Center, Indiana University School of Medicine, Indianapolis, IN

Primary intraosseous rhabdomyosarcoma (IORMS) is a rare, metastatic, spindle cell-like rhabdomyosarcoma (RMS) subset that occurs in craniofacial bones and less commonly in long bones, or pelvis. IORMS patients typically succumb to the disease within 15 months of diagnosis. This disease is distinguished by specific gene fusions, such as FUS-TFCP2 which blocks myogenic differentiation, inhibits DNA repair, and induces transcription of Anaplastic Lymphoma Kinase (ALK) and Telomerase Reverse Transcriptase (TERT). Although case reports of treatment with ALK inhibitors (ALKi) have shown modest results, resistance always emerges and no other treatment options beyond surgery and chemotherapy exist. The ability to understand disease pathogenesis and identify actionable targets for rare RMS subsets is hindered by the lack of appropriate pre-clinical in vivo models. Thus, there is a critical need for developing such models to identify therapeutic options that will block disease progression, enhance quality of life, and ultimately achieve a cure for these patients. In collaboration with the Pediatric Cancer Precision Genomics Program at the Riley Hospital for Children, we developed a set of FUS-TFCP2 fusion-containing IORMS patient-derived xenografts (PDXs). PDX174 was derived prior to ALKi treatment (lorlatinib) and PDX199 from the same patient following disease progression after 16 months of lorlatinib therapy. Consistent with IORMS characterization, PDX174 transcriptome shows significantly increased expression of ALK and TERT, 10.6 and 14.8-fold respectively, compared to normal human skeletal muscle cells. ALK overexpression was confirmed by western blot but was notably absent in the subsequent PDX199 model. To further investigate the PDX174 model, we conducted an in vivo screen of six different small molecule inhibitors (SMIs) based on previously prioritized biomarkers of therapeutic response. Bivalent BET inhibitor (BETi), AZD5153, resulted in an initial block in tumor growth ($p<0.05$) compared to the vehicle and other SMIs. However, resistance emerged after four weeks of AZD5153 treatment. In addition, while CDK4/6 inhibitor, palbociclib, and CHK1 inhibitor, SRA737, induced moderate inhibition of tumor growth, drug resistance quickly followed within 2 weeks. Global kinome analysis indicated a significant increase in the mitogen- and stress-activated kinase 1 (MSK1) in AZD5153-resistant tumors compared to the vehicle group, revealing a potential therapeutic vulnerability in the BETi-resistant tumors. IORMS models such as PDX174/PDX199 are crucial for revealing actionable molecular signatures before and after targeted therapy and will increase our mechanistic understanding of tumor adaptive responses and aid in designing therapies that mitigate the emergence of therapeutic resistance.

#2607 Multi-omic profiling reveals subtype-specific signaling mechanisms in pediatric B-cell acute lymphoblastic leukemias.

Irina Pushel[1], Zachary Clark[2], Michaella J. Rekowski[2], Lisa A. Lansdon[1], Byunggil Yoo[1], Keith J. August[1], Alan S. Gamis[1], Nicole M. Wood[1], Michael P. Washburn[2], Midhat S. Farooqi[1]

[1]Children's Mercy Kansas City, Kansas City, MO,[2]University of Kansas Medical Center, Kansas City, KS

Genetic subtyping has improved the accuracy of diagnosis, and in turn outcomes, for children with B-cell acute lymphoblastic leukemia (B-ALL). Currently, clinical subtyping is based primarily on mutations in, or fusions involving, known driver genes. This approach is restricted in its power, particularly for subtypes such as *BCR::ABL1*-like B-ALL, which is largely characterized by its transcriptional similarity to *BCR::ABL1*+ cases, but has numerous possible driver fusions. Moreover, even transcriptomic profiling does not fully capture the molecular processes driving leukemogenesis, which are carried out by proteins, yet proteomics has been relatively unexplored in pediatric B-ALL to date. To bridge this gap, we compare genomic, transcriptomic, proteomic, and phosphoproteomic profiles between pediatric patients with *BCR::ABL1*-like and *ETV6::RUNX1* B-ALL to characterize subtype-specific molecular mechanisms. For each subtype, we selected at least five blood or bone marrow aspirates collected from patients at diagnosis. We combined genomic findings from clinical assays (karyotyping, FISH, microarray, and whole exome sequencing) with total RNA sequencing (Illumina). Additionally, we generated global proteomic and phosphoproteomic profiles using label-free quantitation. Peptides were enriched for phosphorylation using the SMOAC method, and all samples were run on an Orbitrap Ascend mass spectrometer (Thermo) using data dependent acquisition. Differential gene expression analysis comparing the two subtypes showed elevated expression of *CRLF2* in *BCR::ABL1*-like cases, consistent with clinical data and prior subtype characterization. Pathway enrichment of the 684 differentially expressed genes ($p < 0.05$) revealed upregulation of cell differentiation in *ETV6::RUNX1* samples, but otherwise provided limited mechanistic insights. Differentially expressed proteins ($n = 644$, $p < 0.05$) showed upregulation of translation-related processes in *ETV6::RUNX1* samples, and calcium-dependent signaling in *BCR::ABL1*-like samples. Kinase activity prediction based on phosphoproteomic data showed significantly higher activity of calcium/calmodulin-dependent protein kinases (CAMKs), including CAMK2B and CAMK4, in *BCR::ABL1*-like samples, which is not observed in corresponding gene expression between subtypes. There is a growing body of work suggesting a role for CAMKs in leukemias, though they have not previously been implicated in *BCR::ABL1*-like pediatric B-ALLs. Using a multi-omic profiling approach, we demonstrate that proteomic and phosphoproteomic data reveal previously undescribed subtype-specific activation of signaling cascades in pediatric B-ALL, which are not captured by genomic or transcriptomic assays. These insights add to our understanding of subtype-specific mechanisms, and can facilitate the identification of novel treatment targets.

#2608 The super enhancer-driven long noncoding RNA lncNB promotes neuroblastoma tumorigenesis by interacting with MSI2 protein and is targetable by small molecule compounds.

Sujanna Mondal[1], Pei Y. Liu[1], Janith Seneviratne[1], Antoine De Weck[1], Pooja Venkat[1], Chelsea Mayoh[1], Jing Wu[1], Jesper Maag[2], Jingwei Chen[1], Matthew Wong[1], Nenad Bartonicek[2], Poh Khoo[1], Lei Jin[3], Louise E. Ludlow[4], David S. Ziegler[5], Toby Trahair[1], Pieter Mestdagh[6], Belamy B. Cheung[1], Jinyan Li[7], Marcel E. Dinger[8], Ian Street[1], Xu D. Zhang[3], Glenn M. Marshall[1], Tao Liu[1]

[1]Children's Cancer Institute Australia, Sydney, Australia,[2]Garvan Institute of Medical Research, Sydney, Australia,[3]University of Newcastle, Callaghan, Australia,[4]Murdoch Children's Research Institute, Melbourne, Australia,[5]Kids Cancer Centre, Sydney, Australia,[6]Center for Medical Genetics Ghent, Ghent, Belgium,[7]Shenzhen Institute of Advanced Technology, Shenzhen, China,[8]The University of Sydney, Sydney, Australia

Background: While *MYCN*-amplified neuroblastoma has been the focus of neuroblastoma research in the past three decades, most human neuroblastomas do not harbour *MYCN* oncogene amplification, and their tumorigenic factors are unknown. Long non-coding RNAs (lncRNAs) regulate tumorigenesis by modulating the expression of molecular targets, however, there is limited literature on therapeutic targeting of lncRNAs with small molecule compounds.

Aims: To determine the oncogenic mechanism though which the lncRNA lncNB promotes neuroblastoma cell proliferation, survival and tumour progression; and to identify a small molecule compound that inhibits the interaction between lncNB and its binding protein MSI2 as an effective anticancer strategy.

Methods and results: Kaplan Meier analysis showed that high levels of lncNB expression in neuroblastoma tissues correlated with poor prognosis in 476 patients. We identified lncNB as the lncRNA most over-expressed in *MYCN* non-amplified, compared with *MYCN*-amplified, neuroblastoma cell lines. lncNB expression was controlled by super-enhancers, and lncNB RNA bound to MSI2 protein. RNA immunoprecipitation and sequencing identified BMX mRNA as the transcript most significantly disrupted from binding to MSI2 protein, after lncNB knockdown. lncNB or MSI2 knockdown reduced, while their over-expression enhanced, BMX mRNA stability and expression, ERK protein phosphorylation and *MYCN* non-amplified neuroblastoma cell proliferation. lncNB knockdown significantly suppressed neuroblastoma progression in mice. AlphaScreen of a compound library identified NSC617570 as an efficient inhibitor of lncNB RNA and MSI2 protein interaction, and NSC617570 reduced BMX expression, ERK protein phosphorylation, neuroblastoma cell proliferation *in vitro* and tumor progression in mice.

Conclusions: Our study demonstrates that lncNB RNA interacts with MSI2 protein to induce neuroblastoma tumorigenesis, and that targeting lncNB and MSI2 interaction with small molecule compounds is an effective anticancer strategy.

#2611 Cellular origin of DICER1 tumor predisposition syndrome informed by lineage-traceable genetically engineered mouse model.

Joyce Zhang[1], Felix Kommoss[1], Branden Lynch[1], Shary Chen[1], Janine Senz[1], Yana Moscovitz[1], Lesley Ann Hill[2], Wilder Scott[3], Jonathan Bush[4], William Foulkes[5], Gregg Morin[6], Michael Underhill[2], Yemin Wang[1], David Huntsman[1]

[1]Molecular Oncology, BC Cancer Research Centre, Vancouver, BC, Canada,[2]Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada,[3]Sunnybrook Research Institute, Toronto, ON, Canada,[4]Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada,[5]Department of Human Genetics, McGill University, Montreal, QC, Canada,[6]Medical Genetics, University of British Columbia, Vancouver, BC, Canada

Introduction: DICER1 tumor predisposition syndrome is a genetic disorder driven by germline *DICER1* pathogenic variants that predisposes pediatric and young adult patients to cancers of various organs. The second, missense mutation in RNase IIIb domain leads to systemic loss of mature 5p-miRNAs. Tumours of various sites are histologically and molecularly similar, suggesting a shared cellular origin and oncogenic mechanisms. To this end, we expanded our first-ever genetically engineered mouse model (GEMM) that recapitulated human Müllerian adenosarcomas, a DICER1 neoplasm, through inducing *Dicer1* mutations in a lineage-traceable, tamoxifen inducible, Hypermethylated in Cancer 1 (Hic1)-creERT2-driven mouse strain. Hic1 marks mesenchymal progenitors. This GEMM histologically resembles DICER1-renal neoplasms such as cystic nephroma and anaplastic sarcoma. We leveraged single-cell whole transcriptomics (scRNA-seq) and Xenium spatial transcriptomics platform (379 genes) to uncover cellular origin and hierarchy of Dicer1 sarcomagenesis.

Methods: We profiled normal kidney mesenchymal stromal cells (n=3 for scRNA-seq, n=3 for Xenium) and mesenchymal tumor components (n=5 for scRNA-seq, n=25 for Xenium). Trajectory analysis deconvoluted hierarchy of sarcomagenesis.

Results: In normal mesenchymal stromal niche, scRNA-seq identified 5 Hic1+ clusters including 2 clusters of universal fibroblasts (UniFibro): *Pi16*^{high} and *Col15a1*^{high}, and a cluster of *Dpt*$^{-}$ *Itga8*$^{+}$ fibroblasts. Spatially,*Pi16*^{high} UniFibro are enriched in renal vascular niche, whereas *Col15a1*^{high} UniFibro reside in subepithelial basement membrane. ScRNA-seq of tumours revealed a *Col15a1*^{high} *Mfap4*^{high} "Progenitor" cluster that is transcriptionally similar to control *Col15a1*^{high} UniFibro, suggesting the latter represent putative progenitors of the tumors. ScRNA-seq also identified a "ground" population that is transcriptionally similar to control *Dpt*$^{-}$*Itga8*$^{+}$ kidney fibroblasts, one cluster of *Pax7*$^{+}$ *satellite cells,* a committed Myog^{+} muscle cluster and a highly proliferative cluster. Pseudotime trajectory analysis showed *Col15a1*^{high} *Mfap4*^{high} progenitors can gives rise to a myogenic lineage that progresses via *Pax7*$^{+}$ transitional state and holds the potential to progress to highly proliferative sarcoma cells via "Ground" state of cells. Spatially, "Progenitor" cells have low-grade morphology, supporting their role in cancer initiation. Lastly, scRNA-seq of tumors revealed the expansion of *Col15a1*^{high}*Mfap4*^{high} UniFibro but not *Pi16*^{high} ones into the "Progenitor" cells.

Conclusion: Single cell profiling of renal tumours from *Dicer1*-GEMM supports *Mfap4*^{high} *Col15a1* ^{high}universal fibroblasts as cell of origin, and delineates progression underlying DICER1 sarcomagenesis, thereby providing opportunities for therapeutic intervention and mechanistic studies.

#2612 Elucidation of PAX3::FOXO1 initiation mechanisms in human induced pluripotent stem cell models.

Bradley T. Stevens, Yang Zhang, Jamaica F. Siwak, Shondra M. Pruett-Miller, Brian J. Abraham, Mark E. Hatley

St. Jude Children's Research Hospital, Memphis, TN

Rhabdomyosarcoma (RMS) is the most common pediatric soft tissue sarcoma. Alveolar RMS (ARMS), an aggressive subtype of RMS, is driven by either t(2;13)(q35;q14) or t(1;13)(p36;q14) resulting in the PAX3-FOXO1 (P3F) or PAX7-FOXO1 (P7F) fusion oncoproteins. Despite rigorous scientific advances and clinical trials, the survival rate for high-risk ARMS has remained at 20% over the last three decades. A deeper understanding of the basic biology driving P3F mediated tumorigenesis is needed to discover novel therapeutic targets. The P3F oncofusion protein is the key oncogenic driver and a potential candidate for therapeutic intervention. Current *in vivo* model systems fail to faithfully recapitulate the human disease in terms of timing and location and are complicated by the formation of other tumor types. A deeper understanding of the cells of origin and mechanisms of P3F tumor initiation are essential to enhancing models and preclinical efforts. Previously, our lab generated an ARMS model system derived from *TP53*-null human induced pluripotent stem cells (iPSCs), in which forced P3F expression during endothelial cell directed differentiation blocked endothelial maturation and instead reprogrammed cells to skeletal muscle-like cells that form ARMS tumors in mice. Generation of iPSC-derived ARMS (iARMS) occurs over 15 days and provides a unique model to determine the mechanism of P3F mediated transformation from non-myogenic origins. To elucidate this mechanism, I utilized CUT&RUN for P3F and H3K27ac to assess P3F occupancy and enhancer landscape, ATAC-seq to assess chromatin accessibility, and RNA-seq to assess gene expression changes at timepoints throughout the transformation event. These data define the fundamental genomic changes required for transformation and uncovers the key determinants of ARMS identity. Removal of P3F utilizing a guide RNA targeting the P3F breakpoint allowed iARMS cells to form endothelial-like tubes *in vitro*, indicating RMS cells retain endothelial potential after oncogene withdrawal. Finally, to explore alternative cells of origin and endogenous regulation of P3F during development, we created t(2;13) iPSCs (tiPSCs). In proof of principle experiments tiPSCs formed teratomas with discrete regions of ARMS in immunocompromised mice and differentiation of tiPSCs into muscle organoids revealed an abrogation in normal developmental trajectory upon P3F induction. Our novel cellular models provide a unique platform to uncover how P3F establishes and maintains ARMS cell state, dissect the specific dependencies required to maintain the ARMS cell state, and uncover how P3F is endogenously regulated during development. Understanding the fundamental mechanism of P3F-driven tumorigenesis from translocation regulation to transformation provides greater resolution into the key disease determinants to generate faithful model systems to focus pre-clinical efforts.

#2613 The role of the RNA methyltransferase RNAMT1 as a tumorigenic driver and therapeutic target in neuroblastoma.

K. Chok[1], K. Ip[2], J. Wu[2], S. Gadde[2], S. Mondal[2], J. Wong[3], B. Cheung[4], T. Liu[5];
[1]Children's Cancer Institute Australia and School of Women's and Children's Health, UNSW, Sydney, Australia, [2]Children's Cancer Institute Australia, Sydney, Australia, [3]Epigenetics and RNA Biology Program Centenary Institute and Sydney Medical School, Sydney, Australia, [4]Children's Cancer Institute Australia and School of Clinical Medicine, UNSW Medicine & Health, UNSW Sydney, Sydney, Australia, [5]Children's Cancer Institute Australia and University of New South Wales Centre for Childhood Cancer Research, Sydney, Australia

Neuroblastoma is the most common extracranial solid tumor in children worldwide. We have found that high expression of the *RNAMT1* gene in tumor tissues is associated with poor prognosis in both *MYCN*-amplified [Overall survival (OS): $p = 0.0409$ and event-free survival (EFS): $p = 0.0061$] and *MYCN* non-amplified neuroblastoma patients (OS: $p < 0.0001$ and EFS: $p < 0.0001$). Multivariable Cox regression analysis for neuroblastoma patient prognosis of RNAMT1 gene expression [OS: hazard ratio (HR) = 1.92, $p = 0.003$ and EFS: HR = 1.72, $p = 0.0001$] is independent from current prognostic markers: MYCN amplification (OS: HR = 3.39, $p = 5.1E^{-8}$ and EFS: HR = 1.77, $p = 0.0001$), age older than 18 months (OS: HR = 2.73, $p = 2.9E^{-5}$ and EFS: HR = 1.59, $p = 0.01$), and International Neuroblastoma Staging System stages 3&4 (OS: HR = 5.68, $p = 5.00E^{-6}$ and EFS: HR = 3.00, $p = 6.83E^{-8}$). Doxycycline (DOX)-inducible RNAMT1 knockdown in *MYCN*-amplified and MYCN non-amplified neuroblastoma cells decreased cell viability and colony formation capability, and induced apoptosis *in vitro*. DOX-inducible RNAMT1 knockdown delayed tumor growth and improved survival in mice bearing SK-N-BE(2)-C shRNA1 (OS: $p = 0.0034$) and SK-N-AS shRNA2 (OS: $p < 0.0001$). RNAMT1 regulates protein translation based on previous literatures, we demonstrated that RNAMT1 did not affect global mRNA translation alteration via puromycin incorporation assay and slightly affected polysome profile. The subset of mRNA transcripts after RNAMT1 knockdown and RNAMT1 inhibitor treatment will be analyzed with translating ribosome affinity purification sequencing (TRAP-Seq). RNAMT1 inhibitor was discovered by AlphaScreen of 2952 small molecule compounds provided by National Cancer Institute (NCI). Unravelling the molecular mechanisms of RNAMT1 in neuroblastoma tumorigenesis and mechanism of actions of RNAMT1 inhibitor, may provide novel insights to develop a more effective treatment for neuroblastoma patients.

#2615 The Open Single-cell Pediatric Cancer Atlas project: Collaborative analysis of pediatric tumor data.

Joshua A. Shapiro, Stephanie J. Spielman, Allegra G. Hawkins, Deepashree Venkatesh Prasad, Jennifer O'Malley, David S. Mejia, Jaclyn N. Taroni

Childhood Cancer Data Lab, Alex's Lemonade Stand Foundation, Wynnewood, PA

The Open Single-cell Pediatric Cancer Atlas (OpenScPCA) project is an open, collaborative project created to analyze publicly available data from the Single-cell Pediatric Cancer Atlas (ScPCA) Portal, with the goal of improving the quality and usability of single-cell pediatric cancer data and driving insights into pediatric cancer biology through deeper analysis of available data sets.

The ScPCA Portal (https://scpca.alexslemonade.org/), developed and maintained by Alex's Lemonade Stand Foundation (ALSF), is an open-source data resource for single-cell and single-nuclei RNA sequencing data of pediatric tumors. The ScPCA Portal currently contains summarized gene expression data for over 680 samples from a diverse set of over 50 types of cancers. All data on the portal is publicly available, uniformly processed with an open-source workflow, and ready for download in formats compatible with popular single-cell data analysis frameworks.

To coordinate further analysis of the ScPCA data, we launched the OpenScPCA project in April 2024. The project aims to engage a broad community of researchers analyzing genomic data from pediatric tumors, building off the previous success of the Open Pediatric Brain Tumor Atlas project (Shapiro et al. 2023). As part of the OpenScPCA project, ALSF provides contributors with support through technical guidance, comprehensive documentation, and access to computational resources.

We focused our initial collaborative efforts on the challenge of labeling cell types in pediatric cancer samples. Automated methods often have limited utility for annotating malignant cells in these samples because many tools and references for single-cell analysis were designed with adult healthy tissues or cancer types in mind. To overcome this limitation, we engage experts in various pediatric cancers who contribute their knowledge and analytical code. All contributions are publicly reviewed on GitHub for scientific content and code quality. In addition, we use automated testing to ensure that the annotation pipelines are robust and reusable. These combined efforts allow us to build a public resource to help improve pediatric cancer cell type annotation in this project and beyond.

As we continue this ongoing work, we invite researchers with expertise in pediatric cancer gene expression and single-cell RNA-seq analysis to join the OpenScPCA Project. We hope those participating will discover new datasets to advance their research, gain experience with cutting-edge technologies, build their research portfolios, and join a supportive community. Get started at https://openscpca.readthedocs.io/en/latest/.

#2616 Epigenetic targeted therapies induce unique MHC-I epitopes identified by immunopeptidome analysis in low mutation-burden sarcomas.

Alice Recho[1], Grace Huang[2], Himavanth R. Gatla[1], Erin E. Resch[1], Stephanie Glavaris[1], Maggie Phillips[1], Isaac Woodhouse[3], Pouya Faridi[3], Brian H. Ladle[1]

[1]Sidney Kimmel Comprehensive Cancer Center, Department of Oncology, Division of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD,[2]Department of Medicine, School of Clinical Sciences, Monash University, Clayton, Australia,[3]Centre for Cancer Research, Hudson Institute of Medical Research and Monash University, Clayton, Australia

Pediatric sarcomas as a group are poorly immunogenic tumors with low mutation burdens and poor responsiveness to immunotherapies such as immune checkpoint inhibitors (ICI). We have been investigating the use of the hypomethylating agent decitabine (DAC) followed by histone deacetylase inhibitor entinostat (Enti) in our murine models of sarcoma to potentially increase the tumor immunogenicity. Using our Kras-driven murine sarcoma KP Sarc, a whole-cell vaccine using DAC and Enti treated tumor cells generates a T-cell dependent, tumor-specific immune response restricted to epigenetically regulated antigens further potentiated with addition of ICI. We showed that epigenetically regulated antigens are shared between unrelated tumors KP Sarc and sarcoma M3-9-M and allow for cross-protection after vaccination. We hypothesized that epigenetically upregulated genes are persistent in vivo and can be used as tumor-specific targets identified by immunopeptidomics. We treated KP Sarc-bearing mice in vivo with DAC or Enti for 5 days, or sequentially with DAC then Enti. Tumors harvested at the end of treatment showed upregulation of the cancer testis antigens (CTA) in DAC- and DAC+Enti-treated mice by expression density analysis and immunohistochemistry compared to no expression in untreated and Enti-treated tumors. Moreover, these changes persisted a week after DAC treatment. We examined the gene expression profile of KP Sarc by RNA sequencing (RNA-Seq). We determined that the sequential in vitro treatment of KP Sarc with DAC then Enti (DAC+Enti) leads to a higher upregulation of CTAs and inflammatory pathways than either treatment alone. We treated human rhabdomyosarcoma (RH30 and RH41) and Ewing sarcoma (CHLA-9) cell lines showing upregulation of 75 shared antigens with DAC+Enti treatment. To investigate changes induced in antigen presentation, we examined the immunopeptidome of KP Sarc under two conditions: Interferon gamma (IFN-γ) treatment alone (n=4) and DAC+Enti+IFN-γ (n=4). Following immunoprecipitation of MHC I, bound peptides were identified via liquid chromatography-mass spectrometry. We combined this analysis with whole transcriptome RNA-seq of those samples. Analysis revealed a total of 4,171 peptides across all conditions and replicates, sourcing from 3,393 proteins, which were matched to the mouse proteome database. On average, 3,417 epitopes were identified in the control group compared to 3,912 epitopes in the treated group. 526 MHC I-bound peptides were unique to the treated group, with no unique peptides observed in the control. We identified epitopes from numerous proteins beyond CTAs indicating broad changes in antigen processing and antigenic peptides in the DAC+Enti treated cells. Further studies will validate the immunogenicity and ways to increase immune responses targeting these shared epigenetically regulated epitopes in sarcomas.

#2617 Uncovering genomic complexity of PAX5 internal tandem duplication using short-read and long-read sequencing.

Yanling Liu[1], Bensheng Ju[1], Li Dong[1], Melanie Loyd[1], Yuan Feng[1], Heather Mulder[1], Pandurang Kolekar[1], Li Fan[1], Hanxia Li[1], Scott Foy[1], Geoff Neale[1], Patrick A. Brown[2], William L. Carroll[3], Mignon L. Loh[4], John Easton[1], Xiaotu Ma[1]

[1]St. Jude Children's Research Hospital, Memphis, TN,[2]Bristol Myers Squibb, Princeton, NJ,[3]NYU Langone Health, New York, NY,[4]Seattle Children's Hospital, Seattle, WA

PAX5 is known to be frequently mutated in childhood B-cell precursor acute lymphoblastic leukemia (B-ALL) via several molecular mechanisms, including chimeric fusion, focal deletion, and point mutations. Among these, patients with PAX5 internal tandem duplication (PAX5-ITD) are reported to have a poor outcome. Unlike other common ITDs (e.g., FLT3), PAX5-ITD often involves gain of more than one copy of involved exons, and the exact nature of these alterations remain elusive. Here we aim to investigate the following questions: 1) what are the typical copy number gains in DNA and RNA among PAX5-ITD cases? 2) are PAX5-ITD always in-frame? 3) are these aberrations a result of multi-step or single-step events? Short-read whole genome sequencing (WGS) and RNA sequencing (RNA-seq) and PacBio ISO-seq, a state-of-the-art long-read sequencing method, are used in this study. By integrative analysis of WGS and RNA-seq data from a relapse cohort (n=584) and a non-relapse cohort (n=1055), we identified PAX5 mutation rate of ~30% in relapsed patients versus that of ~20% in non-relapsed patients. Among the various PAX5 mutation types, the PAX5-ITD mutation shows the greatest degree of enrichment (P=3e-6) in relapsed patients (n=21), compared with those who remain in remission (n=5). Copy number gains in PAX5-ITD cases ranged from 3 to 25 and involved four exon combinations within the gene: E5, E3-E5, E2-E5 and E1-E5 and concordant copy number gains were detected between diagnosis tumor and relapse tumor. We observed a negative correlation between the number of copy gains and the length of duplicated genomic regions. Furthermore, 11 out of the 26 PAX5-ITD cases exhibited multiple structural variants (SVs) and 1 case harbored 2 somatic SNV in ITD region. To investigate the transcriptional consequences of these SV events, we performed ISO-seq on 7 PAX5-ITD cases with available specimen. By mapping SVs and SNVs to full-length RNA transcripts, we observed complex sequences of events driving the formation of ultimate PAX5-ITD in 3 cases. Besides, copy number analysis on full-length RNA transcripts revealed variable copy number gains within tumors due to alternative splicing. Additionally, we identified neo-splice sites in 2 cases, indicating that the splicing process was influenced by the altered DNA context created by SVs. Finally, our data indicated that all PAX5-ITDs can transcribe in-frame mRNAs, suggesting activating nature of these mutations. These findings provide valuable insights into the genomic complexity of PAX5-ITD and highlight the diverse transcriptional and splicing outcomes due to these alterations.

#2618 Methylation-based epigenetic "switches" in group 3/4 medulloblastoma.

Muhammad Awais Khan[1], Arsalan Riaz[2], Faisal F. Khan[2]

[1]Khyber Medical College, Peshawar, Pakistan,[2]Precision Medicine Lab, Peshawar, Pakistan

Medulloblastoma (MB) is the most common primary brain tumor in children, with group 3 and group 4 (G3/4) being the most aggressive. Methylation studies have identified eight distinct subgroups within G3/4 MB, with observed differences in survival patterns. However, the contribution of specific methylation-based epigenetic changes to the ontogeny of the disease remains poorly understood. We analyzed publicly available methylation profiles of 1,370 G3/4 MB samples spanning all subgroups. To identify methylation probes important for classifying G3/4 MB into subgroups, we employed a wrapper-based feature selection machine learning (ML) algorithm on 400 samples. Subsequently, we trained a k-nearest neighbor (kNN)-based ML model to classify the remaining 970 samples, evaluating the sensitivity and specificity of the selected methylation probes. The kNN model achieved an accuracy of 90.41% using a panel of 541 methylation probes. We further refined this panel to 179 probes based on sensitivity and specificity metrics and observed a sequential alteration in beta values, suggesting a common developmental lineage for these subgroups. To identify specific genes driving the differentiation of the cells of origin or their transition to a cancerous state via methylation mechanisms, we selected a cohort of 460 samples that best represented the subgroups. Matched expression profiles for 103 samples were integrated with methylation data to infer candidate genes. To determine the spatiotemporal origins of these subgroups, we performed gene set enrichment analysis (GSEA) using published spatiotemporal gene sets of the developing human cerebellum. Our findings suggest that distinct subgroups originate from the Rhombic Lip Ventricular Zone, Intermediate Zone, Sub-ventricular Zone, and Choroid Plexus Epithelium. Further GSEA traced the cells of origin to Rhombic Lip - Progenitor, Unipolar Brush Cell - Progenitor, Differentiating and Defined, and Excitatory Cerebellar Neuron - Defined. In summary, we identified a prioritized methylation signature capable of accurately classifying G3/4 MB into subgroups and developed an R package, PriorityMeth, for further analysis. We also propose a developmental model outlining the origins of the subgroups of G3/4 MB and provide insights about the probable methylation-based epigenetic “switches” that drive the ontogeny of this group.

#2619 Exploring the genomic landscape of pediatric chronic myeloid leukemia stem cells.

Ryan S. Sathianathen[1], Julietta Picco[2], Hye Na Kim[1], Minyoung Youn[1], Ramesh Nair[3], Nobuko Hijiya[4], Kathleen M. Sakamoto[1]

[1]Pediatrics, Stanford School of Medicine, Stanford, CA,[2]Biology, San Jose State University, San Jose, CA,[3]Genetics, Stanford School of Medicine, Stanford, CA,[4]Pediatrics, Columbia University Irving Medical Center, New York, CA

Pediatric chronic myeloid leukemia (CML) accounts for 2-9% of leukemias in children. CML in children has been reported to present with a more aggressive clinical manifestation than adult CML, including a higher white blood count and larger spleens. The molecular basis for these clinical differences remains unknown. Therefore, we hypothesize that the molecular pathogenesis of pediatric CML differs from that of adult CML. Furthermore, CML relapse and resistance to tyrosine kinase inhibitors are due to the persistence of CML stem cells. Bulk RNA-seq data with mRNA from bone marrow (BM) CD34+ cells previously demonstrated differential gene expression and uniquely enriched pathways in pediatric CML compared to adult CML stem cells. Our data also showed significant downregulation of Rho pathway-related genes such as *ARGHAP27*, *VAV2,* and *DLC1*, suggesting different molecular pathways in pediatric and adult CML stem cells. To study the clonal heterogeneity and diversity of pediatric CML stem cells, we performed single-cell RNA seq on CD34+ cells from pediatric CML (n=7) and healthy pediatric (n=2) BM samples using the Stem Pro $CD34^+$ system (Miltenyi Biotec, Inc.) and Chromium Next GEM Single Cell 3' kit from 10X Genomics. Our preliminary data show 13 clusters from CML and healthy $CD34^+$ cells based on gene expression. Overall, CML clusters show a significant downregulation of immune related genes compared to healthy BM clusters. Pathway enrichment analysis shows differential enrichment of immune-related and inflammatory signaling pathways, such as the immune activation and T cell inhibitory pathways in pediatric CML. Our results suggest that immune dysregulation in pediatric CML stem cells contributes to disease pathogenesis. Current work focuses on characterizing 1) the role of immune-related genes in pediatric CML stem cells and their impact on T cell response and 2) cell surface markers of pediatric CML stem cells to identify potential targets for immunotherapy.

#2620 m^{6}A demethylase ALKBH5 regulates medulloblastoma growth and progression.

Panneerdoss Subbarayalu[1], Daisy Medina[1], Pitta V. Prabhakar[1], Shahad Abdulsahib[1], Saif R. Nirzhor[1], Desiree Denman[1], Santosh Timilsina[1], Deepika Singh[1], Phat Do[1], Krishna Evani[2], Dhiya Billa[3], Esha Reddy[4], Meera Nair[5], Peter Houghton[1], Yogesh Gupta[1], Yidong Chen[1], Suryavathi Viswanadhapalli[6], Ratna K. Vadlamudi[6], Gangadhara R. Sareddy[6], Andrew Brenner[6], Manjeet K. Rao[1]

[1]UT Health San Antonio Greehey Children's Cancer Res. Inst., San Antonio, TX,[2]UT San Antonio, San Antonio, TX,[3]Health Careers High School, San Antonio, TX,[4]Southern Methodist University, Dallas, TX,[5]Brennan High School, San Antonio, TX,[6]UT Health San Antonio, San Antonio, TX

Introduction: Medulloblastoma (MB) is pediatric brain cancer originate from the cerebellum, and accounts for large number of all childhood cancer related deaths. MB grows vigorously, and spreads to central nervous system (CNS) through cerebrospinal fluid, leading to leptomeningeal metastases in 66% brain cancer patients. MB are commonly treated with a combination of surgery, radiation, and chemotherapy drugs like vincristine. Unfortunately, at the young age, radiation exposure and chemotherapy treatment lead to high toxicity which ultimately compromise the quality of life for those kids. Therefore, it is critical to understand the molecular mechanism that regulates MB tumor growth, metastasis and relapse so that safe and novel therapeutics can be developed to treat pediatric MB. In this study, we investigated the role of RNA demethylase ALKBH5, in regulating MB growth and progression.
Methods: Medulloblastoma cell lines including HD-MB03, D556, D425 and DAOY were purchased from the ATCC. MB cells were transfected either with ALKBH5 overexpression (OE) plasmid or siRNA (KD). These OE/KD MB cells were analyzed for cell viability, migration, invasion, colony formation, cell cycle, apoptosis assays, RNA sequencing, RT-qPCR, western blotting, RNA immunoprecipitation, and *in vivo* tumor xenograft study.
Results: Our results showed that depletion of ALKBH5 significantly reduced short term cell viability, migration, invasion and colony forming ability of MB cells. ALKBH5 knockdown MB cells showed increased apoptosis. Further, our results show that ALKBH5 silencing suppressed the self-renewal/proliferation of MB cancer stem cells (MBCSC), including medullosphere formation. In orthotopic xenograft study, ALKBH5 knockdown cells intracranially injected into mouse showed reduced tumor growth compared to the scrambled siRNA transfected MB cells. To understand the molecular mechanism of ALKBH5, we performed transcriptome analysis of ALKBH5 depleted MB cells. Silencing of ALKBH5 showed alterations in several metabolism related pathways. Further, ALKBH5-depletion led to significantly decreased levels of cancer stem cell marker proteins including Nanog, OCT4 and SOX9.
Conclusion: Together, our data suggests that m^{6}A RNA demethylase ALKBH5 may play a critical role in MB growth and tumor progression by regulating MB tumor initiating stem cells and ALKBH5 serves as a potent therapeutic target to treat MB.

#2621 Mitotic activities of Ewing sarcoma proteins.

Evan Schulz, Mizuki Azuma

University of Kansas, Lawrence, KS

Ewing sarcoma (ES) is a pediatric bone tumor in critical need of targeted chemotherapies with fewer side effects. ES's driving hallmark, the t(11:22) chromosomal translocation, generates two aberrations of the EWS protein: the loss of an *EWS* allele and expression of *EWS/FLI1* fusion protein, denoted as EWS aberrations. Identifying drug targetable EWS aberration-induced changes to tumor biology and drug sensitivity is required to optimize current treatment strategies and develop new targeted therapies. To accomplish this, we established a DLD-1 cell line that lacks the t(11:22) chromosomal translocation and EWS aberrations, while enabling conditional *EWS/FLI1 expression* with doxycycline (Tet-On system), single-allele *EWS knockdown* with auxin (auxin-inducible degron system), or a combination of both (*EWS/FLI1-EWS KD*). This allows us to dissect the contribution of each EWS aberration to phenotypic changes in the cell. Since EWS is a known regulator of tubulin acetylation, we investigated whether tubulin acetylation levels changed under EWS aberration conditions. Both immunocytochemistry and western blotting revealed *EWS/FLI1 expressing* and *EWS/FLI1-EWSKD* cells displayed lower acetylated tubulin signal intensity after one and seven days, while *EWS knockdown* cells displayed higher acetylated tubulin signal intensity. As tubulin acetylation prevents microtubule damage, we probed cells with an antibody that visualizes microtubule damage and repair sites. *EWS/FLI1 expressing* and *EWS/FLI1-EWS KD* cells exhibit a higher signal intensity, covering a broader area compared to the control cells. Our data suggests that the combination of *EWS/FLI1-EWS KD* increases microtubule damage sites by reducing microtubule acetylation. When the EWS/FLI1-EWS KD cells were treated with nocodazole, the rate of cell death increased compared to control nocodazole-treated cells, indicating the cells had been sensitized to microtubule disruption. Currently, we are investigating how EWS aberrations change the regulation of microtubule acetylation and how this mechanism affects sensitivity to microtubule disruptors. Understanding this mechanism could identify new drug targets and treatment strategies in ES to improve drug efficacy and reduce secondary side effects for patients.

#2623 Targeted therapy with DFMO and immunotherapy equalizes survival in MYCN-amplified neuroblastoma: insights from genomic and network analyses.

Anderson O. Cox[1], Abhinav Nagulapally[2], Deha Ay[1], Qianqian Song[3], Liang Liu[1], Hong-Gang Wang[2], Abigail Moore[2], Valerie I. Brown[2], Wei Zhang[1], Giselle L. Saulnier Sholler[2]

[1]Atrium Health Wake Forest Baptist Comprehensive Cancer Center, Winston-Salem, NC,[2]Penn State College of Medicine, Hershey, PA,[3]University of Florida College of Medicine, Gainesville, FL

Background: This study evaluates the efficacy of difluromethylornithine (DFMO) combined with immunotherapy for its potential as a targeted therapy to mitigate outcome differences associated with MYCN amplification in neuroblastoma (NB).
Methods: A clinical trial was conducted involving high-risk (HR) NB patients, who completed standard HR induction and consolidation, were then treated with standard of care immunotherapy adding DFMO either during and/or after immunotherapy. Patients were categorized based on MYCN amplification status. Survival analysis, differential gene expression, and pathway enrichment analyses were performed using RNA sequencing data. STRING and Bayesian network analyses were employed to identify biological relationships among differentially expressed genes (DEGs). Centrality analysis was performed to identify the top nodes in the regulatory network. Cox proportional hazards (CPH) models were used to determine the impact of individual genes on survival, and a multivariate Lasso model was developed to predict risk scores based on gene expression profiles.
Results: Gene copy number variation analysis showed that among the 55 cases, 19 cases had MYCN amplification. There are slightly more responders to immunotherapy and DFMO among MYCN-amplified (MNA) patients (not statistically significant). Survival analysis showed that immunotherapy and DFMO treatment achieved similar survival rates for both MNA and non-amplified patients. 112 DEGs were identified between responders and non-responders, with 190 DEGs in the MNA group and 74 in the MYCN non-amplified (MNN) group. Key genes such as PDZRN4, MGDA2, LINC00632, and ENTPD3 were identified as significant for survival in MNA patients. The DFMO-treated cohort with MYCN amplification did not show a significant relationship with poor survival (p-value = 0.8). A multivariate CPH model subjected to Lasso penalization identified five genes that distinguished high-risk and low-risk patients with significant survival disparity (p-value < 0.001). Pathway analysis showed that the Hippo signaling pathway was suppressed in MNN responders. Ribosomal protein gene expression was enriched in responders overall and in MNN responders, but not in MNA responders. STRING analysis revealed highly connected networks in DEGs, with stem cell factor SOX2 being a central node in MNA cases, indicating its role in maintaining stemness and promoting tumor propagation.
Conclusion: DFMO combined with immunotherapy shows promise as an effective targeted therapy for both MNA and MNN NB, equalizing survival rates between MNA and MNN patients. This treatment may particularly target stem cell populations in MNA cases. Further validation is required to confirm these findings and refine the associated risk prediction models.

#2624 Aneuploidy induction mechanism in Ewing sarcoma.

Priyani H. Harsha Hapugaswatta, Mizuki Azuma

University of Kansas, Lawrence, KS

Ewing sarcoma (ES) is the second most prevalent sarcoma that develops in the bones of adolescents and children. A major aberration in Ewing sarcoma is the chromosomal translocation between chromosomes t(11;22), resulting in the loss of one allele of *EWSR1* and acquisition of *EWSR1-FLI1* fusion gene. Trisomy 8 (~50%) is the major aneuploidy in ES tumors and is associated with low survival rate in patients. This study aims to elucidate the molecular mechanism underlying the aneuploidy induction in ES. To study the role of loss of one *EWSR1* allele and gain of the *EWSR1-FLI1* fusion gene inducing aneuploidy, we established a conditional DLD-1 cell line that enables knockdown of EWS derived from one *EWSR1* allele using Auxin-induced Degron system and expression of EWSR1-FLI1 using a Tet-on system. The DLD-1 cell line was employed in this study because it is a near diploid cell line that has been utilized to investigate aneuploidy induction by the gene of interest. Treatment of the cell with Auxin (AUX) degrades EWSR1 protein expressed from one allele of *EWSR1*, while treatment with Doxycycline (DOX) induces the expression of EWS-FLI1. Simultaneous degradation of EWSR1 and EWSR1-FLI1 expression is achieved by treating the cell line with both AUX and DOX. To investigate the effect of loss of one *EWSR1* allele and gain of *EWSR1-FLI1* fusion gene, cells were treated with AUX (EWSR1 knockdown derived from one allele), DOX (EWSR1-FLI1expression), and AUX/DOX (EWSR1 knockdown and EWSR1-FLI1 expression), for 2 to 8 days. The results showed that all three-drug treated samples led to an increase in cell size. Further, Fluorescence-activated Cell Sorting analysis (FACS) revealed that the majority of the small cells were diploid (2N), whereas the majority of large cells were aneuploid (>3N). While Ewing sarcoma cells are described as small round cells, there was a variation observed in Ewing sarcoma cell sizes, A673 and SKES1, but not in the normal MSC cells.Next, we investigated whether the treatment of AUX and DOX induces trisomy 8 using FISH assay. Both AUX and DOX treated cells displayed a higher incidence of trisomy 8 compared to the control group. Furthermore, the AUX/DOX treated cells displayed a significantly higher incidence of trisomy 8 compared to AUX, DOX treated, and control cells, suggesting that the expression of EWSR1-FLI1 fusion protein and EWSR1 knockdown have a cumulative effect on trisomy 8 induction. While trisomy 8 has been reported in various cancers with a poor prognosis, the induction mechanism remains unclear. To the best of our knowledge, this is the first observation describing the collaborative activities between the EWSR1-FLI1 fusion protein and EWSR1 knockdown in inducing trisomy 8. We are currently investigating the molecular function of trisomy 8 induction in this cell line and in Ewing sarcoma cell lines.

#2625 Role of base deaminase and splicing deregulation in pediatric B cell acute lymphoblastic leukemia stem cell persistence.

Mrinal Joshirao[1], Inge Van Der Werf[2], Jessica Pham[2], Antonio W. Ruiz[2], Neha Katragadda[2], Emma E. Klacking[2], Elsa Molina[3], Ludmil Alexandrov[1], Thomas Whisenant[4], Catriona Jamieson[2]

[1]Pediatric Hematology Oncology, University of California San Diego, San Diego, CA,[2]Division of Regenerative Medicine, University of California, San Diego, San Diego, CA,[3]Next Generation Sequencing & Genomics Core, Salk Institute for Biological Studies, La Jolla, CA,[4]Center for Computational Biology and Bioinformatics, University of California San Diego, San Diego, CA

Introduction: B cell acute lymphoblastic leukemia (B ALL) is the most common childhood malignancy with more than ninety percent cure rates and current research efforts are directed towards development of curative therapy in patients who relapse. Leukemia stem cell (LSC) persistence contributes to relapse. Whole genome sequencing and RNA sequencing (RNA seq) have revealed APOBEC3C and ADAR1 base deaminase induced splicing alterations in LSCs in both adult and pediatric acute myeloid leukemia. Through our study we strive to determine the role of base deamination deregulation in LSC persistence in pediatric B ALL.
Methods: We designed a longitudinal early relapse detection study by collecting bone marrow aspirates and/or peripheral blood samples from patients ages 1 to 25 years diagnosed with B ALL at University of California, San Diego according to Institutional Review Board guidelines. Timepoints include diagnosis, end of induction cycle and/or subsequent cycle until they achieve remission or relapse. Cord blood and pediatric non leukemic (pNL) samples were used as controls (*Van Der Werf, ⋯Jamieson. Cell Reports Medicine 2023, March cover*). Mononuclear cells were isolated followed by CD34+ cell selection. Fluorescence activated cell sorting purification of HSCs ($CD34^+CD38^-Lin^-$) and HPCs ($CD34^+CD38^+Lin^-$) was followed by RNA extraction (Qiagen), library preparation, sequencing (Illumina Hi Seq) and RMATS as well as A to I editome analysis.
Results: To date, twelve B ALL patients have been enrolled in the study, with 67 percent belonging to high risk and 33 percent to standard risk NCI subgroups, and 7 patients available for analysis. RNA seq analysis was performed on purified HSCs and HPCs from three patients. While there was a trend toward APOBEC3C overexpression in B ALL versus pNL control HSCs, there was a statistically significant upregulation of ADAR1 in B ALL HSCs and HPCs and ADARp150 splice isoform overexpression in B ALL HPCs. Furthermore, RMATS differential splicing analysis detected alternative splicing deregulation, including exon skipping (ES), intron retention (IR), and alternative 5 prime splice site (A5SS) as well as alternative 3 prime splice site (A3SS) usage. With more than 2000 differential events identified, ES was the most frequent event in our HSC and HPC RNA seq analyses, which has been linked to increased adenosine to inosine (A to I) splice acceptor site editing by ADAR1p150.
Conclusions: Preliminary data suggests RNA splicing deregulation and ADAR1p150 splice isoform mediated A to I RNA editing activity may contribute to LSC persistence following therapy. To validate our findings, we will perform lentiviral ADAR1 nanoluciferase GFP reporter and splicing reporter assays in combination with functional survival and self renewal assays with the goal of developing base deaminase targeted strategies to predict and prevent pediatric B ALL relapse.

#2626 Leveraging FFPE single-nucleus RNA-sequencing for Osteosarcoma.

Danh Truong, Clement Agyemang, Davis Ingram, Alexander Lazar, Valerae O. Lewis, Joseph Ludwig

UT MD Anderson Cancer Center, Houston, TX

Osteosarcoma (OS), a heterogeneous class of bone sarcomas, can be subclassified based on predominant histological features. This molecular heterogeneity cannot fully be resolved with bulk sequencing. However, due to the rarity of several OS subtypes, including low-grade and small-cell, parosteal, periosteal, and high-grade surface, acquiring fresh specimens for single-cell omics is difficult. Logistical challenges exist when acquiring fresh specimens, such as transportation or adequate storage. Here, we leverage archival formalin-fixed paraffin-embedded (FFPE) samples of OS, which are routinely processed and preserved in pathology laboratories. We utilized 10x Flex assay to perform single-nucleus RNA-sequencing (snRNA-seq) from FFPE samples of OS, including osteoblastic OS, chondroblastic OS, low-grade, and periosteal. We compared fixed-frozen to FFPE samples to determine if both methods yielded concordant results. Two 25 µm FFPE scrolls and matched fixed-frozen tissue of approximately 60 mg were dissociated using the gentleMACs Dissociator. After confirming adequate cell count, we performed snRNA-seq on the fixed samples using the 10x Flex assay. Fixed-frozen (5201±3410 cells) had higher cell counts than FFPE (1185±823 cells), which may be attributed to tissue area in the FFPE scrolls. The confidentially mapped reads were similar for fixed-frozen (64%±13%) and FFPE (55%±17%). Higher UMIs and genes were detected in fixed-frozen (8566±110 UMIs and 2342±15 genes detected) than in FFPE (1464±25 UMIs and 835±9 genes detected). Regardless of specimen type, we detected the subtype-specific gene expression. Fixed-frozen and FFPE specimens of osteoblastic OS expressed osteoblastic markers, SPP1, CHD11, and IBSP. Chrondroblastic markers (SOX9 and ACAN) were expressed in both conditions for chondroblastic OS. Significantly, CDK4 and MDM2 were overexpressed in low-grade OS due to the amplification of CDK4 and MDM2 copy numbers, confirmed by CopyKAT and inferCNV. Overall, we found that the 10x Flex-based snRNA-seq adequately preserved each OS subtype's biology. FFPE had lower quality control metrics than fixed-frozen, possibly due to the smaller amount of tissue available from the scrolls. Future work will investigate the common theme of genetic drift from normal osteoblasts and their varied degrees of dedifferentiation observed along mesenchymal lineages among OS subtypes.

#2627 Integrated multi-omics analyses discovers lineage plasticity in desmoplastic small round cell tumors.

Danh Truong[1], Emre Arslan[1], Veena Kochat[1], Roberto Cardenas[1], Jiaqian Fan[1], Clement Agyemang[1], Adewale A. Adebayo[1], Davis Ingram[1], Akshay Basi[1], Hannah C. Beird[1], Jared Burks[1], P Andrew Futreal[1], Alexander Lazar[1], Ravin Ratan[1], Najat C. Daw[1], Andrea Hayes-Dixon[2], Kunal Rai[1], Joseph Ludwig[1]

[1]UT MD Anderson Cancer Center, Houston, TX,[2]Howard University, Washington, DC, DC

Desmoplastic small round cell tumor (DSRCT) is a rare and usually incurable aggressive sarcoma subtype. Less than 20% of patients survive beyond five years with standard of care. All tumor cells harbor a pathognomonic EWS::WT1 fusion protein (FP), but FP-targeted agents are nonexistent. Given the male to female ratio of 6:1, we sought to understand androgen receptor (AR) biology and its role as a therapeutic target in DSRCT. Our preliminary data suggested that a subset of DSRCT cell's epithelial lineage expressed AR, which is the driver of prostate cancer (PC). A separate subset of DSRCT cells exhibited neural (NE) markers without AR expression. We explored gene expression, chromatin accessibility, and protein expression using multi-omic analyses (n=9) to understand the mechanisms driving AR and NE expression in DSRCT. We identified DSRCT, fibroblasts, endothelial cells, immune cells, and smooth muscle cells in the snRNA-seq data. Using AR and NE signatures, we generated three subsets of DSRCT cells. One subset was high in AR expression, and the other was high in NE markers, but not both. The third subset appeared to exhibit both markers - implying a hybrid phenotype or a poorly differentiated phenotype. To validate protein expression, we used the Lunaphore COMET. In AR-positive tumor nests, AR was localized to the nucleus, suggesting downstream activation of this pathway, and correlated with pan-cytokeratin (Ck) expression - an epithelial marker. Tumor nests marked by neural-specific enolase (NSE), an NE marker, demonstrated little to no expression of AR or Ck. However, patient subsets that harbored a hybrid transcriptomic profile had different cell states within the tumor nests, which were AR/Ck positive or NSE positive, but not both. This suggested that tumors may harbor cells of different cell states. The ATAC-seq data found that Epithelial/AR-positive subtypes were enriched in motifs for nuclear receptors (ARE and GRE). The NE subtype lacked the ARE and GRE motifs. EMT-related motifs were associated with the NE and hybrid subtypes, such as ZEB1, SNAI1, and SNAI2 (Slug). Transcription factor binding prediction showed that ZEB1 had higher activity in the NE subtype, while AR, FOXA2, and GRHL2, a co-regulator of AR, had higher activity in the AR subtype. Although the neuroendocrine subtype in PC usually evolves in response to therapy, how the NE phenotype emerges in DSRCT remains unknown. It has yet to be discovered how transcription factors play a role in the Epithelial/AR and NE in DSRCT dimorphic states. ZEB1 and GRHL2 form a double negative feedback loop, where ZEB1 suppresses GRHL2. This suggests that there may be an interaction between the ZEB1 and AR to regulate epithelial and NE phenotype in DSRCT, which may have implications for treating DSRCT with AR inhibitors.

TUMOR BIOLOGY: Invasion and Migration
Poster Session

#2631 Trop-2 is expressed in tumor budding cells and drives colon cancer cell migration and invasion through a β-catenin, CDC42, PKCα, Akt signaling network.

Saverio Alberti[1], Valeria Barresi[2], Rossano Lattanzio[3], Marco Trerotola[3], Emanuela Guerra[3], Martina Ceci[3], Roberta Di Pietro[3], Donato F. Altomare[4], Raffaella Depalo[4], Arcangelo Picciariello[5], Laura Antolini[6], Federica M. Previtera[7]

[1]BIOMORF, University of Messina, Messina, Italy,[2]University of Verona, Verona, Italy,[3]University of Chieti, Chieti, Italy,[4]University of Bari, Bari, Italy,[5]University of Lecce, Lecce, Italy,[6]University of Milano Bicocca, Monza, Italy,[7]University of Messina, Messina, Italy

TROP2 was previously shown to drive metastatic diffusion of colorectal cancer (CRC), upon proteolytic activation by ADAM10. Trop-2 activation was shown to lead to cleavage of E-cadherin, with release from the scaffolding cytoskeleton and disruption of cell-cell junctions. This suggested that Trop-2-driven loss of cell adhesion is pivotal for the acquisition of invasion capacity in CRC. Tumor budding was shown to play a role in CRC invasion at the tumor/stroma interface and to impact on disease outcome. We thus investigated whether Trop-2 is associated with CRC cell budding. Our findings show that essentially all CRC buds express Trop-2. Trop-2-positive tumor cell buds and poorly differentiated clusters associated with metastatic relapse in CRC patients in independent CRC case series. Trop-2 was shown to drive cell migration and matrix invasion upon induction of β-catenin signaling, via expression of CDC42, phosphorylation/activation of PKCα at Ser657 and of Akt at Thr308. The highest impact on CRC patient prognosis was jointly shown by Trop-2, CDC42 and phosphorylated PKCα, supporting a model of Trop-2-driven CRC progression through induction of migration and invasion of tumor budding cells.

#2632 IL10RB is a key molecule that regulates tumor escape through invadopodium formation and immune dysfunction.

C. Kudo-Saito, H. Ozawa, H. Imazeki;
National Cancer Center Research Institute, Tokyo, Japan

Purpose: Many molecular mechanisms underlying tumor escape, in which cancer cells undergo EMT and thereby acquire metastatic potential and cancer stemness, have been elucidated, and these efforts have led to the development of various novel drugs. However, many patients do not necessarily benefit from the treatments. This may be because cancer cells diversify and evolve through intrinsic changes that occur within the cancer cells themselves via EMT, and extrinsic changes that are modified by the host environment, in an attempt to escape the attacks of therapeutics and immune surveillance. Considering this situation, further in-depth research is needed to achieve complete cure in more patients. In this study, we focused on the changes in gene expression that occur in cancer cells after achieving EMT, and attempted to elucidate the evolutionary mechanisms that further promote tumor escape leading to robust treatment resistance.
Results: We comprehensively analyzed gene expression in mouse melanoma B16-F10 cells stably expressing Snail, a key EMT-governing transcription factor, by GeneChip microarray, and found that IL10RB expression was strikingly increased as compared to that of mock control. Transfection with siRNA-snail into the cells abrogated both Snail and IL10RB expression, suggesting that this is regulated by Snail. Transfection with siRNA-il10rb significantly reduced cell invasion, adhesion, and chemoresistance as compared to transfection with control siRNA, suggesting a key functional role of IL10RB in tumor malignancy. Il10rb gene transduction into mouse IL10RB(low) cell lines (NHOS and Colon26) significantly enhanced cell invasion, adhesion, and chemoresistance, accompanied by dramatic morphological changes - formation of numerous tentacles/invadopodia. RNA-sequencing analysis of the IL10RB transfectants revealed that gene expression of actin and related genes, which are required for invadopodia formation and drug resistance, and of enzymes, which are required for invasion and metastasis, was markedly increased than that in mock control. In the in vivo settings, IL10RB+ tumor growth and metastasis were extremely slower after implantation in mice than those of mock control. However, T cells and NK cells were dramatically decreased in the spleens of the IL10RB+ tumor-implanted mice, and their cytotoxic activity was also significantly reduced, suggesting induction of immune suppression and dysfunction. Surprisingly, chemotherapy significantly exacerbated both IL10RB+ tumor growth and metastasis in the mice, while immunotherapy with anti-IL10RB blocking mAb significantly induced anti-tumor effects without such adverse events.
Conclusions: These results suggest that IL10RB is a key molecule that regulates tumor escape and intractability post Snail-induced EMT. Targeting IL10RB may be a promising strategy for improving clinical outcomes in cancer therapy.

#2633 Mechanisms of SEMA4D mediated blood brain barrier transmigration.

A. D. Sunkara, R. Klotz, M. Yu;
University of Maryland, Baltimore, Baltimore, MD

Brain metastasis poses a challenge in cancer treatment due to its prevalence, diagnostic complexities, and the limited efficacy of systemic therapies due to the blood brain barrier (BBB). Previous work in our lab utilized patient-derived Circulating Tumor Cell (CTC) lines established from the peripheral blood of patients with metastatic luminal breast cancers to investigate the molecular features that allow a subset of CTCs to adapt and grow in the brain. This study identified Semaphorin 4D (SEMA4D), a transmembrane receptor that facilitates BBB transmigration, both *in vitro* and *in vivo*, through its interaction with the Plexin B1 (PLXNB1) receptor. Together with oncogene MYC, SEMA4D facilitates the colonization of the brain and promotes brain metastasis of CTCs. In this study, we propose investigating the hypothesis that the reverse signaling via the cytoplasmic region of SEMA4D activates the Yes Associated Protein (YAP) pathway, facilitating BBB transmigration. Our data shows that truncating the cytoplasmic region of SEMA4D (deleting the PDZ binding domain) in the BT474 HER2 positive cell line reduces BBB transmigration. In addition, cells that are overexpressed with SEMA4D showed nuclear localization of YAP via immunofluorescence. Hence, using patient-derived CTC cultures and a model system of breast cancer cell lines we aim to elucidate SEMA4D's link to YAP signaling and the mechanism of BBB transmigration. Understanding the mechanisms underlying metastatic invasion through the BBB is crucial for developing targeted interventions in the future.

#2634 IL34-induced Arg1 positive macrophage cells at the edge of invasion in cerebellum metastasis model of HER2-positive breast cancer.

X. Cheng[1], K. Patel[2], Y. Fu[1], R. Cleary[1], B. Zhou[1], M. Highkin[1], J. Hsia[1], X. Jin[1], J. L. Prior[1], M. Michie[1], R. Sun[1], I. S. Hagemann[1], T. Li[1], V. Jain[2], S. Gregory[2], A. Kim[1], R. Bose[1];

[1]Washington University in St. Louis, St. Louis, MO, [2]Duke University, Durham, NC

Brain metastases occur in about 30% breast cancer patients. The cerebellum is a frequent location for metastases in HER2-positive breast cancer patients, but the mechanisms for this is unknown. We hypothesize that the cerebellar microenvironment plays a crucial role in promoting the growth of metastatic HER2+ breast cancer cells. To study the interaction between cerebellar cells and metastatic breast cancer, we developed a syngeneic, immunocompetent mouse model for breast cancer brain metastasis, by stereotactically injecting mouse breast cancer organoids with HER2V777L; PIK3CAH1047R activating mutations or HER2V777L; TP53fl/fl1 into the cerebellum. Growth of these cerebellar metastasis was monitored both by MRI and also with Herceptin imaging using a Near-Infrared fluorophore conjugated to Herceptin. We observed significant tumor growth in the cerebellum for up to 7 weeks post injection. We further investigated cellular interactions within the pro-tumorigenic microenvironment and HER2+ breast cancer cells using spatial transcriptomics. We identified inflammation-induced ARG1+ macrophage cells at the edge of the cerebellar metastasis. Further, the cytokine IL34 is upregulated in the brain metastasis. IL34, which is secreted by HER2+ breast cancer, induces Arg1 expression in both homeostatic microglial cells and bone marrow derived macrophages. These results suggest IL34 polarizes macrophages facilitating tumor invasion in the brain. These novel mouse models and findings elucidate the molecular mechanisms and the role of the tumor microenvironment that promotes cerebellar metastasis, and suggest a therapeutic approach to inhibit breast cancer invasion into the brain.

#2635 E3 ubiquitin ligase ARIH1 mechanism and regulation in triple-negative breast cancer.

Casey B. Staby[1], Vanessa Zapata[1], Sean Cruz[2], Kelly Anderson[1], Abigail Quesnelle[1], Breege Howley[1], Philip Howe[1]

[1]Medical University of South Carolina, Charleston, SC,[2]College of Charleston, Charleston, SC

We have recently identified a novel role for the ubiquitin E3 ligase ARIH1 in Epithelial-to-Mesenchymal transition (EMT) induction, tumor initiation, and metastatic progression of triple-negative breast cancer (TNBC). In TNBC cells, ARIH1 knockdown (KD) leads to a reduction in cell invasion and mammosphere formation, and loss of tumor initiation and metastasis. In this current study, we aim to define the underlying mechanisms controlling ARIH1 expression and contributing to ARIH1 function in TNBC. Quantitative proteomic analysis of control and ARIH1 silenced TNBC cells revealed an enrichment of mitochondrial proteins consistent with ARIH1's role in mitophagy. Additionally, a striking deregulation of proteins involved in oxidative stress response was observed. This analysis revealed that ARIH1 increases in response to various oxidative stressors, as detected by qPCR and immunoblot. The ARIH1 promotor contains conserved motifs for transcription factors (TFs), including CREB1 and HIF1α sites, linked to oxidative stress. Of note, CREB1 is positively correlated with ARIH1 transcript in breast cancer patient tumors. These findings support the transcriptional upregulation of ARIH1 in response to oxidative stress and may explain why we see an upregulation of this protein during breast cancer progression.As ARIH1 plays a role in both mitochondrial dynamics and EMT, we tested ARIH1 silencing in response to Doxorubicin (Dox), a DNA-damaging agent that induces oxidative stress, and saw improved sensitivity compared to WT MDA-MB-231 cells. Next, we assessed ARIH1 expression in the Dox-resistant cell line of our model, showing ARIH1 is upregulated in these cells at the transcript level, supporting the oxidative stress model. To further understand the crucial players impacting chemoresistance mechanisms in relation to this protein, we will test the contribution of downstream targets in response to chemotherapy. We hypothesize ARIH1's upregulation in response to oxidative stress and DNA-damaging treatment promotes cancer cell survival and enhances chemoresistance. This study expands on our novel discovery of ARIH1's role in EMT and cancer progression. The significance of ARIH1 in TNBC is highlighted in patient data, where high ARIH1 expression is correlated with worse patient survival.

#2636 Targeting the HGF/MET/TWIST1 pathway in lung adenocarcinoma brain metastases.

Xiaxuan Wu[1], Charitha Marni[2], Veronica Zhang[2], Prarthana Mocherla[1], Jacob George[1], Purva Rumde[1], Rohan K. Goyal[3], Lora H. Rigatti[2], Princey Devadassan[4], Autumn Gaither Davis[4], Timothy F. Burns[4], Laura P. Stabile[5]

[1]School of Medicine, University of Pittsburgh, Pittsburgh, PA,[2]UPMC Hillman Cancer Center, Pittsburgh, PA,[3]University of Pittsburgh, Pittsburgh, PA,[4]Department of Medicine, Division of Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA,[5]Department of Pharmacology & Chemical Biology, University of Pittsburgh, Pittsburgh, PA

Lung adenocarcinoma (LUAD) is the most common primary tumor to metastasize to the brain, with ~40% of patients developing brain metastases (BM) which is associated with poor prognosis. No brain specific targeted therapies currently exist, highlighting the need for novel treatments. We identified a significant enrichment of *MET* amplification in LUAD BM compared to primary LUAD and liver metastases. MET, a tyrosine kinase receptor, and its ligand hepatocyte growth factor (HGF), mediate proliferation, epithelial-mesenchymal transition (EMT), angiogenesis, and metastasis. We have found that MET-driven tumorigenesis is dependent on the EMT transcription factor, TWIST1, which is regulated by the HGF/MET pathway and is overexpressed in LUAD BM. These findings led us to hypothesize that the HGF/MET/TWIST1 axis is a potential therapeutic target for LUAD BM. To examine the role of the HGF/MET/TWIST1 pathway in LUAD BM, we utilized an *ex vivo* organotypic brain slice model. Using a patient derived LUAD cell line pair, H2073 (primary tumor, *MET* wildtype; WT) and H1993 (metastasis, *MET* amplified), we found increased brain colonization with the *MET* amplified H1993 cells. In addition, HGF promoted brain colonization of *MET* WT H2073 cells, while the MET inhibitor capmatinib reduced brain colonization of *MET* amplified H1993 cells. Similarly, using our murine syngeneic LUAD lines, FVBW-17 (MET WT) and FVB-HGF (HGF overexpression; OE), we found that HGF OE led to increased brain colonization. Additionally, conditioned medium (CM) from H1993 cells increased astrocyte migration compared to CM from *MET* WT H2073 cells. Capmatinib reduced H1993 CM-mediated astrocyte migration, while HGF induced H2073 CM-mediated astrocyte migration. Further, these HGF/MET driven processes appeared to be TWIST1 dependent as TWIST1 inhibition with harmine decreased brain colonization in both *MET* amplified H1993 and *MET* mutant H1437 cells, and inhibited astrocyte migration induced by CM from H1993. We next examined the role of the HGF/MET/TWIST1 pathway on BM *in vivo*. Using an intracardiac injection metastasis model, we observed a higher frequency of BM in HGF OE mice compared to WT SCID mice in all LUAD lines assessed. In WT SCID mice, time to BM development was significantly shorter in mice injected with *MET* amplified cells compared to *MET* WT cells. Further, BM was accelerated in HGF OE mice compared to WT mice injected with H2073 *MET* WT cells. In syngeneic LUAD models, 40% of mice injected with HGF OE cells developed BM versus 0% of mice injected with WT cells. Moreover, orthotopic intracranial injections showed a two-fold faster growth rate of HGF OE cells compared to WT cells. Finally, capmatinib or harmine treatment in mice with BM led to BM disappearance, with harmine showing a sustained effect lasting over three months after end of treatment. These findings suggest that targeting the HGF/MET/TWIST1 axis may be an effective treatment strategy for *MET* amplified LUAD BM.

#2637 Investigation of cell shape, focal adhesion, and cytoskeletal changes induced by SIAH inhibition in malignant human cancer cell lines.

Daniel J. McWilliams[1], Jonathan M. Baker[1], Amy H. Tang[1], Emanuel Petricoin[2], Julia Wulfkuhle[2], Andrew Howell[3]

[1]Old Dominion University, Norfolk, VA,[2]George Mason University, Fairfax, VA,[3]EVMS, Norfolk, VA

INTRODUCTION: SIAH is an evolutionarily conserved E3 ubiquitin ligase that plays an important gatekeeper role downstream of the tumor-driving EGFR/HER2/RAS pathway. SIAH expression is prognostic in human cancer, including pancreatic ductal adenocarcinoma (PDAC) and triple negative breast cancer (TNBC). Our lab has demonstrated that SIAH is a potent cancer target. Here, we found a novel molecular mechanism of how SIAH inhibition changes cell shape, focal adhesion, mechano-sensing, and cytoskeleton organization in SIAH-deficient cancer cells. In this study, we focus on validating and quantifying the changes of phospho-YAP, phospho-cofilin, and collagen I proteins in MDA-MB-468, MDA-MB-231, and MiaPaCa cancer cell lines.
METHODS: The reverse protein phase array (RPPA) technology in combination with immunofluorescence (IF), Flow, and western blots (WB) were used to determine the SIAH inhibitor-induced changes in phospho-YAP, phospho-cofilin, and collagen I proteins in human PDAC and TNBC cell lines. Triplicated RPPA assays were performed to quantify the altered expression of these phosphorylated proteins utilizing a nitrocellulose coated plate dotted with these pair-matched cell lysates with SIAH proficiency and deficiency in triplicates. We then performed WB/IF/FACS assays to verify the changes of these protein expression in the DOX (+/-) cancer cell lines independently.
RESULTS: We found that phospho-cofilin was upregulated, and phospho-YAP were downregulated in a few selected SIAH-deficient cancer cell lines as compared to their SIAH-proficient cancer cells. These molecular changes were consistent with the altered cellular shape, increased cell detachment, and altered cytoskeleton observed in the SIAH-mutant cells. Further investigations will be conducted to identify the crosstalk of the Hippo/Yap/Cofilin/Collagen signaling pathways with the EGFR/RAS/SIAH signaling pathway in human cancer cells.
CONCLUSION: Our results showed that SIAH deficiency altered the cell shape, adhesion, and cytoskeletal dynamics in malignant cancer cells. Increased phospho-cofilin expression suggested that SIAH inhibition may disrupt actin cytoskeleton organization, alter cell shape, decrease focal adhesion, increase cell detachment, and impede cell motility. The changes in the Hippo/YAP pathway indicate that the mechano-sensing pathway may be altered in SIAH mutant cells. These documented changes in the Hippo/YAP/Cofilin/Collagen Type 1 pathways may provide a novel mechanism to explain tumor suppression phenotype of SIAH-deficient cancer cells in xenograft mouse models.

#2638 Study of the effect of ribosomal protein L23 on the metastasis related protein of human osteosarcoma cell lines.

Chia-Hsuan Chou[1], Shun-Fa Yang[2]

[1]Department of Medical Research, Chung Shan Medical University Hospital, Taichung, Taiwan,[2]Institute of Medicine, Chung Shan Medical University, Taichung, Taiwan

Introduction: Lung metastases are the main cause of death and poor prognosis in patients with osteosarcoma. Its high propensity to metastasize is the leading cause for treatment failure and poor prognosis. Human ribosomal protein L23 (RPL23), a novel RBP, has been reported that involved in various physiological and pathological processes, including cell proliferation, cell apoptosis and cycle arrest. The higher expression of RPL23 is associated with the aggressiveness of the disease. However, the underlying functions and mechanisms of RPL23 in osteosarcoma metastasis has not been explored.
Material and methods: The GSE33382, GSE19276, and GSE 21257 database from Gene Expression Omnibus (GEO) were analyzed. Boyden chamber assay was used to evaluate the effects of cell migration and invasion. The FAM111B mRNA level and transcription activity were assessed by PCR, real-time PCR and luciferase reporter assay in osteosarcoma cells (U-2OS and HOS) after transfected with RPL23 siRNA.
Results: We found that RPL23 was upregulated in osteosarcoma tissues and its high expression was associated with poor prognosis in osteosarcoma patients. Using RNA-seq, microRNA-seq, and bioinformatic analysis, we revealed FAM111B and miR-30b-5p as downstream targets of RPL23. Knockdown of RPL23 significantly reduced the migration, invasion, and metastatic potential of osteosarcoma cell lines in vitro. However, these effects were reversed by the miR-30b-5p inhibitor.
Conclusions: RPL23 may be a novel osteosarcoma treatment strategy and a useful biomarker for predicting osteosarcoma progression.

#2639 Role of annexin A2 in triple-negative breast cancer metastasis.

P. Chaudhary;
University of North Texas Health Science Ctr., Fort Worth, TX

Introduction: Emerging evidence indicates that AnxA2 plays a role in the invasion and metastasis of breast cancer. However, the clinical significance of AnxA2 expression in breast cancer remains unknown.
Methods/Materials: The TNBC cells were purchased from the American Type Culture Collection (Manassas, VA). The expression of AnxA2 in cell lines, tumor tissues, and serum samples of breast cancer patients were analyzed by immunoblotting, immunohistochemistry, and enzyme-linked immunosorbent assay, respectively.
Results: We observed that AnxA2 was significantly elevated in the tumor tissues and serum samples of breast cancer patients compared to normal controls. High levels of serum AnxA2 were significantly correlated with tumor grade and poor survival in breast cancer patients. When we analyzed molecular subtypes, we found that AnxA2 expression was notably higher in the tumor tissues and serum samples of triple-negative breast cancer (TNBC) patients compared to those with other breast cancer subtypes. Our studies on breast cancer cell lines indicated that the secretion of AnxA2 is linked to its phosphorylation at tyrosine 23 (Tyr23). Additionally, phosphorylation of AnxA2 at Tyr23 facilitates its translocation to the cell surface in TNBC cell lines. The increased expression of AnxA2 on the cell surface enhances plasmin generation in these cell lines, and an inhibitory hexapeptide against AnxA2 can neutralize this activity. Furthermore, our analysis of AnxA2 phosphorylation in clinical samples confirmed that the phosphorylation at Tyr23 was significantly higher in the tumor tissues of TNBC patients when compared to matched adjacent non-tumorigenic breast tissues.
Conclusions: These findings suggest that serum AnxA2 concentration could be a potential diagnostic biomarker for TNBC patients.

#2640 Prevention of distant metastasis by disrupting the CTC-platelet interaction.

Lei Zhu[1], Nina Wang[1], Ting Jiang[1], Louisa Channon[1], Lena Lemmer[1], Dominic Helm[2], Sebastian Scholch[1]

[1]Translational Surgical Oncology, German Cancer Research Center, Heidelberg, Germany,[2]Proteomics Core Facility, German Cancer Research Center, Heidelberg, Germany

Circulating tumor cells (CTCs) are the primary mediators of hematogenous metastasis. During their journey in circulation, CTCs actively recruit platelets (PLTs) to form a protective cloak that facilitates immune evasion, enhances survival under shear stress, and promotes vascular adhesion and extravasation. We identified Neuraminidase 1 (NEU1) as a pivotal regulator of CTC-PLT interactions through its control of α2,6-sialylation, a critical post-translational protein modification that mediates PLT recruitment. We observed that diminished NEU1 expression in CTCs is associated with elevated sialylation, increased platelet cloaking, and poor prognosis in gastrointestinal cancer patients. This suggests that CTC sialylation drives PLT-mediated immune evasion and correlates with metastatic efficiency. Glycosylation profiling of CTCs from genetically engineered mouse models revealed a dynamic interplay in which NEU1 regulates α2,6-sialylation on the extracellular domains of glycoproteins. CRISPR-mediated knockout of NEU1 in tumor cells significantly enhanced sialylation, transendothelial migration, and metastatic seeding, whereas NEU1 overexpression suppressed platelet cloaking, inhibited CTC-PLT clustering, and reduced metastasis in vivo. NEU1 depletion increased metastatic efficiency, as evidenced by elevated proliferation of PLT-associated tumor cells in primary and metastatic tissues. Glycoproteomic analyses identified fibronectin 1 (FN1) as a potential NEU1-regulated, α2,6-sialylated target, further linking glycosylation changes to tumor progression. These findings establish a mechanistic connection between NEU1, CTC glycosylation, and PLT interactions, highlighting the functional significance of α2,6-sialylation in driving metastasis. To explore therapeutic potential, we investigate dual strategies targeting NEU1-mediated sialylation and CTC-PLT interactions. Preliminary experiments suggest that combining desialylation treatments with chemotherapy may effectively limit metastatic seeding by reducing CTC sialylation and disrupting PLT cloaking, thereby interfering with key steps of the metastatic cascade. Ongoing studies aim to validate these findings and assess their potential for clinical translation. Our findings underscore the central role of sialic acid metabolism in regulating CTC-PLT dynamics and establish NEU1 as a key regulator of this process. Unraveling how NEU1-mediated sialylation drives platelet cloaking and metastasis, this work opens avenues for novel therapeutic interventions to disrupt CTC-driven dissemination, thus reducing the metastatic burden and improving outcomes in cancer patients.

#2641 Glycosyltransferases at the helm of organ specific metastasis of pancreatic ductal adenocarcinoma.

Venkatesh Varadharaj, Frank Leon, Nivedeta Krishna Kumar, Palanisamy Nallasamy, Wyatt D. Petersen, Zahraa Wajih I. Alsafwani, Annant Bir Kaur, Kirtana Arikath, Sanchita Rauth, Saravanakumar Marimuthu, Surinder K. Batra, Moorthy P. Ponnusamy

Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE

Background: Pancreatic cancer (PC) deaths, incident cases, and disability-adjusted life-years globally have more than doubled from 1990 to 2017 with five-year survival rate of less than 14%, a trend likely to persist with population aging. The most common cause of mortality in pancreatic cancer patients is the metastasis of neoplastic cells to vital organs like the lungs and liver, and patients develop an inoperable condition due to late diagnosis. Malignant transformation of cancer cells is associated mainly with altered tumor-cell glycosylation at the cell surface. The expression of glycosyltransferases (GTs) is instrumental in modulating the cellular phenotype and promoting cancer cell survival at the metastatic niche. Specifically, we found that upregulation of (glucosaminyl (N-acetyl) transferase 3) GCNT3 and (beta-1,3-N-acetylglucosaminyltransferase 3) B3GNT3 expression are key mediators in altering glycosylation patterns in PC cells and enhancing the metastatic proclivity towards the liver and lung, respectively.
Methodology: We utilized two different metastatic models to replicate key aspects necessary to study the lung and liver-specific metastasis of PC. The RT^2 PCR array was used to analyze the global gene expression of GTs between primary PC cells and lung/liver metastatic models. Further, qPCR, ddPCR, and western blot techniques were used to confirm the differential expression of GTs at RNA and protein levels. Immunohistochemistry and Immunofluorescence experiments on the matched human primary and metastatic PC tissues validated the higher expression of specific GTs in the metastatic PC tissues when compared to the primary tumor.
Results: An unbiased transcriptional screen revealed a reciprocal >2-fold increase in GCNT3 and B3GNT3 expression in the liver and lung metastatic cell lines, respectively. Further, qPCR, dd-PCR, and western blot results confirmed the same expression pattern in liver and lung-specific metastatic cells compared to the PC controls. These results were further validated in human tissue from the same patient's primary pancreatic tumor and metastatic lung and liver tissues collected through the UNMC Rapid Autopsy program (UNMC-RAP).
Conclusion: Our data suggest that a clonal population of PC cells that highly express GCNT3 and B3GNT3 plays a pivotal role in reshaping glycosylation profiles, thereby augmenting their tendency for liver and lung-specific metastasis, respectively. This study highlights the critical correlation between glycosylation and organ-specific metastasis in PC.

#2642 High expression of N-acetyl transferase 9 in cholangiocarcinoma and its possible role in tumor progression.

T. Hoteit, H. P. Jones, P. Chaudhary;
The University of North Texas Health Science Center at Fort Worth, Texas Coll+, Fort Worth, TX

Cholangiocarcinoma (CCA) is a rare and aggressive subtype of liver cancer known for its limited number of biomarkers and its resistance to anticancer drugs, leading to difficulty in its early detection. The five-year survival rate for CCA varies between 2% and 24%, depending on factors such as the severity of the cancer, the presence of metastasis, and the timing of diagnosis. Currently, surgery is the most effective treatment option, but only under certain criteria, such as early cancer detection and absence of metastasis. N-terminal acetylation is an epigenetic modification that plays an important role in the regulation of cellular growth and function. This process is modulated by the enzyme N-acetyl transferase (NAT), which is involved in various functions, such as protein stability, membrane targeting, gene silencing, and drug resistance. These functions can regulate cell cycle progression, cell proliferation, and energy metabolism, all of which are key characteristics of cancer. NAT9, a subset of NATs, has abundant transcripts in breast, ovarian, and endometrial cancers; however, its role and expression in CCA have not been studied. In this study, we aimed to assess the expression, role, and function of NAT9 in CCA progression and metastasis using cell lines and patient tissue samples. According to The Cancer Genome Atlas (TCGA) database, NAT9 is overexpressed in patients with CCA, and its expression increases with the increase in the grade of CCA. NAT9 was also overexpressed in CCA cell lines and patient tissue samples compared to their normal and non-cancerous counterparts at both RNA and protein levels. In vitro, NAT9 knockdown experiments showed that NAT9 plays a role in CCA cellular proliferation and migration. These findings suggest that NAT9 plays a critical role in the development and progression of CCA.

#2644 Investigating major vault protein promoting migration and its clinical relevance in oral squamous cell carcinoma.

Sheng-Yen Hsiao[1], Shu-Fang Sun[1], Yuh-Ling Chen[2], Tse-Ming Hong[3]

[1]Hemato-oncology, Chi Mei Medical Center, Liouying, Tainan, Taiwan,[2]Institute of Oral Medicine, College of Medicine, National Cheng Kung University, Tainan, Taiwan,[3]Hemato-oncology, Institute of Clinical Medicine, College of Medicine, National Cheng Kung University, Tainan, Taiwan

Introduction: Head and neck squamous cell carcinoma (HNSCC), particularly oral squamous cell carcinoma (OSCC), has emerged as a significant health concern in Taiwan. It is the sixth leading cause of cancer-related death in the country, posing major challenges to public health and healthcare systems. The limited treatment options for unresectable or metastatic HNSCC highlight the need for new therapeutic targets. Several studies have reported that major vault protein (MVP), the primary component of ribonucleoprotein particles known as vaults, plays a role in regulating drug resistance in cancer therapy. However, the effect of MVP on OSCC progression remains largely unknown. In this study, we investigated the mechanisms through which MVP contributes to OSCC progression and its impact on clinical outcomes.

Materials and Methods: The migration ability of OSCC cells was assessed using wound-healing assays, two-chamber transwell invasion assays, and cell mobility tracking. Cisplatin resistance was evaluated using WST-1 cytotoxicity assays. Western blotting (WB), qRT-PCR, and RNA sequencing (RNA-seq) were conducted to explore potential mechanisms. Immunohistochemical (IHC) staining was used to determine MVP expression in OSCC tissues.

Results: Analysis of the TCGA dataset showed that HNSCC patients with high MVP expression had lower overall survival rates. OSCC cells with MVP knockdown exhibited reduced migration ability, while cells with MVP overexpression demonstrated increased migration capacity compared to control cells in wound-healing, two-chamber transwell invasion assays, and cell mobility tracking. MVP knockdown in OSCC cells led to increased cisplatin sensitivity, whereas MVP overexpression resulted in cisplatin resistance, as demonstrated by WST-1 cytotoxicity assays. RNA sequencing data suggested that MVP may regulate cell differentiation, EGFR signaling, and cisplatin resistance, as indicated by GSEA analysis. Additionally, GO enrichment analysis suggested that MVP may influence the PI3K-AKT signaling pathway, focal adhesion, and ECM-receptor interaction. Western blotting assays confirmed that MVP overexpression in OSCC cells activated the PI3K-AKT-mTOR pathway. Furthermore, HNSCC patients with higher MVP expression levels or IHC H-scores were more likely to experience poorer recurrence-free survival.

Conclusion: MVP may serve as a promising marker influencing clinical outcomes in HNSCC by regulating the PI3K-AKT-mTOR signaling pathway. Further validation of its clinical application is warranted.

#2645 Rnd3 depletion in lung cancer cell lines decreases cell invasion and migration in a ROCK1 independent manner.

Noemi Garcia Garcia[1], **Thanh Ha Vy Nguyen**[1], Dane Richey[1], Cody Ashby[2], Analiz Rodriguez[3], Katie R. Ryan[1]

[1]Biochemistry and Molecular Biology, University of Arkansas for Medical Sciences, Little Rock, AR,[2]Biomedical Informatics, University of Arkansas for Medical Sciences, Little Rock, AR,[3]Neurosurgery, University of Arkansas for Medical Sciences, Little Rock, AR

The purpose of this study is to investigate how altered expression levels of the small Rho GTPase, Rnd3, affects lung cancer cells. Lung cancer is among the most common and deadliest forms of cancer in the US. Most lung cancers metastasize, with lung to brain metastasis being the number one killer of lung cancer patients. Studying mechanisms that drive metastatic potential is key to unlocking new strategies for the treatment of this deadly form of cancer. Our focus for this study is Rnd3, an atypical GTPases, which has roles in regulating proliferation and cell migration in other cancer types. Our analysis of The Cancer Genome Atlas data predicts that lung adenocarcinoma patients with low levels of Rnd3 have significant higher survival rate. We investigated the role of Rnd3 by depleting its expression in the lung adenocarcinoma cell line (A549), and also patient-derived lung to brain metastasis (PDLBM) cell lines (601 and 620) as a proxy for advance disease. We observed no significant difference in cell viability or cell cycle progression between Rnd3-depeled and control groups. We did observe a significant effect on cell invasion and migration, Rnd3 depletion significantly decreases cell invasion and migration across all three tested cell lines. Previous studies on Rnd3 in melanoma cells found that Rnd3 signals via the RhoA-ROCK1 pathway, which impacts cell adhesion and the actin cytoskeleton, ultimately regulating cell invasion. However, when we either chemically inhibited ROCK1 or knocked down ROCK1 expression in our lung adenocarcinoma and PDLBM cells, it did not rescue the invasive phenotype. Our findings indicate that Rnd3 regulates cell invasion and migration, two hallmarks of metastasis, in lung cancer via a distinct pathway, independently from ROCK1. Identifying this novel mechanism will provide crucial insights for developing treatment for lung cancer metastasis.

#2646 Ankrd1 enhances lamellipodia formation and cell motility in clear cell renal cell carcinoma.

Hiromi Ito, Yuki Takai, Sei Naito, Takafumi Narisawa, Norihiko Tsuchiya

Urology, Yamagata University, Yamagata, Japan

Introduction: Clear cell renal cell carcinoma (ccRCC) displays more mesenchymal traits compared to other cancers. These traits include mesenchymal motility, which involves membrane protrusions like lamellipodia formed by actin polymerization. Ankyrin repeat domain 1 (Ankrd1) is regulated by YAP and ERK5, and contains structures that facilitate protein-protein interaction. Ankrd1 has been linked to epithelial-mesenchymal transition (EMT), cancer progression, and drug resistance in various cancers. However, its role in ccRCC remains unexplored. This study investigates Ankrd1 expression, regulation, and function in ccRCC.
Methods: We analyzed Ankrd1 expression using the TCGA database and tissue samples via immunohistochemistry. Regulation of Ankrd1 was examined by observing its response to YAP inhibitor and ERK5 inhibitors. Functional studies included siRNA, MTS assay, cell invasion assay, Western blotting, and immunofluorescence imaging.
Results: High Ankrd1 expression correlated with poor prognosis of ccRCC patients in TCGA cohort. In tissue samples, metastatic tissues showed higher Ankrd1 levels compared to primary tissues in the same patients. YAP regulated Ankrd1 in all ccRCC cell lines, while ERK5 influenced expression in some ccRCC cell lines. Ankrd1 silencing reduced cell viability under low-density conditions, where YAP activity is prominent. Ankrd1 silencing decreased cell motility, whereas overexpression enhanced motility without altering EMT-related protein levels. Ankrd1 co-localized with F-actin in lamellipodia stimulated by TPA. Ankrd1 silencing altered cell shape and reduced lamellipodia formation. Ankrd1 also interacted and co-located in lamellipodia with Talin-1. Ankrd1 depletion repressed activation of integrin pathway by Talin-1.
Conclusion: Ankrd1 is critical for lamellipodia formation and cell motility in ccRCC.

#2647 Essential roles of CRK and CRKL in glioblastoma cell migration and invasion.

Piyanka Hettiarachchi, Neka Large, Taeju Park

Children's Mercy Research Institute, Kansas City, MO

The dysregulation of CT10 regulator of kinase (CRK) and CRK-like (CRKL) expression has been implicated in various human cancers, notably glioblastoma, in which their elevated levels are associated with poor prognosis. Although CRK and CRKL have been proposed as therapeutic targets for invasive cancers, the mechanism underlying the contribution of CRK and CRKL to tumorigenesis was unclear. Previously, we induced transient knockdown of CRK, CRKL, or both in the U-118MG human glioblastoma cell line and demonstrated the requirement of CRK and CRKL for glioblastoma cell migration and invasion. CRKL knockdown induced cell shrinkage and inhibited cell proliferation, adhesion, and invasion, while CRK knockdown exhibited little or modest inhibitory effects. Combined knockdown of both CRK and CRKL knockdown resulted in pronounced morphological alterations and a complete inhibition of cell migration and invasion, highlighting their overlapping roles. To establish this finding as a generally accepted proof of principle for various glioblastoma cells and prepare mutant glioblastoma cell lines for orthotopic xenograft mouse models, we induced transient and stable knockdown of CRK/CRKL in LN-229 and U-87MG glioblastoma cell lines, which are proven to form tumors with high efficacy upon orthotopic transplantation. The gene knockdown of CRK and CRKL using siRNAs demonstrated substantial decreases in CRK and CRKL protein levels in LN-229 cells, as confirmed by Western blot analyses. We utilized the xCELLigence real-time cell analysis system to analyze the effects of CRK/CRKL knockdown on cell migration, adhesion, and invasion. CRKL knockdown caused modest inhibition of cell proliferation and substantial inhibition of cell adhesion, migration, and invasion. CRK/CRKL double knockdown resulted in pronounced morphological alterations, more robust inhibition of proliferation, and complete inhibition of cell adhesion, migration, and invasion. Stable knockdown of CRK and CRKL using lentiviral infection of shRNAs showed similar results. The results suggest similar responses of both U-118MG and LN-229 cells to CRK and CRKL knockdown. The similar and consistent outcomes between the two glioblastoma cell lines underscore the critical requirement of CRK and CRKL in glioblastoma cell migration and invasion. In addition to testing the cellular functions of CRK/CRKL in U-87MG cells, we plan to transplant the glioblastoma cells with stable knockdown of CRK/CRKL to immunodeficient mouse brains and study the requirement of CRK and CRKL for *in vivo* tumor formation and diffuse invasion of glioblastoma into surrounding brain tissues. These *in vitro* and *in vivo* studies will establish CRK and CRKL as therapeutic targets for blocking diffuse invasion of glioblastoma in the brain.

#2648 ZFP36L2 orchestrates stress adaptive plasticity during injury repair and metastasis.

Qingwen Jiang, Manisha Raghavan, Britney Forsyth, Aileen Rodriguez, Cyrus Tam, Sasha Balkaran, Saskia Hartner, Morgan Lallo, Ahmed Mahmoud, Andrew Moorman, Jura Pintar, Dana Pe'er, Richard Koche, Quaid Morris, Joe Chan, Karuna Ganesh

Memorial Sloan Kettering Cancer Center, New York, NY

Phenotypic plasticity is emerging as a key hallmark of cancer progression, yet the molecular mechanisms of cancer cell reprogramming remain poorly understood. Using single cell RNA sequencing of synchronously surgically resected matched trios of normal colon, primary and metastatic tumors from colorectal cancer (CRC) patients, we recently demonstrated that CRC undergoes highly conserved sequential phenotypic transitions during tumor progression: (1) differentiated epithelial cells dedifferentiate into an LGR5+ intestinal stem cell (ISC) state during primary tumor initiation (2) disseminating cancer cells adopt an injury-induced fetal-like state and (3) at the metastatic site again dedifferentiate into LGR5+ ISC states, or alternatively undergo lineage plasticity into non-canonical neuroendocrine and squamous states, associated with aggressive behavior and poor clinical outcomes. Cancer cells thus dedifferentiate into LGR5+ ISC states at two steps during tumor progression. Seeking regulators of dedifferentiation, computational analysis identified the RNA binding protein ZFP36L2 as a stress-associated ISC state marker in normal intestinal crypts and in primary and metastatic tumors. In mouse models, we demonstrate that ZFP36L2 is dispensable for intestinal homeostasis, but is required for epithelial regeneration after DSS induced colitis or ISC ablation. Using human tissue samples, organoids and orthotopic mouse models, we show that loss of ZFP36L2 impairs progenitor regeneration and metastatic seeding—both of which require dedifferentiation into an intestinal stem cell state—while promoting proliferation and lineage plasticity into non-canonical states. Multiplex immunofluorescence staining of clinical samples demonstrates that loss of function mutations in ZFP36L2, found in 5-10% of human CRC, are associated with non-canonical differentiation in metastasis. Mechanistically, using HyperTRIBE and mRNA decay analysis, we show that ZFP36L2 binds to stress-associated mRNAs containing AU-rich 3’UTRs, in turn inducing the formation of dynamic phase-separated biomolecular condensates. Unexpectedly, IP-MS identifies the intestinal differentiation transcription factor CDX2, and the NCOR nuclear corepressor complex as lead ZFP36L2 interactors. Nuclear/cytoplasmic fractionation and super resolution live cell microscopy demonstrate that while ZFP36L2 is largely cytoplasmic, it can shuttle into the nucleus, where it induces transcriptional repression of the intestinal differentiation program through CDX2-NCOR complex formation and chromatin compaction. Together, our work identifies ZFP36L2 as a key orchestrator of stress-induced phenotypic plasticity, driving cellular dedifferentiation and epigenetic reprogramming essential for re-establishing the ISC state during metastatic seeding and wound healing.

#2649 Defining how Rnd3, a novel regulator of breast cancer invasion, affects the metastatic potential of triple-negative breast cancer.

Noemi Garcia Garcia, Thanh Ha Vy Nguyen, Dane Richey, Katie R. Ryan

Department of Biochemistry & Molecular Biology, University of Arkansas for Medical Sciences, Little Rock, AR

The purpose of this study is to investigate whether the atypical Rho GTPase, Rnd3, affects triple-negative breast cancer (TNBC) cells metastatic potential (invasion and migration rates). One of the most dangerous attributes of cancer is its ability to metastasize and spread. The 5-year survival rate for localized breast cancer is 90%. However, this drops to 29% when breast cancer metastasizes. Identifying key regulatory proteins and signaling pathways involved in cell migration and invasion, two hallmarks of metastasis, will pave the way to potential therapeutic targets for reducing the metastatic potential of breast cancer. Rho GTPases regulate cellular processes that are commonly dysregulated in cancer with many studies focusing on what roles these proteins play in tumorigenesis. The expression level of the atypical Rho GTPase, Rnd3, rather than Rnd3 mutations, has been linked to cancer. High expression of Rnd3 increases cellular migration and invasion in several cancers, while depletion of Rnd3 decreases cellular proliferation and migration. How Rnd3 expression affects breast cancer progression is unknown. Here we assayed a panel of TNBC cell lines and assessed their migration and invasion potential, we observed a correlation of high Rnd3 expression and high cell migration and invasion rates. After knocking down Rnd3 expression in these cell lines we observed a significant reduction in cell invasion in MB-231, HCC1937, and MCF7 cells, and decreased cell migration in MB-231 cells. Rnd3 has been shown to regulate cell migration via the RhoA-ROCK1 pathway in melanoma. We were unable to rescue invasion rates in Rnd3 knockdown MB-231 cells following either chemical inhibition or knockdown of ROCK1, indicating Rnd3 is regulation cell invasion via a novel pathway in TNBC cells. Our findings indicate that Rnd3 regulates cell invasion and migration, two hallmarks of metastasis, in TNBC cells.

#2650 Inhibition of glucose uptake by targeting GLUT3 reduces cell invasion and metastasis of triple-negative breast cancer cells through modulating AMPK-mediated cell mechanics.

Aadil Qadir Bhat[1], Seeun Oh[2], Cristina V. Iancu[3], Jun-yong Choe[3], Dongjoon Lee[4], Donghoon Yoon[4], **Tae-Hyung Kim**[1]

[1]Pathology, University of New Mexico, Albuquerque, NM,[2]Molecular Genetics & Microbiology, University of New Mexico, Albuquerque, NM,[3]Chemistry, University of New Mexico, Albuquerque, NM,[4]Internal Medicine, University of Arkansas for Medical Sciences, Little Rock, AR

Obesity is accompanied by dysregulated metabolic functions including hyperglycemia, hyperinsulinemia, and hypertriglyceridemia. In clinics, obesity has been associated with increased breast cancer metastasis. Since cancer cells are highly dependent on aerobic glycolysis, called the Warburg effect, we hypothesized that the elevated extracellular glucose level that cancer cells experience with hyperglycemia in obesity promotes cancer metastasis.

The capacity of cancer cells to deform and exert contractile force, known as cell mechanics, plays a crucial role in various stages of metastasis. Our previous study demonstrated that elevated extracellular glucose levels boost glycolysis and activate the RhoA signaling pathway in human triple-negative breast cancer (TNBC) cells, resulting in heightened cell stiffness and increased contractility. Such modified cell mechanics are associated with enhanced cell migration and invasion, consistent with other in vitro studies showing that high extracellular glucose levels promote cancer cell motility.

In the current study, we present our new findings indicating that inhibition of glucose transporter 3 (GLUT3) significantly diminishes the motility of TNBC cells, including human (MDA-MB-231) and mouse (EO771) TNBC cells. Mechanistic investigations reveal that inhibition of glucose uptake by targeting GLUT3 pharmacologically using GLUT3-selective inhibitor (G3iA) or genetically using GLUT3 knock-out cells reduces glucose uptake and glycolysis without affecting cell viability. Such reduced glycolysis activates 5' AMP-activated protein kinase (AMPK) and decreases total F-actin levels and non-muscle myosin II activity, which results in decreased cell stiffness. We further elucidated that the decreased F-actin level is mediated by actin regulators including VASP and cofilin. These changes are associated with a reduction in cell migration. To confirm the anti-metastatic effects of GLUT3 inhibition in vivo, we developed two obese-TNBC mouse models using diet-induced obesity (DIO) strategy in NSG mice and C57BL/6J mice with orthotopic implantation of human and mouse TNBC cells, respectively. GLUT3 deficient MDA-MB-231 cells showed significantly reduced lung metastasis compared to wild-type MDA-MB-231 cells.

In summary, our results suggest that inhibiting GLUT3 modifies the mechanics of TNBC cells, leading to a decrease in cell motility and metastasis. Given that GLUT3 is notably elevated in TNBC and is linked to metastatic progression and a poor prognosis in breast cancer patients, our findings underscore the need for further in vivo studies to validate G3iA as a potential anti-metastatic drug in obese TNBC patients.

#2651 Nuclear prothymosin α suppresses TGF-β-induced EMT by stabilizing smad7: implications for lung cancer progression and metastasis.

Bing-Hua Su, Li-Hsin Cheng

Taipei Medical University, Taipei, Taiwan

Elevated expression of prothymosin α (ProTα), a 12.5-kDa acidic protein encoded by the PTMA gene, is frequently observed in cancers, including lung cancer, where it correlates with poor prognosis. Although ProTα is primarily localized to the nucleus, advanced-stage tumors exhibit its translocation to the cytoplasm, indicating a potential involvement in disease progression. In this study, we aim to elucidate the molecular mechanisms by which nuclear ProTα regulates epithelial-to-mesenchymal transition (EMT) and metastasis in lung cancer. Our findings demonstrate that nuclear ProTα suppresses TGF-β-induced EMT by enhancing Smad7 acetylation and stability. This acetylation disrupts the binding of Smad2 to the promoters of EMT transcription factors SNAI1, TWIST1, and ZEB1, thereby reducing their expression. Conversely, the loss of nuclear ProTα resulting from caspase-3-mediated cleavage of its nuclear localization signal (NLS) enables cytoplasmic translocation, associated with increased metastatic potential. Moreover, the use of mutant Smad7 constructs confirmed that the inhibitory effect of ProTα on EMT is dependent on Smad7 acetylation. Our clinical analyses of lung cancer specimens demonstrate that high nuclear ProTα levels are prevalent in early-stage tumors, while metastatic cases exhibit significant nuclear ProTα loss. These observations identify nuclear ProTα as a potential biomarker for tumor progression and a suppressor of lung cancer metastasis through TGF-β signaling interruption. In conclusion, this study underscores the importance of nuclear ProTα in lung cancer progression and highlights its potential as a prognostic indicator and therapeutic target for metastasis prevention. Further research into ProTα-targeted therapies could open new avenues in cancer treatment.

#2652 Glucose-transporter 1 (GLUT1) is highly expressed in many tumor types and often linked to tumor progression.

Seyma Buyucek[1], Katharina Moller[1], Florian Viehweger[1], Ria Schlichter[1], Anne Menz[1], Andreas M Luebke[1], Viktor Reiswich[1], Martina Kluth[1], Claudia Hube-Magg[1], Elena Bady[1], Lisa Hornsteiner[1], Andrea Hinsch[1], Florian Lutz[1], Soren Weidemann[1], Frank Jacobsen[1], **Maximilian Lennartz**[1], David Dum[1], Christian Bernreuther[1], Patrik Lebok[1], Guido Sauter[1], Andreas H Marx[2], Ronald Simon[1], Christoph Fraune[1], Natalia Gorbokon[1], Eike Burandt[1], Sarah Minner[1], Stefan Steurer[1], Till Olchers[3], Sonke von der Weihe[3], Martin Reck[3], Till S Clauditz[1], Till Krech[1], Viktoria Chirico[1]

[1]University Medical Center Hamburg-Eppendorf, Hamburg, Germany,[2]Academic Hospital Fuerth, Fuerth, Germany,[3]German Center for Lung Research, Grosshansdorf, Germany

Glucose transporter 1 (GLUT1) is a key protein for transmembranous glucose uptake of cells which is often overexpressed in cancer. To better comprehend the prevalence and role of GLUT1 expression in different cancer types, a tissue microarray containing 14,966 samples from 134 different tumor entities was analyzed in this study. GLUT1 expression was generally markedly higher in cancer than in corresponding normal tissues. A total of 122 of 134 tumor categories showed GLUT1 expression in at least one case, and 97 tumor categories included at least one case with strong GLUT1 staining. The frequency of GLUT1 positivity was particularly high in squamous cell carcinomas of various sites of origin (92.9%-100%), urothelial neoplasms (91.3%-98.7%), and carcinomas of the ovary and the endometrium (up to 100%). Elevated levels of GLUT1 staining were often associated with parameters of cancer aggressiveness. For example, high GLUT1 staining was associated with invasive growth of urothelial carcinomas ($p<0.0001$), high grade ($p=0.0015$), advanced pT stage ($p=0.0050$), and shorter survival ($p<0.0040$) in clear cell renal cell carcinoma, high grade ($p=0.0500$), advanced pT stage ($p=0.0460$), nodal ($p=0.0460$) and distant metastasis ($p=0.0022$), as well as shorter recurrence free survival ($p=0.0253$) in papillary renal cell carcinoma, high BRE grade in invasive breast cancer of no special type ($p<0.0001$), advanced pT stage ($p<0.0001$), nodal metastasis ($p<0.0001$), V1 status ($p=0.0005$), L1 status ($p<0.0001$), and mismatch repair protein (MMR) deficiency ($p=0.0378$) in colorectal adenocarcinoma, advanced pT stage ($p=0.0153$) and MMR deficiency ($p=0.0006$) in gastric cancer, advanced pT stage in pancreatic adenocarcinoma ($p=0.0068$), nodal metastasis in endometrioid carcinoma of the ovary ($p=0.0136$), advanced pT stage ($p=0.0305$), nodal metastasis and higher grade ($p<0.0001$ each) in lung adenocarcinomas, and with overall survival in non-small cell lung cancer (NSCLC, $p=0.0139$). It is concluded, that GLUT1 is highly expressed in a broad range of tumor entities, that it occurs more often in malignant than in benign tumors, and that it is linked to aggressive behavior in many different entities. These findings identify GLUT1 as a critical prognostic cancer marker, which may be clinically useful in many cancer types.

#2653 Non-muscle myosin II a role in breast cancer proliferation, invasion and metastasis.

Wasim Feroz[1], Sarah Storr[2], Andrew Stiles[3], Marykate Kilroy[1], Olamide Ogunleye[1], Joan T. Garrett[1]

[1]University of Cincinnati, Cincinnati, OH,[2]University of Nottingham, Nottingham, United Kingdom,[3]University of Notre Dame, Indiana, OH

We recently identified non-muscle myosin IIa (NMIIA) as a novel binding partner for HER3 in HER2+ breast cancer cells. This interaction was observed through HER3 immunoprecipitation experiments following inhibition of the HER family, compared to vehicle control treatments. NMIIA, a hexameric protein, is encoded by the Myosin heavy chain 9 (*MYH9*) gene, which provides the heavy chain necessary for its structure and function. NMIIA plays a critical role in cytoskeletal dynamics and cellular mechanotransduction, processes implicated in cancer progression and metastasis. To investigate the clinical significance of NMIIA, we analyzed its protein expression in early-stage invasive breast cancer samples using immunohistochemistry. Tumor samples were stained with an antibody against NMIIA and subsequently stratified into two groups: the lower 50% and the upper 50% based on NMIIA expression levels. This stratification was performed by a trained pathologist. Focusing on patients with lymphovascular invasion (LVI), we found that those with high NMIIA expression levels exhibited significantly worse disease-specific survival compared to patients with low NMIIA levels ($p = 0.010$). Interestingly, no difference in survival was observed among LVI-negative patients, regardless of NMIIA expression levels ($p = 0.948$). These findings underscore a potential interplay between NMIIA expression and tumor vasculature, suggesting NMIIA may contribute to tumor progression in the presence of LVI. Ongoing studies aim to determine whether NMIIA is more highly expressed in matched brain metastases of breast cancer compared to their primary tumors, mirroring a pattern previously reported for HER3. This research will help elucidate NMIIA's role in metastatic progression and its potential as a therapeutic target. Additionally, we are exploring whether NMIIA contributes to breast cancer development in a mechanically sensitive manner using a novel parent NMII inhibitor compound. This compound has already led to the development of a small molecule inhibitor that has entered clinical trials, highlighting the translational potential of targeting NMIIA. Our findings suggest NMIIA as a key player in HER3 signaling and tumor progression, particularly in the context of LVI, and provide a foundation for further research into its mechanistic and therapeutic implications.

#2654 MTAP deficiency is highly homogeneous in advanced, muscle-invasive urothelial carcinoma of the urinary bladder.

Natalia Gorbokon[1], Viktor Reiswich[1], Florian Lutz[1], Sebastian Dwertmann Rico[1], Henning Plage[2], Maximilian Lennartz[1], Margit Fisch[1], Sarah Minner[1], Elena Bady[1], Lisa Hornsteiner[1], Ronald Simon[1], Guido Sauter[1], Henrik Zecha[3], Stefan Steurer[1], Thorsten Schlomm[2], Lukas Bubendorf[4], David Horst[2], Thorsten Ecke[5], Stefan Koch[5], Martina Kluth[1], Florian Viehweger[1], Morton Freytag[1]

[1]University Medical Center Hamburg-Eppendorf, Hamburg, Germany,[2]Charite Berlin, Berlin, Germany,[3]Albertinen Hospital, Hamburg, Germany,[4]University Hospital Basel, Basel, Switzerland,[5]Helios Hospital Bad Saarow, Bad Saarow, Germany

Complete expression loss of S-methyl-5′-thioadenosine phosphorylase (*MTAP*) is caused by homozygous 9p21 deletion and results in a critical vulnerability of cancer cells towards drugs targeting multiple different pathways. MTAP deficiency is common in urothelial cancer, but data on its intratumoral heterogeneity - a potential obstacle for targeted therapies - are lacking. To study the heterogeneity of MTAP expression loss and 9p21 deletions in advanced primary urothelial cancers of the urinary bladder, a tissue microarray (TMA) was constructed from 5 different sites from different tissue blocks of 105 pT2-4 urothelial carcinomas and analyzed by immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH). In addition, all 1-15 tumor containing blocks (average 6.1) from 41 consecutive pT2-4 carcinomas were analyzed by IHC. Complete absence of MTAP staining (MTAP deficiency) was seen in 132 of 385 interpretable TMA samples. All 80 samples with a complete MTAP expression loss and FISH data had a homozygous 9p21 deletion while there were no cases with homozygous deletions within 148 samples with retained MTAP expression (100% FISH/IHC concordance). On a patient level, there was a homogeneous MTAP deficiency in 33%, a heterogeneous MTAP deficiency in 1% and a retained MTAP expression in 66% of these 98 tumors with at least 3 interpretable TMA samples. Among the 41 consecutive pT2-4 carcinomas from which whole sections were analyzed, MTAP was homogeneously deficient in 34%, heterogeneously deficient in 4.9% and homogeneously retained in 61%. It is concluded that MTAP deficiency is mostly homogeneous in advanced urothelial carcinoma. MTAP IHC is a near perfect surrogate for the detection of homozygous 9p21 (MTAP) deletions. Drugs targeting MTAP-deficiency could be highly useful in a relevant subset of invasive urothelial bladder cancers.

#2655 Novel stress-induced extracellular regulatory mechanism leads to decreased cellular invasion in prostate cancer.

Katelyn L. O'Neill, Johnny Zigmond, Raymond Bergan

University of Nebraska Medical Center, Omaha, NE

Background: Cancer cells are exposed to multiple stressors in their environment. The ability to overcome stress involves mechanisms that drive aggressive behavior such as cell motility and subsequent metastasis. Expression and secretion of HSP90α has been linked to many forms of cell stress and plays an important role in cancer cell migration and invasion. It's been shown to do so through co-chaperone mediated activation of extracellular proteases such as MMPs, which are responsible for degradation of the extracellular matrix allowing for cell migration/invasion. Yet how MMPs respond to cellular stress and subsequent levels of extracellular HSP90α is not well understood. We conducted a comprehensive evaluation of the above factors focusing on human prostate cancer (PCa).
Methods: Cell stress was induced in PCa cell lines via heat shock (43°C) and serum starvation (SS). Cell lysate and conditioned media (CM) were probed separately to examine intracellular vs. extracellular proteins by Western blot. MMP-2 activation was measured by zymography and gelatin dequenching assays. Cell invasion was measured using scratch wound and Matrigel drop assays. HSP90α knockout (KO) was performed in PC3 cells utilizing CRISPR-Cas9 transient transfection and verified by genomic sequencing and Western blot.
Results: We examined human PCa cells in vitro, demonstrating that under stress conditions (i.e., increased temperature and SS), cytosolic and extracellular HSP90α increased. In contrast to the findings of others, we demonstrate that this increase is associated with a decrease in MMP-2 activity. We went on to corroborate the functional relevance of MMP-2 decrease by demonstrating that CM from stressed cells decreased PCa cell invasion compared to media from non-stressed cells. Investigating further we found that decreased MMP-2 activity is mediated by processes dependent on extracellular protease/phosphatase activity. To examine the primary role of HSP90α in these processes, we created HSP90α KO PCa cells. KO cells exhibit normal proliferation and decreased invasion. We are currently using HSP90α KOs to investigate the direct role of extracellular HSP90α in stress-induced MMP-2 responses.
Conclusion: While others have examined separate components of this complex regulatory process, to our knowledge this is the first comprehensive evaluation integrating cell stress, the composition and function of secreted factors, how they are regulated and the resultant impact on PCa cell motility. Cell stress in all PCa cells tested led to increased expression and secretion of HSP90α. Surprisingly, this is associated with a decrease in MMP-2 activity. Decreased MMP-2 is due to a novel regulatory mechanism involving extracellular protease/phosphatase activity. HSP90α is involved in PCa cell invasion. We are currently testing its role in stress-related changes of MMP-2.

#2656 Sec23b governs the migration of MDA-MB-231 breast cancer cells by regulating collagen I processing and secretion..

E. Emily Joo[1], Audrey Astori[2], Jonathan St-Germain[2], Brian Raught[2], Michael F. Olson[1]

[1]Toronto Metropolitan University, Toronto, ON, Canada,[2]Princess Margaret Cancer Centre, University Health Network, Toronto, ON, Canada

Cancer metastasis is a complex, multi-step process that begins with the dissociation of primary cancer cells from their original site. These cells then migrate to distant areas, where they establish colonies and undergo uncontrolled proliferation at secondary locations. Thus, dysregulation of cell migration is one of the hallmarks of solid tumour metastasis. Given that the actin cytoskeleton plays crucial roles in normal cell migration, we developed a robust method that combines an amino acid sequence that binds to actin (LifeAct) with biotin-mediated proximal labelling (BioID) to identify actin-binding proteins. Specifically, to identify actin-associated protein complexes during the early stages of cells migrating into scratched areas, we conjugated LifeAct with the newest derivation of BioID (miniTurbo-LifeAct-BioID) and controlled its expression with doxycycline in MDA-MB-231 cells. After inducing cell migration by scratch wounding, we allowed cells to migrate into the scratched areas for 1.5 hours then pulse-labelled with biotin for 30 minutes. As controls, using the same system, we labelled actin-associated proteins in resting cells and in cells that had been treated with cytochalasin D (CD) to depolymerize actin filaments. Compared to the untreated cells, the CD-treated cells increased labelling of the G-actin binding proteins (e.g., profilin and JMY) while decreased labelling of the F-actin binding proteins (e.g., Coronin2A and ABLIM1/ABLIM2/ ABLIM3), validating the ability of miniTurbo-LifeAct-BioID to detect dynamic changes in cytoskeleton-associated protein complexes. By comparing miniTurbo-LifeAct-BioID labelled proteins in migrating versus stationary cells, eighteen proteins were significantly more biotin labelled and eight proteins were less biotin labelled. Unexpectedly, Sec23b, a component of the COPII secretion complex, was labelled to a greater extent in cells migrating into scratched areas. Depletion of Sec23b increased secretion of procollagen I but decreased deposition of collagen I filaments. Interestingly, the reduced migration of cells depleted of Sec23b was rescued by collagen I but not by fibronectin or gelatin. Based on our findings, metastatic breast cancer MDA-MB-231 cells appear to control the secretion and processing of collagen I to govern their extracellular matrix organization for efficient cell migration.

#2657 Impact of STRN4 knockdown on TNBC migration and survival.

Caroline Rinderle, Jordan Wright, Olivia Mayer, Bruce Bunnell

University of North Texas Health Science Ctr., Fort Worth, TX

Introduction: Striatin 4 (STRN4) is a member of the STRIPAK protein complex, including protein phosphatase 2A (PP2A) and other interacting protein kinases. These proteins interact to play a role in a range of signaling cascades, including MAPK and Hippo signaling. STRN4 has been shown to play a role in several cancer types, as it is a negative prognostic marker of renal, ovarian, and liver cancers. It has also been shown to contribute to liver cancer migration, and its knockdown diminishes pancreatic cell migration and proliferation. However, although STRN4 is associated with a trend of decreased overall survival in breast cancer patients, it is relatively understudied in the context of the disease.

Experimental Methods: To better understand the role of STRN4 in breast cancer survival and related processes, an siRNA-mediated knockdown of STRN4 was performed in a patient-derived xenograft-derived triple-negative breast cancer (TNBC) cell line: TU-BcX-4IC (4IC). Using three pre-validated siRNAs (A, B, and C) specific to STRN4 paired with a polymer-based transfection reagent, we knocked down the expression of STRN4. We then monitored the effects of the knockdown on 4IC cell migration and invasion, proliferation, metabolism, and gene expression via Boyden chamber migration assays, colony-forming unit assays, XTT assays, and qRT-PCR, respectively.

Results: STRN4 gene expression was significantly diminished 24 hours post-transfection, which was maintained 72 hours post-transfection. However, there was no significant difference in the migration of 4IC cells through a Boyden chamber, and only minor alterations in the expression of epithelial-to-mesenchymal transition markers E-cadherin, Vimentin, CD24, and Jagged1 24, 48 and 72 hours post-knockdown, despite significantly lower expression of STRN4 at these timepoints. However, there was substantially lower colony-forming unit potential and metabolic output in the C siRNA group despite there being no difference between the A and B siRNA groups.

Conclusions: Overall, STRN4 knockdown has minimal effects on TNBC cell migration and gene expression 24, 48, and 72 hours after the onset of diminished expression. While this may suggest that STRN4 is not as crucial to TNBC-related processes, much research remains. In the future, we plan to add additional cell lines to the knockdown experimental groups and monitor protein expression during STRN4 knockdown.

#2658 GATA2 loss promotes Piezo1 expression and stiffness-dependent invasion in uterine serous carcinoma.

Brittany Baikie, Mayuri Dutta, Pamela K. Kreeger, Daniel R. Matson

Pathology and Laboratory Medicine, University of Wisconsin-Madison, Madison, WI

Background: Piezo1 is a mechanosensitive ion channel that couples extracellular matrix (ECM) properties to intracellular signaling cascades that can modulate cell phenotypes. Piezo1 was recently shown to regulate metastasis in high-grade ovarian serous carcinoma (HGSOC) by promoting tumor budding in an ECM stiffness-dependent manner. Uterine serous carcinoma (USC) is an aggressive gynecologic malignancy that is increasing in incidence and responsible for 40% of uterine cancer deaths. USC rapidly invades and metastasizes via mechanisms that remain incompletely understood. Whether Piezo1 may have a similar function in USC, which shares many molecular and clinical features of HGSOC, is not known. We recently showed that expression of the transcription factor GATA2 is lost in USCs that locally invade into the wall of the uterus versus non-invasive USCs. However, the transcriptional targets of GATA2 that mediate this activity are not known.

Methods: We performed RNAseq in patient-derived USC cells lines after GATA2 depletion to identify differentially expressed genes. We performed anti-GATA2 ChIPseq in patient derived USC cells to identify genome wide sites of GATA2 occupancy. Western blots were performed for GATA2, Piezo1, and Tubulin after GATA2 depletion in patient-derived USC cells modified to express doxycycline-inducible anti-GATA2 shRNAs or shScramble control. *In vitro* models of ECM with different stiffnesses (3.7 and 14 kPa) were generated using an interpenetrating network of collagen I and methacrylated gelatin (GelMA), crosslinked within transwell inserts. USC cells were seeded on top of the gels and monitored over 24 hours for invasion in response to GATA2 depletion.

Results: GATA2 depletion led to an increase in *Piezo1* transcripts in patient-derived USC cells (log2fold change = 0.28, FDR<0.005), while western blot revealed a significant increase in Piezo1 protein expression after GATA2 depletion in two unique patient-derived USC cell lines. Anti-GATA2 ChIPseq identified two significant peaks of GATA2 occupancy within intron 1 of the *Piezo1* gene, each harboring conserved canonical *GATA* motifs. Depletion of GATA2 in patient-derived USC cells led to increased tumor cell invasion, but only on the stiffer substrates.

Conclusions: GATA2 binds two putative GATA enhancers within intron 1 of the *Piezo1* gene in USC. GATA2 depletion leads to increased Piezo1 RNA and protein expression, which is accompanied by increased tumor cell invasion in a stiffness-dependent manner. Our findings support a model where loss of GATA2-mediated Piezo1 suppression facilitates increased Piezo1 expression, and Piezo1-driven ECM stiffness-dependent USC tumor invasion. They justify further studies to evaluate whether a GATA2-Piezo1 axis is a critical driver of USC invasion *in vivo*.

#2659 Erythropoietin stimulation in BRAF mutated metastatic melanoma confers a highly proliferative and invasive phenotype.

Jayesh Menon[1], Raza Ahmed[2], Muneeb Aslam[3], Rakesh Singh[2], Philip Friedlander[4], Omar Aljitawi[2]

[1]University of Rochester School of Medicine, Rochester, NY,[2]Wilmot Cancer Center, Rochester, NY,[3]University of Rochester, Rochester, NY,[4]Icahn School of Medicine at Mount Sinai, New York City, NY

Introduction: Currently, there is a lack of understanding of the mechanisms underlying the progression of primary melanoma to a metastatic phenotype. Interestingly, RNA-sequencing data from the cancer genome atlas has demonstrated that patients with cutaneous melanoma with high expression of EPOR have poor long-term survival outcomes. This finding may be related to why some patients with anemia of malignancy treated with erythropoietin (EPO) have progression of their cancer. There has been significant discussion on this topic and whether membrane-bound EPOR is functional in solid malignancies. Here we report on how modulation of EPOR affects melanoma cell proliferation and invasion in an in-vitro model of metastatic disease.

Methods: A metastatic melanoma cell line, SK-MEL1, with mutant BRAFV600E was treated with varying doses of EPO and a novel EPOR inhibitor, URV3, for 24 hours. Cell proliferation was quantified by determining absolute cell number using a hemocytometer. Further, an invasion assay was utilized to assess the effect of EPOR modulation on cell invasiveness. ~50,000 cells were seeded into 1:5 diluted Matrigel overlaying a porous membrane and allowed to invade for 24 hours. After 24 hours, Matrigel was removed from the membrane and cells were fixed, stained, and imaged in 4 different positions. Invaded cells were quantified by averaging the cell density in each imaged field (cells/micrometer^2) and multiplying by total membrane area. All data were performed in duplicates and reported as mean fold change from control. Non-parametric ANOVA was used for statistical analysis.

Results: Modulation of EPOR with EPO, 8uM URV3, 8uM URV with EPO, 32uM URV3, and 32uM URV3 with EPO yielded a mean fold change in cell number over control of 1.43 (95% CI: 1.09-1.78), 0.89 (95% CI: 0.56-1.24), 1.38 (95% CI: 0.95-1.81), 0.88 (95% CI: 0.46-1.30), and 1.59 (95% CI: 1.15-2.04), respectively (p=0.0027). Cell invasion after 24 hours of treatment with EPO, 8uM URV3, 8uM URV with EPO, 32uM URV3, and 32uM URV3 with EPO yielded a mean fold change in cell invasion over control of 1.96 (95% CI: -0.80-4.71), 0.59 (95% CI: -4.82-5.99), 0.48 (95% CI: 0.03-0.92), 0.48 (95% CI:-1.22-2.19), and 0.60 (95% CI: -1.22-3.96) respectively (p=0.059).

Discussion: We demonstrate that direct EPOR stimulation causes increased cell proliferation and invasion. EPOR blockade with URV3 impedes cell growth; however, it is unable to overcome the proliferative effect of additional EPO stimulation. Interestingly, URV3 demonstrates a strong inhibitory effect on melanoma cell invasion despite EPO stimulation. These results illustrate the functional capabilities of the cell-surface bound EPOR receptor in metastatic melanoma and warrant further investigation of downstream signaling that contributes to this invasive and proliferative phenotype.

TUMOR BIOLOGY: Microenvironment-Driven Cancer Evolution
Poster Session

#2663 Mapping clonal heterogeneity and stromal dynamics in prostate cancer.

Sandy Figiel[1], Mengxiao He[2], Wencheng Yin[1], Emmanouela Perisynaki[2], Renuka Teague[1], Thineskrishna Anbarasan[1], Eleanor O'Roberts[2], Nithesh Ranasinha[1], Sophia M. Abusamra[1], Trishna Desai[3], Dimitrios Doultsinos[1], Andrew Erickson[1], Srinivasa Rao[1], Clare Verrill[1], Richard Colling[1], Pelvender Gill[1], Tuomas Mirtti[4], Ibrahim Kulac[5], Karl Smith-Byrne[3], Ruth Travis[3], Charlotte Stadler[2], Richard J. Bryant[1], Freddie C. Hamdy[1], Dan J. Woodcock[1], Ian G. Mills[1], Joakim Lundeberg[2], Alastair D. Lamb[1]

[1]Nuffield Department of Surgical Sciences, University of Oxford, Oxford, United Kingdom,[2]Science for Life Laboratory, KTH Royal Institute of Technology, Solna, Sweden,[3]Cancer Epidemiology Unit, Oxford Population Health, University of Oxford, Oxford, United Kingdom,[4]Department of Pathology, University of Helsinki & Helsinki University Hospital, Helsinki, Finland,[5]Department of Pathology, Koc University School of Medicine, Istanbul, Turkey

Introduction: Prostate cancer (PCa) exhibits significant intratumoral heterogeneity, driving a spectrum of phenotypes ranging from indolent disease to aggressive metastasis, challenging risk stratification and treatment. A key feature of this heterogeneity is clonal diversity, encompassing both cancer cells and their interactions with the surrounding stromal microenvironment. Understanding clonal dynamics and stromal influences on tumor progression is crucial for identifying factors that contribute to metastasis and disease lethality, ultimately improving risk stratification and therapeutic strategies.

Methods: We performed organ-wide spatial transcriptomic analyses (Visium^{TM} v2, 10x Genomics) on formalin-fixed paraffin-embedded tissues from ten patients with primary, nodal metastatic PCa and biopsy samples, recruited to a local trial (ISRCTN10046036). Two pathologists meticulously annotated each spot, including benign, Gleason grade, stroma, and immune cells. Fastq data were processed using SpaceRanger^{TM}, and inferred clonal genomic identities were analyzed with SpatialInferCNV (https://github.com/aerickso/SpatialInferCNV). We reconstructed clonal evolution using phylogenetic trees and analyzed stromal gene expression around distinct tumor clones using differential expression analyses. In addition, we performed multiplex imaging on consecutive sections to assess protein expression and correlate it with gene expression data, enabling the identification of key tumor-stroma interactions associated with metastatic progression.

Results: We analyzed 122 spatial transcriptomics capture areas, collectively representing over 1,000,000 spots (55 µm diameter), or approximately 16,000,000 cells. We identified clonal subtypes across biopsy, primary and metastatic tissues, revealing distinct clonal relationships and polyclonal lymph node colonization at different evolutionary stages. Stromal cells around metastatic progenitor clones showed upregulation of antigen presentation and inflammatory pathway genes, contrasting with stromal profiles surrounding lethal clones (as defined by their ability to metastasize to lymph nodes). These findings suggest a dynamic interplay between tumor cells and their stroma, potentially influencing metastatic potential and immune evasion.

Conclusion: This study provides a detailed cellular-level characterization of clonal heterogeneity in PCa and its relationship with stromal dynamics, offering insights into mechanisms driving metastatic progression. These insights could inform strategies for risk stratification and therapeutic intervention, including leveraging dual tumor-stromal profiles as biomarkers to distinguish lethal from indolent disease. Understanding the interplay between tumor clones and their stroma opens new avenues for targeted treatment approaches aimed at preventing metastasis and improving patient outcomes.

#2664 Spatial and single-cell transcriptomics reveal molecular heterogeneity in pulmonary pleomorphic carcinoma.

Atsushi Matsuoka[1], Kazuhiko Shien[2], Shuta Tomida[3], Hirofumi Inoue[3], Kazuya Hisamatsu[1], Ryota Fujiwara[1], Kousei Ishimura[1], Ryunosuke Fujii[1], Ryo Yoshichika[1], Tomoaki Higashihara[1], Naohiro Hayashi[1], Kazuhiro Okada[1], Fumiaki Mukohara[1], Mao Yoshikawa[1], Ken Suzawa[2], Hidetaka Yamamoto[4], Shinichi Toyooka[1]

[1]Thoracic, Breast and Endocrinological Surgery, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan,[2]Thoracic, Breast and Endocrinological Surgery, Okayama University Hospital, Okayama, Japan,[3]Center for Comprehensive Genomic Medicine, Okayama University Hospital, Okayama, Japan,[4]Pathology and Oncology, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan

Background: Pulmonary pleomorphic carcinoma (PPC) is a rare and aggressive subtype of non-small cell lung cancer characterized by the presence of both epithelial and sarcomatoid components. We conducted multi-omics analyses on surgically resected specimens from nine primary PPC cases to explore characteristics of this tumor at molecular level.
Materials and Methods: Whole-exome sequencing and RNA sequencing on bulk tumor specimens to identify mutational profiles. Spatial transcriptomics using the Digital Spatial Profiler was employed to analyze gene expression separately for epithelial and sarcomatoid tumor components. Single-cell RNA sequencing (scRNA-seq) was conducted on three cases to explore intratumoral heterogeneity and clonal evolution. Gene signature based on extracellular matrix (ECM) remodeling was developed and validated in public lung cancer datasets to assess its association with tumor aggressiveness and prognosis.
Results: Mutational analyses revealed *MET* exon 14 skipping in two cases and an *ALK-EML4* fusion in one case, while no *EGFR* mutations were observed. We found various differential expressed genes (DEGs) between components. Further analysis (GSEA and Transcriptional factor scoring) revealed there was a common enrichment trend observed among pathways related to MYC, such as those involved in cell proliferation, division, and the cell cycle. On the other hand, significant differences were observed in pathways related to cancer invasion and cell-cell interactions, such as extracellular matrix (ECM) remodeling and hypoxia. identified an atypical cell population bridging epithelial cells and fibroblasts, which we defined as sarcomatoid cells. The clusters defined as epithelial tumor cells and sarcomatoid cells showed upregulation of DEGs corresponding to the respective component identified through spatial transcriptomics. Trajectory analysis visualized tumor evolution, suggesting a transition from epithelial tumor cells to sarcomatoid cells. A consistent upregulation of seven ECM remodeling-related genes was observed in both tumor components compared to normal lung tissue. When applied to a GEO lung adenocarcinoma cohort, this gene signature was associated with more aggressive histological subtypes ($P < 0.01$). Survival analysis using TCGA demonstrated that high ECM remodeling signature scores correlated with significantly poorer prognosis ($P < 0.01$).
Conclusion: This study provides a comprehensive molecular analysis of PPC, revealing both shared and distinct features between its components. The trajectory analysis supports the hypothesis of a common cellular origin for these components and highlights the transition to a more aggressive sarcomatoid phenotype. These findings provide new insights into the biology of PPC and identify potential therapeutic targets to address its intratumoral heterogeneity and clonal evolution.

#2665 Single-cell analysis and cytokines modulation of intra-tumor subpopulations in colorectal cancer tumoroids.

Sabrina Johanna Fletcher[1], Irene Catalano[2], Elena Grassi[1], Sofia Borgato[1], Barbara Peracino[3], Luca Primo[1], Livio Trusolino[1], Andrea Bertotti[1], Alberto Puliafito[1]

[1]Department of Oncology, University of Turin, Candiolo, Italy,[2]Candiolo Cancer Institute, Candiolo, Italy,[3]Department of Clinical and Biological Sciences, San Luigi Hospital, University of Turin, Orbassano, Italy

Colorectal cancer (CRC) is still one of the most commonly diagnosed cancers worldwide. Treatment strategies include chemotherapy, radiotherapy, targeted therapy, and immunotherapy. Despite the availability of such a diverse set of therapeutic strategies, around a million people still die from this disease each year worldwide. Phenotypic intra-tumor heterogeneity, arising from both genetic and non-genetic origins, has become a significant focus of study due to its impact on treatment response. Among the various subpopulations within a tumor, the stem-like cells have been extensively investigated, as they are recognized as tumor initiators. In contrast, the subpopulations identified by the expression of genes associated with differentiation has received comparatively less attention. An interesting hypothesis is that differentiated populations might plastically give rise to stem cell populations fueling tumor regrowth. Here we examine phenotypic intra-tumor heterogeneity in patient-derived metastatic CRC (mCRC) tumoroids. Our goal was to decipher the unknown role of differentiated cells and to relate it to growth and therapeutic response. In particular, we sought to determine whether manipulating exogenously the proportions of differentiated cells within CRC tumoroids could alter the drug response. We analysed one KRAS wild type (wt) model and one mutant (*kras*) model by scRNAseq. Our data confirmed that tumoroids present two main subpopulations, one associated to stemness (with high expression of LGR5), and the other associated to differentiation genes (with high expression of KRT20), coherently with reported studies. First we identified two novel cell surface markers associated to the KRT20+ subpopulation: GABRA2 and GPRC5C. Using FACS, we confirmed that our models present a double-positive subpopulation at the protein level. RT-qPCR confirmed that the expression of both genes increased over time. We next studied the effect of different cytokines on the modulation of this subpopulation. We found that exogenously adding IL6 and TGF-b1 alters the proportion of our markers, with a stronger effect in the wt sample. For both models, ELISA assays did not indicate any significant secretion into the culture medium of these cytokines. Interestingly, we found a release of IL6 receptor (IL6R) in the medium, particularly from the wt sample, likely as a results of the previously characterized cleavage of its membrane-bound form. Furthermore, RT-qPCR showed that TGF-b1 induced its own expression, a phenomenon known as autoinduction. Our preliminary results using the wt sample indicate that pre-treatment with these cytokines affected the response to Oxaliplatin, making it more sensitive to the chemotherapeutic reagent. Overall, our results indicate that cytokines released in the tumor microenvironment might reshape the intra-tumor phenotypic heterogeneity impacting drug-response.

#2666 Mapping intratumoral heterogeneity in colorectal cancer: Spatially resolved subclones and tumor microenvironment.

YeonJu Lee[1], Woong-Yang Park[2]

[1]Sungkyunkwan Uiversity, Seoul, Korea, Republic of,[2]Samsung Genome Institute, Seoul, Korea, Republic of

Background: Colorectal cancer (CRC) is the third most common malignancy, with over 1.85 million new cases and 850,000 deaths annually. Significant intratumoral heterogeneity in CRC contributes to recurrence, chemotherapy resistance, and poor prognosis. This study aimed to explore the spatial distribution of subtype clones and the diversity of the tumor microenvironment (TME), which are not captured by the traditional gene expression-based CMS classification. Additionally, it sought to investigate cancer trajectories and their contributions to metastatic phenotypes using spatial transcriptomics (ST).
Methods: Spatial analysis was performed using public 10X Genomics Visium data from 4 CRC and 4 CRC-liver metastasis (CRC-LM) patients (GSE226997, GSE217414). Cell-type deconvolution utilized single-cell RNA-seq datasets (GSE178318, GSE132465). Copy number alterations (CNA) were inferred, and subclone development trajectories were modeled using inferCNV, DPT, and PAGA analyses. Pathway and functional enrichment analyses, expression score calculations, and correlation analyses were conducted using ClusterProfiler, AddModuleScore, and statistical methods. A Wilcoxon test with an adjusted p-value < 0.05 was used to determine statistical significance.
Results: Distinct CRC and CRC-LM subclones were identified through CNA inference, revealing spatially segregated CNA clusters. These included malignant subclones and boundary-associated clusters, characterized by varying proportions of differentiation and mesenchymal traits. Immune-related signaling pathways demonstrated differential activation, with increased MAPK, JAK-STAT, and TNFα-NFκB in specific regions and elevated WNT, VEGF signaling, MYC, and E2F4 in others. Certain subclones also showed enrichment of SPP1+ macrophages and myofibroblasts, indicating diverse invasive characteristics. Evolutionary trajectories of subclones, inferred through hierarchical trees, revealed CSC features and a common ancestral clone. Progression toward malignancy was associated with enhanced pathway activity linked to critical biological processes. In CRC-LM, subclones were categorized by TAM subtypes, with one subtype displaying significantly elevated SPP1 expression compared to primary CRC. Immune-related features were reduced in metastatic tissues, reflecting a less immunogenic TME.
Conclusion: Intratumoral heterogeneity in CRC evolves from a single common ancestral clone into distinct progression states, resulting in spatially unique TMEs. Understanding the interactions between clones across different progression states offers valuable insights into disease dynamics and therapeutic opportunities.

#2667 Full spectrum profiling flow cytometry to study cancer-associated fibroblast heterogeneity.

Kevin Munoz Forti, Marta Storl-Desmond, Daniel Martinez, Sayana Issac, Shan Cao, Simon Schworer

Medicine, Section of Hematology and Oncology, The University of Chicago, Chicago, IL

It is now well appreciated that tumor growth depends on the tumor microenvironment (TME) comprising various non-malignant stromal cell types, including cancer-associated fibroblasts (CAFs). Cancer-associated fibroblasts (CAFs) are responsible for secreting the extracellular matrix (ECM) prominent in certain solid tumors such as pancreatic adenocarcinoma (PDAC). Despite our increasing knowledge of CAFs, therapeutic targeting of CAFs is currently not a feasible strategy, as CAFs are highly heterogeneous and extremely plastic, with each CAF population able to adopt both tumor-promoting and -restraining functions. We hypothesize that the plasticity and functional heterogeneity of CAFs can be explained by their flexible metabolism in response to environmental cues and the existence of discrete metabolic states within CAF subpopulations. While metabolic states can be predicted from single-cell transcriptomic data, this does not provide information on metabolic activity and potential, nor does it allow perturbations required for validation. Scalable and tractable methods to assess metabolic activity and CAF heterogeneity in parallel at the single cell level are needed to distinguish numerous existing CAF states do not exist. To address this need, in this work, we developed a strategy to study CAF metabolic activity and phenotypic heterogeneity at the single-cell level. We designed and optimized a 25-plex immunophenotyping panel of CAF and fibroblast markers that can be combined with numerous metabolic probes via Full Spectrum Profiling (FSP) flow cytometry. In addition, we compiled an analysis pipeline to facilitate the analysis of high-dimensional flow cytometry data. Using established 2D and 3D mono- and co-culture assays, we demonstrate the potential of our panel to be multiplexed with chemical probes for cell proliferation, lipid content, lipid uptake, fatty acid oxidation, glucose uptake, cholesterol content, hypoxia, or mitochondrial potential. Deploying our strategy in a KPC organoid-derived murine model of PDAC, we observed subpopulations of CAFs with differing metabolic potentials that are consistent with our predictions from transcriptomic metabolic modeling. With the high throughput and single-cell nature of FSP, our strategy represents a novel and modular tool for studying CAF phenotypic and metabolic heterogeneity.

#2668 Spatial-temporal diversity of extrachromosomal DNA shapes urothelial carcinoma evolution and tumor-immune microenvironment.

Extrachromosomal DNA (ecDNA) presents a promising target for cancer therapy; however, its spatial-temporal diversity and influence on tumor evolution and the immune microenvironment remain largely unclear. Here, we apply computational methods to detect and reconstruct ecDNA from whole-genome sequencing data from 595 patients prospectively recruited into the Chinese Urothelial Carcinoma Genome Atlas (CUGA) study. We demonstrate that ecDNA contributes to clonal evolution through structural rearrangements and copy number variation during malignant transformation and recurrence of urothelial carcinoma (UC). This supports a model wherein tumors evolve via the selective expansion of ecDNA-bearing cells. Through multi-regional sampling of tumors, we demonstrate ubiquitous ecDNA presence across clones in multi-focal cancers, directly linking ecDNA to the evolution of multifocality. Notably, we observe highly variable levels of ecDNA across multiple foci within the same tumor, and ecDNA contributes to increased intratumoral heterogeneity and serves as a substrate for natural selection and evolution. EcDNA is present in 36% of UC tumors and correlates with an unstable cancer genome, an immunosuppressive phenotype, and significantly reduced 5-year survival. Single-cell RNA sequencing analyses reveal that ecDNA$^+$ malignant cells exhibit diminished expression of major histocompatibility complex class I molecules, enabling them to evade T-cell mediated immune responses. Finally, we show that sequencing of urinary sediment-derived DNA has excellent specificity in detecting ecDNA, underscoring its diagnostic potential. This study delineates the evolutionary trajectory of ecDNA during tumor progression and provides further insights into immune evasion mechanisms associated with ecDNA.

#2669 Solid tumor microenvironments cause more mutations than liquid or soft tumor microenvironments -- even before selection.

Dennis E. Discher, Markus Sprenger

University of Pennsylvania, Philadelphia, PA

Sequencing of many types of tumors shows that solid tumors are far more mutated than liquid tumors and soft tumors such as brain tumors, but it is unclear whether the differences are caused by induction of more mutations or subsequent selective pressures. Our pan-cancer analyses of clinical data shows increased chromosomal changes associate with collagen-I and further shows that genetic variance between patients also increases with the mean for a given tumor type. Using a 3D hydrogel-based model with tunable stiffness and of cancer spheroids, we discover that matrix stiffness increases mitotic aberrations including micronuclei and also increases chromosome loss as detected using live cell chromosome reporters (ChReporters). However, stiffness suppresses growth and size variation, which indicates more mistakes per division. Our approach is >10-fold more sensitive than sequencing approaches, and we quantify colonies of ChReporter-negative cells within cancer spheroids. Our results are consistent with Luria-Delbruck's theory of heritable genetic changes which predicts inter-spheroid variance greatly exceeds Poisson statistics. Knockdown of myosin-II, a well-known mechanosensor, increases chromosomal loss and variance without affecting spheroid growth, consistent with a tumor suppressor role. Various drug strategies provide deeper insight into mechanisms, and use of clinically deployed CDK4/6-inhibitor reveals this drug on its own drives micronuclei formation and genetic variation.

#2670 Understanding cell-of-origin influence on cancer-associated fibroblasts in lung adenocarcinoma.

Minxiao Yang[1], Tawfeeq Al-Mansur[2], Chunli Yan[1], Zea Borok[3], Crystal Marconett[2]

[1]Department of Surgery, Keck School of Medicine, USC - University of Southern California, Los Angeles, CA,[2]Department of Integrative Translational Sciences, Beckman Research Institute of City of Hope, Los Angeles, CA,[3]Division of Pulmonary, Critical Care and Sleep Medicine, Department of Medicine, University of California San Diego, San Diego, CA

Lung cancer remains the top cause of cancer mortality worldwide, with lung adenocarcinoma (LUAD) representing the most common and heterogeneous subtype of non-small cell lung cancer (NSCLC). This heterogeneity lies in cell of origin, histological presentation, therapeutic response and clinical outcome, posing challenges for precision in diagnosis, prognosis and effective therapeutics. Our previous research in mouse models determined that GRAM domain containing-2 (Gramd2)-positive alveolar epithelial type 1 (AT1) cells can give rise to LUAD, exhibiting histological, cellular and molecular characteristics that are distinct from LUAD derived from surfactant-secreting type 2 (AT2) cells, which are a widely regarded cell of origin for LUAD. Additionally, we recently leveraged single-nucleus RNA sequencing (snRNA-seq) to dissect the composition of the tumor microenvironment (TME) of the *Gramd2*$^+$ AT1 cell-derived LUAD and *Sftpc*$^+$ AT2 cell-derived LUAD, demonstrating a distinct immune landscape of LUAD based on cell-of-origin. Significantly, immunosuppressive myeloid cells, such as myeloid-derived suppressor cells (MDSCs) and tumor-associated macrophages (TAMs), dominated the TME of *Sftpc*$^+$ AT2 cell-derived LUAD, whereas immunoreactive macrophages and pro-inflammatory monocytes were highly enriched in *Gramd2*$^+$ AT1 cell-derived LUAD. These findings may partly answer why only a subset of LUAD patients respond to immunotherapy. However, the role of mesenchymal cells in the TME and how they influence LUAD progression are unknown. To address this, snRNA-seq data of cancer-associated fibroblasts (CAF/M) cells from both cell of origin models was analyzed. We identified a distinct *Lcn2*$^+$, *Mmp2*$^+$, *Cxcl14*$^+$ CAF/M cell population specifically enriched in *Sftpc*$^+$ AT2-derived LUAD TME. These CAF/M cells exhibited upregulated mitochondrial activity, oxidative phosphorylation, and extracellular matrix remodeling, supporting tumor development and invasion. In contrast, fibroblasts in the TME of *Gramd2*$^+$ AT1-derived LUAD showed elevated RNA processing, mRNA metabolism, and DNA damage repair. To further investigate the aberrations of cancer cells, we employed InferCNV, an R package to infer genomic alterations associated with cancer, to analyze large-scale copy number variations (CNVs) of LUAD cells between two models. The results reveal significantly higher CNV scores in *Sftpc*$^+$ AT2-LUAD compared to *Gramd2*$^+$ AT1-LUAD, suggesting a more pronounced genomic instability and an aggressive tumor phenotype. These significant variations may interact with CAF/M cells and thereby impact survival outcomes. This study demonstrates that it is critical to stratify properties of the LUAD TME and establish how LUAD evolves based on cell-of-origin, yielding knowledge for elucidating LUAD heterogeneity and consequently boost development of precision medicine strategies in the clinic.

#2671 Divergent evolutionary trajectories of the molecular subtypes of breast cancer are driven by differential selection and selective epistasis.

Jessica Liu[1], **Krishna Dasari**[2], Nicholas Fisk[3], Carolyn Kravitz[4], Lajos Pusztai[5], Jeffrey Townsend[2]

[1]Yale University, New Haven, CT,[2]Biostatistics, Yale School of Public Health, New Haven, CT,[3]Computational Biology, The University of Rhode Island, South Kingstown, RI,[4]Pathology, Yale School of Medicine, New Haven, CT,[5]Medical Oncology, Yale School of Medicine, New Haven, CT

The molecular subtypes of breast cancer—defined by estrogen-receptor, progesterone-receptor, and human epidermal growth factor receptor status—have established differences in mutational profiles, prognoses, and response to standard treatments. However, the evolutionary trajectories underlying these differences are not well understood. Knowledge of these differential trajectories would empower predictive modeling of treatment benefit. To characterize these trajectories, we first aggregated a multi-institutional cohort of 23,247 breast cancer patients with whole exome or targeted sequencing data, including from AACR Project GENIE. We then calculated variant-specific background mutation rates, and subsequently quantified the selective benefit of known and potential driver mutations across breast cancers and within each subtype. We then assessed how the selective benefit of such mutations changed throughout cancer progression and due to the epistatic influence of prior mutations. Finally, we confirmed the ordering of mutational acquisition determined by epistasis by performing phylogenetic reconstruction of the evolution of ten breast cancers.

In a subtype-agnostic analysis, we found that PIK3CA H1047R and H1047L, SF3B1 K700E, and multiple TP53 variants experienced the strongest selection. Interestingly, the selective benefit of mutations to oncogenesis varied between subtypes: the PIK3CA H1047R variant experienced maximal selection in the Luminal A subtype, while the TP53 I195T variant experienced maximal selection in TNBC. Additionally, we found that PIK3CA E542K experienced significantly higher selection in the Luminal A and B subtypes than the TNBC subtype. These mutations also experienced differential selection throughout cancer progression: PIK3CA and CDH1 variants were under stronger selection during early carcinogenesis, whereas TP53, ERBB2, and multiple other variants experienced stronger selection in late stage cancer. These differences in subtype- and stage-specific selection are partially explained by asymmetric synergistic and antagonistic epistatic interactions between mutations in PIK3CA, TP53, AKT1, CDH1, and other driver genes, which create preferential mutation orderings and combinations. These analyses enable inference of subtype-specific tumor evolutionary trajectories with quantitative measures of the selective benefit of mutations across molecular contexts and stages of cancer progression. Such measures are useful for predicting response to targeted therapeutics and therefore facilitate the development and testing of targeted therapies—and the optimization of current regimens—for the molecular subtypes of breast cancer.

#2672 Eco-evolutionary profiling of the UV-driven clonal dynamics and tumor initiation.

Stanislav S. Avdieiev[1], Leticia Tordesillas[1], Karol Prieto[1], Omar Chavez Chiang[1], Zhihua Chen[1], Nihir Patel[2], Sofia Cordero[1], Luiza Silva Simoes[1], Y. Ann Chen[1], Noemi Andor[1], Robert A. Gatenby[1], Elsa R. Flores[1], Christopher J. Whelan[1], Joel S. Brown[1], Kenneth Y. Tsai[1]

[1]Moffitt Cancer Center, Tampa, FL,[2]Admera Health, South Plainfield, NJ

Classically, cancer initiation is attributed to a sequential acquisition of discrete genetic events such as driver mutations. However, homeostatically-stable tissues, including skin, harbor numerous somatic mutations spread across the tissue's clones. Yet, most of these clones never give rise to cancer. Using the model of UV-driven cuSCC, we tested our hypothesis that cancer initiation occurs in three phases: 1) tissue disruption and the emergence of unusually large "goliath" clades (ecological driver), 2) clonal selection within a subset of goliaths as evidenced by the presence of cell density hotspots and higher mutational burden (evolutionary driver), and 3) emergence of macroscopic lesions. We tracked these tissue level drivers via *in-vivo* serial imaging and 3-D reconstruction of fluorescently labeled keratinocyte clades, yielding 25,085 clades from 14 mice over 3 months, and 14,525 clades from 4 of these mice over 6 months. While median and mean clade sizes differed little across UV exposure, our ecological survey revealed the emergence of large goliath clades (> cc. 4.2×10^6 μm^3) observed essentially only within UV-exposed skin and occupying the extreme tail of the distribution of clade sizes. Goliath clades arose as serpentine structures, intercalating between adjacent keratinocytes, some with areas of unusually high local densities ("micro-lumps"). Targeted DNA sequencing of goliath revealed *Kmt2a, Kmt2d, Prex2,* and *SCN11A* as the most mutated genes. Giant clades do not typically possess common driver mutations of SCC, e.g. *TP53* and *NOTCH,* and display two extremes of mutational profiles, with some goliaths having dominant clones (VAF >0.75), and others having no discernable clonal structure (VAF <0.025), demonstrating that strong mutational drivers are not a prerequisite for developing goliaths. scRNAseq analysis of both bulk skin and sorted clades revealed upregulation of the fraction of cycling basal-like cells, and downregulation of Alox12e-expressing granular cells, along with increased proportions of plasmacytoid dendritic cells (pDC) and CD4+ regulatory T-cells (Tregs) in UV-exposed samples, reflecting early epidermal de-differentiation and immunosuppression. By month 7, mutational burdens were significantly larger in goliath clades, particularly for those with micro-lumps. Finally, lesions emerged between months 6 and 7, only in UV-exposed skin. Based on our adaptation of the Drake equation, we conclude that the probability of observing macroscopic lesions arising in 2 of the 21 randomly sampled goliaths we followed for 3 months to be less than 10^{-7}. Taken together, our results support the interplay between cell autonomous and non-cell autonomous compartments during cancer initiation, the earliest phase of which *presage* the acquisition of driver mutations. Our data constitute an unprecedented look at clonal dynamics in UV exposed skin defining the transition from normal tissue to tumor.

#2673 Tumor heterogeneity and stemness can be shaped by mechano-structural parameters in osteosarcoma.

Zunaira Shoaib[1], Aleczandria S. Tiffany[2], Brendan Harley[2], Joseph Irudayaraj[3], Timothy M. Fan[4]

[1]University of Illinois at Urbana-Champaign, Urbana, IL,[2]Chemical and Biomolecular Engineering, University of Illinois at Urbana-Champaign, Champaign, IL,[3]Bioengineering, University of Illinois at Urbana-Champaign, Champaign, IL,[4]Pathobiology, University of Illinois at Urbana-Champaign, Urbana, IL

The aim of the study was to identify factors in the physical tumor microenvironment that might participate in Osteosarcoma Cancer Stem-like Cells (OS-CSC) development, which might underlie chemoresistance and recurrence of OS. It was hypothesized that within an OS tumor, spatial localized niches possessing distinct microenvironmental structural and mechanical properties could favor the genesis and survival of different OS cell populations, and certain niches might be more conducive for OS-CSCs formation and maintenance. Mineralized and porous collagen scaffolds mimicking heterogenous bone niches were fabricated by changing crosslinking and pore alignment and their distinct structural and mechanical properties were determined using electron microscopy, Atomic Force Microscopy (AFM) and compression tests. The 3D scaffolds were cultured with highly metastatic human OS cell lines and were assessed for cytoskeletal changes, cell stiffness, epigenetic pathways, chemoresistance and chemoresistance-related pathways, and the differential expression of stemness genes. A consistent trend of OS-CSC phenotype was observed in OS cells grown within softer bone niches (~10 kPa) with aligned pores as compared to niches with non-aligned pores and increased stiffness (~30 kPa). The cell population growing in softer, aligned scaffolds had significantly higher expression of stemness genes (OCT4, NANOG, SOX2, ALDH1A1) and drug efflux gene ABCB1 along with increased chemoresistance to doxorubicin and cisplatin, and gave rise to larger colonies in soft agar. Epigenetic modifications associated with cisplatin resistance in OS including decreased methyltransferase EZH2 and concurrent upregulation of LIF/Notch and PRKCA pathways were observed in softer, aligned niche cultures. Fluorescent imaging of scaffold cultures and AFM measurements showed rounder, softer cells in soft, aligned niches indicative of a CSC phenotype, and stretched, elongated, stiffer cells in the non-aligned, stiffer niche with higher YAP nuclear localization, indicative of a differentiated phenotype. RNA Sequencing showed differential expression of 87 genes between scaffold types, with enrichment in ECM-receptor interaction and PPAR signaling pathways; particularly interesting was the enhancement of stem cell reprogramming mediator RAD50 in aligned, soft cultures. In summary, our investigation demonstrates that both the mechanical and structural properties of bone niches influence the formation of distinct OS cell populations. A softer niche with an aligned structure is more conducive for maintaining OS-CSCs, and these findings could be translated to designing therapeutic strategies that modify the microarchitecture to potentially reduce CSC-favoring niches.

#2674 Cellular plasticity facilitates therapy resistance through enhancing adaptability.

Alicia Bjornberg[1], Xierali Aobuli[1], Matthew Froid[1], Rowan Barker-Clarke[2], Jeff Maltas[2], Jacob Scott[2], Berkley Gryder[3], David Bassanta[1], Alexander Anderson[1], Virginia Turati[4], Andriy Marusyk[1]

[1]H. Lee Moffitt Cancer Center, Tampa, FL,[2]Cleveland Clinic, Cleveland, OH,[3]Case Western Reserve University, Cleveland, OH,[4]Lund University, Lund, Sweden

In oncology, patients treated with targeted therapies often have strong and durable responses early in treatment; however, the development of resistance hinders long-term therapeutic benefit. A subset of tumor cells can develop resistance, often from both genetic and non-genetic mechanisms through gradual, multi-step resistance. Nonetheless, predicting which cells will evolve to become resistant, and strategies to suppress adaptability contributing to resistance remain unknown. While resistance may emerge in cells harboring driver mutations, the adaptation process necessitates substantial modifications to the phenotype facilitated by cellular plasticity. Therefore, plasticity serves as a crucial facilitator of resistance by enhancing adaptability, rather than functioning as a direct cause of resistance. We hypothesize that the direct selection for therapy resistance leads to indirect selection for enhanced plasticity. We propose that as treatment selects for drug-resistant phenotypes, concurrent selection for cells exhibiting greater adaptability occurs. Thus, enhanced plasticity is indirectly favored during selection for drug resistance. We have found strong support for this hypothesis through in silico modeling, with subsequent validation through functional assays. In our functional assays, we utilize the H3122 cell line derived from a patient with ALK+ non-small cell lung cancer (NSCLC) to model targeted therapy resistance. This well-studied model effectively mimics the initial responsiveness and subsequent resistance observed in clinical settings. Utilizing single-cell sorting and the expansion of clonal isolates from the parental H3122 population, we identified heterogeneity in the ability to adapt where subgroups exhibited a range of high adaptation potential (HAP) to low adaptation potential (LAP) based on their response to numerous independent stressors, including targeted ALK inhibitors. We have found that therapeutic stressors lead to selection of subpopulations with higher adaptability potential, enriching for a more lethal subgroup than the original tumor. HAP cells display increased multi-drug resistance and metastatic potential compared to LAP cells. HAP cells are significantly enriched in plasticity-related pathways overlapping with those found in cells that have developed strong resistance to ALK inhibitors. In subcutaneous tumor models, LAP cells show a 1,000-fold reduction in tumor burden, while HAP cells develop resistance. Our findings suggest that disrupting cellular adaptability can prevent resistance, maintaining cells in a therapy-sensitive state. This approach shifts the focus from killing tumor cells to blocking their ability to adapt, opening up a novel angle for overcoming resistance. Addressing adaptability reveals intervention points that conventional strategies might overlook, offering new, proactive strategies in cancer treatment.

#2675 Tumor clones display intrinsic and stable rates of progression and coordination of the tumor microenvironment in association with epithelial mesenchymal plasticity.

Timothy N. Trotter, Jason McBane, Xing Gao, Carina Dagotto, Tao Wang, H. Kim Lyerly, Zachary C. Hartman

Duke University, Durham, NC

Delayed relapse is attributable to residual tumor cells that remain minimally proliferative/quiescent until favorable conditions for growth are met, but what determines the overall duration of remission is unresolved. Recent evidence suggests that epithelial-mesenchymal plasticity (EMP) facilitates phenotypic switching between dormant and proliferative cell states, in addition to enabling chemoresistance, metastasis, and immune evasion. However, which features of EMP are responsible for each or multiple of these phenotypes, and to what extent EMP is restricted to certain tumor populations remains unclear. To address these questions, we initially enriched for features of EMP (CD44hi, CD104low) in the mouse mammary tumor cell line TSAE1. Interestingly, no difference in tumor growth was observed between parental or EMP-enriched mammary fat pad (MFP) tumors in either syngeneic Balb/c or immune-deficient SCID-beige mice. Individual tumors were then cultured ex vivo, revealing a significant EMP-enrichment in parental tumors after one round of selection in vivo. Similar results were observed in the mouse mammary cell line D2.OR, suggesting that implantation alone gives rise to EMP which may mask important tumor cell-intrinsic differences in a heterogeneous tumor. Thus, EMP-enriched TSAE1 cells were further divided by isolating nine clonal lines. Although each expressed less epithelial markers than parental cells (Epcam, E-cadherin), individual TSAE1 clones displayed remarkably divergent growth rates and patterns in 3D culture. In vivo all clones were capable of forming tumors, but some were significantly delayed regardless of being implanted into Balb/c or SCID-beige animals. Furthermore, individual clones recruited distinct immune and stromal populations. To assess if intrinsic phenotypes change over time, 3D culture assays and bulk RNA sequencing was performed on three representative clones before implantation (“Pre”) and on three Balb/c MFP-derived tumors expanded ex-vivo from each clone (“Post”). Surprisingly, for each clone the Post tumors closely resembled the Pre clone and much of the difference in up/downregulated genes between individual clones and parental TSAE1 cells was already found in Pre samples. Finally, MFP tumors from EMP-enriched TSAE1 clones were differently sensitive to Doxorubicin therapy, suggesting that specific aspects of EMP may be important during different stages of BC survival and progression. Together, these data reveal that proliferation itself is intrinsically determined at the clonal level, independent of adaptive immunity, and highlight the potential for individual tumor clones in various EMP states to shape the tumor microenvironment for long-term survival.

#2676 Single cell spatial profiling reveals ERBB2 and EGFR co-expression in primary esophageal adenocarcinoma and brain metastasis tumors.

Nora Lawson[1], Lingqun Ye[2], Chae Yun Cho[1], Bo Zhao[2], Thomas Mitchell[3], Ines Martin[1], Andy Futreal[2], Kadir Akdemir[1]

[1]Neurosurgery-Research, The University of Texas MD Anderson Cancer Center, Houston, TX,[2]Genomic Medicine, The University of Texas MD Anderson Cancer Center, Houston, TX,[3]Genetics, The University of Texas MD Anderson Cancer Center, Houston, TX

Esophageal adenocarcinoma is a prevalent and serious disease, ranking eighth globally, with a low survival rate of 15-25% and a rising incidence in the United States. However, the occurrence of brain metastasis in esophageal adenocarcinoma (EAC) is rare, affecting only approximately 2-6%. Despite its rarity, brain metastasis in EAC is associated with a poor prognosis, compounded by the limited availability of effective treatment options. Due to the infrequent occurrence of brain metastasis in EAC patients, our understanding of the tumor composition in these cases and how they differ from those in primary sites remains limited. To address these gaps, we analyzed the tumor microenvironment of brain metastasis tumors and their matched primary tumors using spatial transcriptomic data generated by the 10x Xenium Analyzer. By employing a brain tumor panel, an immune panel, and a custom panel, we characterized the tumor microenvironment, including neuronal and immune cell populations present in these samples. Overall, primary samples contained a higher proportion of immune cells such as macrophages, T cells, B cells, dendritic cells, plasma cells, and mast cells, compared to brain metastases, which had a greater composition of neuronal cells. We additionally investigated the oncogenic expression patterns at the single-cell level within these matched samples, revealing areas with high *ERBB2* and *EGFR* expression density within malignant cell populations. Notably, brain metastasis samples contained a higher proportion of malignant cells co-expressing *ERBB2* and *EGFR* than primary samples, suggesting clonal evolution during disease progression from primary to metastatic sites. Our findings indicate that *ERBB2* and *EGFR* amplifications may represent potential targets for therapeutic interventions in these patients. These findings enhance our understanding of brain metastasis in EAC, offering insights into the tumor microenvironment that may guide future therapeutic strategies and improve clinical management for this previously understudied metastatic type.

#2677 Multi-omics profiling identifies two epithelioid sarcoma molecular subtypes with distinct signaling and immune characteristics.

Carine Ngo[1], Leo Colmet-Daage[1], Julien Vibert[1], Clemence Henon[1], Riwan Brillet[1], Jia Xiang Jin[2], Daniel Pissaloux[3], **Clemence Astier**[1], Jean-Yves Blay[3], Axel Le Cesne[1], Charles Honore[1], Matthieu Faron[1], Thomas Grunewald[2], Franck Bourdeaut[4], Franck Tirode[3], Sophie Postel-Vinay[1]

[1]Institut Gustave Roussy, Villejuif, France,[2]DKFZ, Heidelberg, Germany,[3]Centre Leon Berard, Lyon, France,[4]Institut Curie, Paris, France

Background: Epithelioid sarcoma (EpS) is an aggressive sarcoma, characterized by the loss of SMARCB1 expression. EpS is traditionally classified as distal or proximal according to clinicopathological features, but its molecular bases remain largely unknown.
Methods: To establish an EpS molecular classification, we combined multiple bulk omics profiling approaches to systematically characterize the genomic, transcriptional and methylome landscapes of EpS. We further investigated inter- and intra-patient heterogeneity and explored molecular subtype-specific transcriptomic signatures, using single-cell RNA sequencing on fresh samples.
Results: We identified two molecular subtypes of EpS: “distal-like” and “proximal-like”. Distal-like tumors include all morphological distal subtypes and a subset of proximal and hybrid EpS. They express a specific single-cell derived epithelial-to-mesenchymal transition signature, which associates with improved patient survival and includes Desmoglein 2 (DSG2), which we identify as a potential routine immunohistochemichal biomarker to improve diagnosis. Distal-like EpS also display higher peri-tumoral CD8+ T cell infiltrates with specific tumor-immune cell interactions. Conversely, proximal-like EpS harbor a higher inter-tumoral molecular heterogeneity, with some cases resembling other SMARCB1-deficient tumors by DNA methylation profiling, and high intra-tumoral pro-tumoral macrophage infiltrates.
Conclusion: Our study introduces a novel molecular classification of EpS with prognostic value, potential diagnostic markers and distinct tumor immune microenvironments, that extends beyond traditional clinicopathological classification. These insights pave the way for more personalized and effective treatment strategies for patients with EpS.

#2679 Tumor heterogeneity in hepatocellular carcinoma demonstrates disruption in gap junctions and calcium signaling pathways.

Katherine M. Barrows[1], Jonathan M. Hernandez[1], Natalie Porat-Shliom[2]

[1]Surgical Oncology Program, NIH-NCI, Bethesda, MD,[2]Thoracic and GI Malignancies Branch, NIH-NCI, Bethesda, MD

Introduction: The liver is an innately heterogeneous organ responsible for diverse metabolic and biosynthetic functions, which are accomplished by regionalization of hepatocytes based on nutrient availability, oxygen tension, biochemical gradients, and intact local cell communication. When exposed to stress, however, hepatocytes forgo tissue heterogeneity and synchronize functions, which has been shown to occur through calcium transfer via gap junctions and the activation of downstream signaling. Not surprisingly, malignant tumors interfere with local homeostasis and disrupt gap junctions. However, the role of calcium dynamics and its regulation have not been examined in primary hepatocellular carcinoma (HCC).

Aim: Identify changes in gap junction and calcium signaling-dependent proteins in a murine model and samples from patients with HCC.

Methods: *Clinical Data Evaluation* Gene query in the TCGA database to determine the clinical correlation of alterations of gap junctions and calcium regulatory proteins in HCC.

Murine HCC Model Male mice aged between 8 and 12 weeks were administered a hydrodynamic injection of Sleeping Beauty plasmids containing mutant Beta-Catenin and Akt. After a time course to allow the development of microtumors, the mouse livers were fixed, cryo-preserved, and sectioned.

Human Tissue Liver tissue was procured from two human subjects undergoing hepatic resection. Both normal adjacent liver parenchyma and histologically confirmed HCC were fixed with 4% PFA, cryopreserved and sectioned.

Immunofluorescence Antibodies and staining for nucleus, actin, gap junctions, IP3R, for periportal regions and pericentral regions were used in immunofluorescence.

Results: On query of 30 genes that encode calcium regulatory proteins in the TCGA database between 30%-59.4% of 1075 cases of HCC had a genetic alteration as a mutation, copy number variance or change in expression.

Images of the gap junction protein immunofluorescence in both normal mouse and human tissues demonstrated an organized periportal signal. Mouse and human HCC tissue demonstrated cellular heterogeneity as well as variable and disorganized fluorescence intensity.

Discussion: Murine HCC models confirm comparable changes that occur to gap junction proteins in human HCC, offering a unique window of interrogation. Comparing changes in the expression of gap junction proteins and calcium signaling-related proteins over a time course in the development of HCC may provide insight into malignant transformation. The role of calcium signaling in the development of malignancies is understudied, may promote tumor heterogeneity and ultimately treatment resistance.

#2680 Volumetric analysis of spatial tumor phylogeny enabled by 3D pathology-guided macrodissection (3DPM).

H.-C. Hsieh[1], Q. Han[1], G. Gao[1], D. Brenes[1], E. Baraznenok[1], R. Serafin[1], K. W. Bishop[2], E. Q. Konnick[1], C. C. Pritchard[1], S. Figiel[3], F. C. Hamdy[3], I. G. Mills[3], L. D. True[1], M. C. Haffner[4], S. R. Rao[3], D. J. Woodcock[3], J. T. Liu[1];
[1]University of Washington, Seattle, WA, [2]Broad Institute, Boston, MA, [3]University of Oxford, Oxford, United Kingdom, [4]Fred Hutchinson Cancer Center, Seattle, WA

Current methods for studying tumor phylogeny primarily rely on manual macrodissection or laser capture microdissection of tumor regions identified in thin 2D histology sections. With the emergence of non-destructive 3D pathology workflows, the study of 3D spatial tumor phylogeny is proposed, whereby distinct tumor regions may be macrodissected based on 3D pathology datasets for downstream DNA sequencing and clonal reconstruction. The tumor phylogenetic tree can then be mapped into 3D space using the spatial locations of different subclones, providing an improved understanding of the spatial spread of tumors along their evolutionary paths. To implement the concept of 3D spatial tumor phylogeny, we are developing a 3D pathology-guided macrodissection (3DPM) system as an alternative to current techniques that are limited to thin 2D tissue sections. In our workflow, tissues stained with H&E-analog fluorescence dyes are first imaged using an open-top light sheet (OTLS) microscope. Based on 3D pathology datasets digitally false colored to mimic the appearance of H&E staining, regions of interest with distinct tumor morphologies are annotated by pathologists. The tissue specimen along with the digital annotations are then transferred to a co-registered 3D macrodissection system, which is based on a portable desktop five-axis CNC milling machine. For each volume of interest, the unwanted background tissue is first milled away from the top, followed by detachment of the volume through angled cuts. The toolpath is optimized to maximize the purity and volume of the dissected tissue. Large FFPE tissue slices from archived prostatectomies (centimeter-scale lateral dimensions and millimeter-scale axial dimensions) are being used for proof-of-concept demonstrations. First, we aim to show that the 3D macrodissection method can achieve high tumor purity comparable to laser capture microdissection, despite the increased challenge of dissecting 3D contours vs. 2D tissue regions. Second, we anticipate that more distinct subclones can be identified in each tumor region due to improved sampling of volumetric tissue regions with distinct morphologies (e.g. different Gleason patterns and sub-variants) in comparison to 2D thin-section dissection methods. Finally, given that prostate cancer is known to be multifocal and exhibits complex clonal expansion within the primary tumor, we aim to elucidate whether these multiclonal expansions are spatially separated, intermixed, or vary between cases using reconstructed 3D spatial phylogenetic trees. In summary, 3DPM aims to deepen our understanding of prostate cancer evolution and to enable many new directions in tumor phylogenetics research.

TUMOR BIOLOGY: Targeting the Tumor Microenvironment: A Brave New World
Poster Session

#2684 The iRGD tumor-penetrating peptide inhibits TGF-β activation mediated by an αvβ5 integrin-rich tumor microenvironment in pancreatic cancer.

Yukihito Kuroda[1], Kodai Suzuki[1], Yuki Kunisada[1], Hotatka Kawai[2], Henri Havia[3], Tero A. H. Jarvinen[3], Moriya Tsuji[4], Kazuki N. Sugahara[1]

[1]Department of Surgery, Columbia University, New York, NY,[2]Department of Oral pathology and Medicine, Okayama University, Okayama, Japan,[3]Faculty of Medicine and Health Technology, Tampere University & Tampere University Hospital, Tampere, Finland,[4]Department of Medicine, Columbia University Irving Medical Center, New York, NY

αvβ5 integrin is highly expressed in pancreatic ductal adenocarcinoma (PDAC) and predicts poor prognosis in PDAC patients. We previously showed that transforming growth factor-β (TGF-β) produced by cancer-associated fibroblasts and cancer epithelial cells induces the expression of αvβ5 integrin in PDAC, contributing to the αvβ5-rich tumor microenvironment (TME). Here, we show that the αvβ5 integrin is a critical activator of TGF-β in PDAC and that the iRGD tumor-penetrating peptide effectively inhibits the activation cascade causing a dynamic modification of the PDAC TME. TGF-β is secreted as a latent complex (LAP-TGF-β) and activated by various stimuli including receptor-dependent mechanisms. αv integrins potently activate TGF-β by binding to the RGD peptide motif within LAP-TGF-β to mechanically release active TGF-β from the complex. Our results show that the αvβ5 integrin is a major activator of TGF-β in PDAC cells because deleting the integrin significantly reduced TGF-β signaling and target gene expression despite the presence of other αv integrins on the cells. The iRGD peptide, which binds to αv integrins (and neuropilin-1) and delivers drugs deep into the tumor tissue, inhibited the integrin-mediated activation of TGF-β in the PDAC cells in an RGD-dependent manner. iRGD effectively inhibited TGF-β signaling *in vivo* evidenced by a dramatic suppression of phosphorylated Smad-2 in orthotopic tumors in syngeneic PDAC mice. Various changes in the TME accompanied the effect, such as reduced regulatory T cells, altered distribution of CD8+ T cells, normalization of blood vessels, and reduced stromal fibers. Similar results were obtained in humanized orthotopic PDAC mice that allow proper characterization of human immune response to tumor antigens. Adding an immune checkpoint blockade (ICB) to the iRGD monotherapy led to enhanced anti-tumor effects in both mouse models. Of note, iRGD, even as monotherapy, caused a striking inhibition of liver metastasis formation in humanized PDAC mice. Our findings suggest that PDAC has assembled a mechanism to maintain high levels of active TGF-β and αvβ5 integrin expression that likely contributes to its desmoplastic and drug resistant nature. iRGD interferes with the mechanism to cause dynamic TME modification and sensitization to ICB. The results justify the concept of the ongoing iLSTA clinical trial that studies the effect of iRGD-based immunotherapy in patients with locally advanced PDAC (ACTRN12623000223639).

#2685 Sensitizing mouse ovarian cancer tumors to immunotherapy.

Elizabeth Anne Allen, Justine Chen, Supreeti Tallapragada, Huyen Pham, Oliver Dorigo

Stanford University School of Medicine, Palo Alto, CA

Introduction: The overall survival of patients with advanced ovarian cancer (OC) is poor and clinical responses to immunotherapy are low, encouraging development of new strategies that sensitize ovarian cancer to immunotherapy. Many studies in OC and other cancers have linked the presence of intra-tumoral B cells, high endothelial venules (HEVs) and lymphoid aggregates that resemble tertiary lymphoid structures (TLSs) with improved prognosis and increased survival. In contrast to the favorable prognosis associated with the presence of TLS, high levels of immunosuppressive T regulatory cells (Tregs) in OC are associated with reduced survival.
Methods: Single, double, and triple combinations of a Treg depleting antibody, an HEV-inducing LTβR agonist antibody, and the anti-PD1 checkpoint inhibitor were tested in immune-competent C57Bl/6 mice inoculated intraperitoneally with homologous recombination defective (HRD) ID8 Trp53-/-Brca2-/- and HR proficient (HRP) ID8 Trp53-/- bioluminescent murine OC tumor models. Mono- and combination therapy was administered in fixed endpoint and survival studies and assessed for tumor burden, Treg depletion, HEV induction, lymphocyte infiltration, other changes to the tumor microenvironment, and overall survival.
Results: High numbers of Tregs were found in control tumors which were significantly reduced in arms which included the Treg depleting antibody along with significantly increased numbers of CD8+ T cells. HEVs were significantly more abundant in arms which included the LTβR agonist along with increased numbers of B cells and plasma cells. Clonal selection of T cells occurred in treated tumors, most notably with triple combination treatment. In fixed endpoint trials, tumor burden was significantly reduced and sometimes completely eradicated in combination arms that included the Treg depleting antibody. Median survival in mice bearing ID8 Trp53-/-Brca2-/- tumors was increased in triple combination tumors vs IgG (130 vs 57 days) with 5/13 animals that completely eradicated tumors and successfully rejected tumor rechallenges. Analogous studies using ID8 Trp53-/- tumor cells produced 7/7 mice without a detectable bioluminescent tumor signal after 75 days (ongoing) while the IgG group had a median survival of 50 days.
Conclusions: This study indicates that OC tumors in immune-competent mice can be sensitized to immunotherapy and potentially eradicated with checkpoint inhibition using a strategy that combines Treg depletion and/or HEV induction. Data generated in this study can provide the rationale for the design of a clinical trial in OC patients, possibly stratified by HR status, as a biomarker driven approach.

#2686 P2X4 purinergic receptor activation on macrophages inhibits phagocytosis and promotes tumor-promoting cytokine secretion.

Vahinipriya Manoharan, Kennedy M. Rains, Jillian K. Landers, Sharvari S. Saraf, Tristan R. Ibarra, Angelo M. De Marzo, David E. Sanin, Janielle P. Maynard

Johns Hopkins University School of Medicine, Baltimore, MD

Prostate cancer (PCa), the most frequent cancer and the second leading cause of cancer-related deaths among men in the U.S., necessitates improved therapeutic strategies. Our previous studies demonstrated elevated P2X4 purinergic receptor expression in PCa tissues, which correlated with poor prognoses. We found that P2X4 receptor knock down or blockade in PCa cells reduces subcutaneous allograft tumor growth *in vivo* and inhibits human PCa cell viability, migration, and invasion *in vitro.* However, the expression profile and functional role of the P2X4 receptor in the PCa tumor microenvironment (TME) remain poorly defined. This study aims to characterize P2X4 receptor expression and functional significance within the prostate TME. Multiplex immunohistochemistry (IHC) analyses revealed P2X4 receptor expression on $CD163^+$ M2 macrophages, but not in $CD8^+$ T cytotoxic cells, $CD4^+$ T helper cells and FAP^+ fibroblast cells in human PCa tissues. IHC performed on FVB mouse allograft primary and metastatic tumors also suggested P2X4 expression on $F4/80^+$ macrophages. Treatment of human THP-1-derived M2 macrophages with CTP (400 μM), a P2X4-specific agonist, significantly reduced phagocytosis *in vitro* ($p = 0.0115$). A human phospho-kinase array revealed that P2X4 activation decreased phosphorylation of AKT (S473) and p70S6 (Thr389), indicating a potential role in suppressing Fcγ receptor-mediated phagocytosis through the PI3K > AKT > mTORC1 > p70S6 pathway. Additionally, decreased phosphorylation of Src and Src family kinases (Hck, Fgr, and Lyn) suggested a Src-mediated mechanism of impaired phagocytosis. Further, a human cytokine array revealed that P2X4 receptor activation with CTP (400 μM) reduced the secretion of tumor-suppressive factors such as Endoglin, IGFBP3, and Serpin E1, while increasing the secretion of tumor-promoting factors including BAFF, RANTES, FGF-19, IL-8, MCP-1, MIP-3α, PDGF-AB/BB, and Relaxin, contributing to PCa growth, metastasis, and recurrence. We generated a macrophage-specific P2X4 receptor knockout mouse (LyzM-$P2X4^{-/-}$), confirmed by flow cytometry and IHC. Supporting our findings in human THP-1 derived M2 macrophages, peritoneal $TIM4^+$ $F4/80^+$ macrophages from LyzM-$P2X4^{-/-}$ mice exhibited enhanced phagocytosis compared to wild-type controls ($p = <0.0001$). However, we observed no apparent difference in TRAMP-C2 tumor growth rates between wild-type and LyzM-$P2X4^{-/-}$ mice. In summary, our findings demonstrate that P2X4 receptors are present on tumor-associated M2 macrophages in PCa tissues. We identified a role for P2X4 purinergic receptors in regulating macrophage cytokine secretion and phagocytic activity *in vitro,* suggesting that P2X4 receptors in macrophages within the prostate TME may contribute to PCa progression. Our ongoing studies are aimed at determining the efficacy of P2X4 purinergic receptors as a potential therapeutic target.

#2687 Exploring the synergistic mechanisms of VEGFR and immune checkpoint inhibitors in clear cell renal cell carcinoma metastases.

Stefan Maksimovic, Nina Costanza Boscolo, Matthew T. Campbell, Eleonora Dondossola

UT MD Anderson Cancer Center, Houston, TX

M.C. and E.D. equally contributed. Clear cell renal cell carcinoma (ccRCC) is the most common malignancy originated from the kidney, with bone and lungs as the main sites of distant spread in vast majority of patients. A key feature of ccRCC is the loss of function of the von Hippel-Lindau (VHL) protein leading to enhanced angiogenesis; in addition, ccRCC exhibits a rich and heterogeneous immune infiltrate. Consequently, different anti-angiogenic tyrosine kinase inhibitors (TKIs) and immune checkpoint inhibitors (ICIs)have emerged as standard of care for these patients, as single agents or in combination. Yet, limited data are available on their efficacy in different metastatic sites, and their impact on the immune infiltrate is unclear. We hypothesized that modulation of the microenvironment with a TKI provides an additive impact on ICI, and the outcome of combinational treatments depends on metastatic sites, treatment doses and tumor size. To this purpose, we implanted a luciferase-GFP-positive RENCA-VHL$^-$ cell line in the tibia of immunocompetent mice, resulting in synchronous bone and lung metastases. Cabozantinib (C), as one of the most potent TKIs, anti-programmed cell death protein 1 (Anti-PD1) and anti-CTLA4 antibodies, were used as single agents or in combination. The outcomes were monitored by macroscopic bioluminescence detection *in vivo,* and 3D multiparametric spatial analysis of bones and lungs, *ex vivo*. Compared to control-treated mice, all agents significantly reduced tumor progression at both tumor sites. Although all these treatments are clinically applied at stage IV of disease development, differences in their efficacy were noted once treatment was withdrawn. Spatial analysis of tumor cells, immune infiltrate and blood vessels revealed significant changes dependent on treatment, tumor site and time, with potential synergistic mechanism by TKIs when used in combination with ICI. We proved the efficacy of standard of care for bone and lung lesions of ccRCC in an immunocompetent mouse model and identified differences between treatments at the cellular level in the tumor microenvironment. We believe our studies may provide important insights and efficacy predictions for therapeutic applications in metastatic ccRCC patients.

#2688 FXIIIa-mediated transferrin sequestration drives cancer stem cell phenotype in colorectal cancer.

Savannah Gregg[1], Rio Boothello[2], Sareh Bayatpour[3], Shoja M. Haneefa[4], Adam Hawkridge[5], Umesh Desai[6], Gretchen Hubbard[7], Andrew Elliott[8], Jose J. Trevino[9], Leopoldo Fernandez[10], Mary Garland-Kledzik[11], Bhaumik Patel[12], Adam Khader[12]

[1]Surgery, Veterans Health Administration, Richmond, VA,[2]VCU School of Medicine, Richmond, VA,[3]U.S. Department of Veterans Affairs, Richmond, VA,[4]VCU School of Medicine, Veterans Health Administration, Richmond, VA,[5]Proteomics Shared Resource, VCU School of Pharmacy, Massey Comprehensive Cancer Center, Richmond, VA,[6]Center for Drug Discovery, VCU School of Pharmacy, Richmond, VA,[7]Caris Life Sciences, Baltimore, MD,[8]Caris Life Sciences, Phoenix, AZ,[9]Surgery, VCU School of Medicine, Massey Comprehensive Cancer Center, Richmond, VA,[10]Surgery, Veterans Health Administration, VCU School of Medicine, Massey Comprehensive Cancer Center, Richmond, VA,[11]Surgery, West Virginia University, Morgantown, WV,[12]Veterans Health Administration, VCU School of Medicine, Massey Comprehensive Cancer Center, Richmond, VA

Background: Colorectal cancer (CRC) is the third most common cancer worldwide. Tumors, often described as wounds that do not heal, exhibit fibrin clot deposition, which may create a niche for cancer stem cells (CSCs). Factor XIII (FXIII), a transglutaminase, cross-links fibrin (XLF) and functionalizes XLF clots by incorporating additional protein into the matrix. Our previous studies suggest that FXIII-XLF promotes the CSC phenotype. This study aims to identify and validate CSC-promoting proteins enriched in the XLF matrix.
Methods: TCGA and CARIS CODEai databases were analyzed for correlations of FXIII expression on CRC survival in primary and CRC peritoneal metastasis (PM). CRC cell lines were grown in an XLF spheroid model with various levels of activated FXIII (FXIIIa). We performed a comparative LC-MS/MS-based label-free proteomics (LFQ) analysis on high-salt washed XLF clots treated with normal plasma (100% FXIIIa activity, N-XLF) and CSC-promoting FXIIIa (150% FXIIIa activity, CP-XLF) matrices. FXIIIa activity was measured using a transglutaminase assay. Differential protein expression in the matrices was further validated by ELISA. The impact of FXIIIa inhibition was tested using the pan-transglutaminase inhibitor T101, and the role of the candidate protein transferrin (Tf) on spheroid formation was assessed with a Tf-neutralizing antibody (Tf ab). We further validated the effects of iron-loaded holo-transferrin versus apo-transferrin on spheroid numbers. Additionally, the effect of FXIIIa on intracellular iron was assessed using an iron-sensitive dye via flow cytometry.
Results: FXIIIA1 RNA expression was 2.7-fold higher in CRC PM compared to primary sites, and higher expression correlated with poor survival in all stages. Further, XLF protein expression in a CRC tumor microarray was present in 39.5% of patients, correlating with notably reduced survival (HR=2.2, $p<0.05$). Proteomics analysis revealed 21 differentially expressed proteins in CP-XLF compared to N-XLF (FDR <0.05). Tf was upregulated (4.5-fold) in CP-XLF. FXIIIa inhibition with T101 disrupted Tf sequestration in the XLF matrix and the FXIIIa-mediated promotion of spheroid formation. Tf neutralizing antibodies significantly reduced spheroid formation in both N-XLF and CP-XLF conditions. FXIIIa preferentially sequestered iron-loaded holo-transferrin over apo-transferrin. FXIIIa was associated with a 2.2-fold increase in cells with high intracellular iron ($p=0.002$).
Conclusions: FXIII RNA expression is associated with worse overall survival in CRC. Transferrin (Tf) and iron saturation are crucial in promoting the CSC phenotype in the CP-XLF matrix. This finding positions Tf as a potential mechanistic lead in the FXIII-XLF-CSC axis and a target for therapeutic intervention.

#2689 Targeting mesenchymal cells with epigenetic therapy in lung cancer and lung disease.

Dave-Preston Esoe[1], Avery R. Childress[1], Xiulong Song[1], Jamie Sturgill[2], Christopher M. Waters[3], Christine F. Brainson[4]

[1]Department of Toxicology and Cancer Biology, University of Kentucky, Lexington, KY,[2]Department of Microbiology, Immunology and Molecular Genetics, Markey Cancer Center, University of Kentucky, Lexington, KY,[3]Department of Physiology, Augusta University, Augusta, GA,[4]Department of Toxicology and Cancer Biology, Markey Cancer Center, University of Kentucky, Lexington, KY

Lung diseases, including fibrosis and cancer, are major health problems that together lead to millions of deaths each year. Non-small-cell lung cancer (NSCLC) has high morbidity and mortality rates, and patient prognosis and survival are very poor. Similarly, pulmonary fibrosis is a life-threatening respiratory disease characterized by scarring and damage caused by increased abundance of collagen-secreting myofibroblasts. An autopsy study showed that as many as one third of non-small cell lung cancer patients have some amount of pulmonary fibrosis[1], suggesting that these two diseases frequently co-exist. Our laboratory has also found that higher abundance of mesenchymal cells in tumors predicts a poor prognosis[2]. Various literature has identified Enhancer of Zeste Homolog 2 (EZH2), which is responsible for mediating histone 3 lysine 27 trimethylation, as a key regulator of lung disease. Several EZH2 inhibitors (tazemetostat and valemetostat) provide a reliable and therapeutically tolerable treatment option for diseased patients. Our central hypothesis is that EZH2 inhibition can prevent or reverse fibrosis via targeting myofibroblasts. To test this hypothesis, we have established pulmonary mesenchymal cell lines from both normal and diseased human lung. We observed that EZH2 inhibition slowed cell proliferation with or without TGF-beta, a cytokine known to drive a myofibroblast fate. In vivo, we have observed that EZH2 inhibition attenuates the fibrosis that occurs after exposure to bleomycin. Next, we are testing the roles of these mesenchymal cells in responses to cancer therapies, including immunotherapy. For our initial experiments, we used murine pulmonary mesenchymal cells grown with tumor cells and immune cells in a 3-dimensional Matrigel co-cultures. This culture system mimics aspects of the tumor immune microenvironment *in vitro* and has allowed us to test therapies including EZH2 inhibition and anti-PD1 immunotherapy in a tractable system. Our preliminary results suggest that EZH2 inhibition can alter cells to be more susceptible to anti-PD1, and we are now examining the contributions of mesenchymal cells to these phenotypes. Together our results suggest that targeting EZH2 may improve aspects of both pulmonary fibrosis and lung cancer, and be a way to target these co-occurring diseases to improve patient outcomes. [1]doi: 10.7196/ajtccm.2020.v26i1.050, [2] doi: 10.1016/j.labinv.2023.100176. Funded by R01 CA237643, R01 HL170193, and P30 CA177558 (Markey Shared Resources).

#2690 Expression profiles of antibody drug conjugate (ADC) targets in breast and lung cancer subtypes and in new HER2 subgroups with their PD-L1 status.

Marie Cumberbatch[1], Woo Ho Kim[2], Milan Bhagat[1], John Cogswell[1]

[1]TriStar Technology Group, LLC, Rockville, MD,[2]Seoul National University Medical College, Seoul, Korea, Republic of

Antibody drug conjugates (ADCs) are transforming the treatment of breast cancer as well as lung, ovarian, and several other cancer indications. ADCs targeting HER2 and TROP2 are currently approved in breast and lung cancer subgroups. Some HER2-targeted therapies are efficacious in breast cancer in newly defined HER2-low and -ultralow subgroups. There has been recent interest and some successes combining ADC's with immune checkpoint inhibitors. Despite these successes, tumors still develop resistance through both target-dependent and independent mechanisms. Previously we investigated which ADC's may be expressed in HER2-positive versus negative breast cancers and adeno versus squamous NSCLC histological subtypes. We have now extended these analyses to explore which ADC's show the highest relative expression levels in these cancers, co-expression with PD-L1 and expression in HER2-low and -ultralow breast cancer subgroups. Optimized IHC assays for B7-H3, B7-H4, Nectin-4, TROP2, PD-L1 and HER2 on Ventana or Dako automated staining platforms were applied to treatment naïve tumor samples from ER+ BC (n=60), TNBC (n=52) and NSCLC (n=134; adeno and squamous) in tissue microarray format (1mm cores). ADC targets were scored by pathologist-assisted digital image analysis to deliver H-Scores and frequencies of positivity at high, moderate, low and negative expression levels. Diagnostic visual scoring methods were employed for analysis of PD-L1 and HER2 (including addition of ultra-low score for HER2). We demonstrate that immune positivity for PD-L1 (CPS >10) was most frequent in HER2-low TNBC compared with HER2-ultralow or negative samples, and that B7-H3 and Nectin-4 H-Scores were higher in TNBC compared with ER+ BC, regardless of PD-L1+ status suggesting potential for immunotherapy combinations in TNBC and especially HER2-low subtype. Furthermore, B7-H4 H-Scores were higher in HER2-low, ultralow and negative ER+ BC compared with HER2 positive samples, while the inverse was observed for B7-H3 revealing potential opportunities for therapies that may overcome resistance to HER2-targeted therapies in this cancer subtype. Squamous NSCLC displayed higher B7-H3 and B7-H4 H-Scores and percent positive cells compared with adeno subtype, and B7-H3 and B7-H4 H-Scores were higher in PD-L1 positive samples (TPS≥1%) supporting ADC therapy for these targets in combination with PD-1/PD-L1 immunotherapies. Taken together, these data may aid the future selection of targets for upcoming therapeutics that can overcome target-independent resistance and provide rationale for immunotherapy combinations.

#2691 Configurable multiplex immunofluorescence panels for emerging ADC targets.

Yvette Cajigas, Cassandra Kysilovsky, Lauren Duro, **Kevin Hwang**, Lorenz Rognoni, Angela Vasaturo

Vizgen, Cambridge, MA

Background: Antibody-drug conjugates (ADCs) are revolutionizing oncology by selectively delivering cytotoxic payloads to cancer cells while sparing healthy tissues. ADC targets are typically cell-surface proteins overexpressed on tumor cells but with limited expression on normal cells, making spatial proteomics assays an ideal complement to this research. However, standard DAB-based immunohistochemistry techniques often lack the specificity and sensitivity needed to confidently quantify the target expression level in tumors with low target abundance, which can result in discordant scoring by pathologists. To support ADC drug development, we present a flexible and scalable approach to the design, development, and validation of mIF panels tailored to ADC targets using the highly sensitive InSituPlex (ISP) technology.
Methods: Antibodies targeting ADC-specific markers were initially optimized using DAB chromogenic staining. Following this, antibodies were conjugated to DNA barcodes, and titrations of both antibodies and fluorophores were performed to achieve optimal signal intensity and staining patterns as evaluated by a pathologist. Singleplex DAB and ISP assays were conducted on serial FFPE sections across multiple tumor types. Validation experiments were designed and performed to test the platform's precision and configurability for ADC-related targets. AI-driven STARVUE software was used for image analysis and assessment of reproducibility of key metrics including cell density and signal intensity.
Results: This approach integrates adaptability to diverse ADC targets, optimized antibody titration, fluorophore selection, and panel construction, achieving high specificity and sensitivity for multiple biomarkers in a single tissue section. The inclusion of STARVUE image analysis enhances the evaluation of spatial relationships between ADC targets and downstream effectors, offering a deeper understanding of drug efficacy and resistance mechanisms. The platform demonstrated high concordance across configurations, with single-target coefficients of variation (CVs) consistently below 20%. Spatial and intensity metrics further confirmed the robustness of the assay in multiple tumor types.
Conclusions: This validated and scalable mIF platform for ADC targets represents a significant advancement in spatial proteomics, providing a robust solution for researchers and clinicians to accelerate ADC development, optimize therapeutic strategies, and improve clinical outcomes.

#2692 3D in vitro models for identifying primary vs. metastatic tumors in targeted breast cancer treatment.

Shrinwanti Ghosh[1], Sangdeuk Ha[1], Anu Gaba[2], Kalpana Katti[3], Jiha Kim[1]

[1]Biological Sciences, North Dakota State Univ., Fargo, ND,[2]Hematology & Oncology, Sanford Roger Maris Cancer Center, Fargo, ND,[3]Civil, Construction and Environmental Engineering, North Dakota State Univ., Fargo, ND

Metastatic disease is responsible for over 90% of cancer-related deaths, with breast cancer patients exhibiting a survival rate of only 5% once bone metastases develop. Traditional 2D in vitro models often fail to accurately replicate the tumor microenvironment (TME) and drug responses observed in vivo. To address these limitations, we utilized advanced 3D in vitro models to better simulate primary and metastatic tumors, enabling the study of cancer-stromal interactions and drug efficacy. Patient-derived cancer cells (PDCs) from three molecular subtypes of breast cancer were used to model both primary tumors (using a hanging drop system) and bone metastases (using a bioengineered bone-mimetic scaffold). Stromal components, including endothelial cells (ECs), macrophages, and cancer-associated fibroblasts (CAFs), were co-cultured with PDCs to mimic TME more closely. As expected, drug sensitivity profiles generated within 48 hours revealed significant differences between 2D and 3D models when treated with paclitaxel (PTX), doxorubicin (DOX), lapatinib (LAPA), and 4-hydroxy tamoxifen (4-OH TAM). PDCs at bone metastatic sites exhibited higher survival rates post-treatment, as indicated by elevated BCL2 and Ki67 expression and lower CAS9 expression compared to primary tumor sites. This suggests site-specific resistance mechanisms, emphasizing that bone metastases may require higher drug doses to achieve comparable efficacy. Stromal interactions significantly influenced angiogenic capacity. While drug treatments substantially altered network formation when ECs and PDCs were cultured together, the presence of CAFs produced opposing effects. These findings underscore the complexity of bone TME and suggest that higher drug doses or combination therapies may be necessary to effectively target metastatic tumors. Additionally, we are incorporating macrophages into the TME in ongoing experiments to further elucidate their contributions to angiogenesis and therapeutic resistance. Moving forward, we will employ single-cell sequencing of 3D models to investigate tumor heterogeneity and refine dose-specific treatments, advancing precision medicine strategies to combat metastasis and improve patient outcomes. This work is currently in progress. Our single-cell sequencing data aims to reveal distinct gene expression differences between primary tumor sites and metastatic sites within the tumor microenvironment. By identifying unique gene expression profiles in cancer cells, stromal cells, and immune cells at each site, we aim to uncover critical pathways driving metastasis. These findings will guide the development of targeted therapies that specifically address metastatic tumors, thereby preventing metastasis and minimizing off-target effects.

#2693 BA3361, a tumor selective, conditionally active biologic (CAB) anti-nectin4-ADC with a novel NextGen linker system enhances therapeutic efficacy in pancreatic cancer.

Jing Wang, Jian Chen, Gerhard Frey, Haizhen Liu, Cathy Chang, William J. Boyle, Jay M. Short

R&D, BioAtla, Inc., San Diego, CA

Antibody drug conjugates (ADCs) are a unique therapeutic combination of the tumor-targeting monoclonal antibody, high-potency cytotoxic drug, and a chemical linker. Together, these components enable the tumor-specific delivery of the highly potent cytotoxin. However, treatment efficacy is often limited by on-target/off-tumor toxicity due to antigen expression in healthy tissue and by unwanted payload release outside the tumor caused by linker cleavage via circulating proteases. In this study, we present BA3361, a NextGen ADC featuring a conditionally active biologics (CAB) anti-Nectin4-ADC, optimized with novel CAB and linker technologies. BA3361 demonstrates pH-selective enhanced target binding in the tumor microenvironment conditions, improved serum stability, increased solubility, and tumor-specific payload release. These advancements effectively address critical clinical challenges by reducing off-tumor, on-target and off-target toxicities. *In vivo* efficacy data showed complete tumor regression in several patient derived cancer models. Notably, compared to an Enfortumab vedotin analogue, superior efficacy was observed in patient-derived pancreatic xenograft models, and the *in vivo* potency was tightly correlated with target expression. Furthermore, we discovered that intracellular glycosidase activity is high in pancreatic tumor tissue, independent of target expression, indicating efficient tumor selective linker cleavage. In conclusion, our NextGen Nectin4-CAB-ADC BA3361 demonstrates comparable or superior activity in lung, breast, and urothelial patient derived cancer models compared to Enfortumab vedotin and outperforms it in pancreatic PDX models. In addition, the conditional binding in the TME should help to reduce side effects of nonCAB ADCs and potentially widen the therapeutic index.

#2694 ID1-4 proteins' contribution to cancer stem-like cell maintenance and ovarian cancer recurrence following chemotherapy.

Megan Anne Keene[1], Mikella Robinson[2], Darren Lighter[2], Carrie House[2]

[1]Cell and Molecular Biology, San Diego State University / University of California San Diego, San Diego, CA,[2]Cell and Molecular Biology, San Diego State University, San Diego, CA

Although most patients initially respond to chemotherapy, ovarian cancer (OC) remains the most lethal gynecological cancer, primarily because over 80% of advanced cases relapse within 24 months. Current research suggests that cancer recurrence can be attributed to a small subpopulation of cancer stem-like cells (CSCs) that possess the ability to resist chemotherapy, self-renew, and asymmetrically divide. ID1-4 proteins, also known as inhibitors of differentiation or inhibitors of DNA binding proteins, regulate cell fate and differentiation in normal stem and progenitor cells. In gliomas, ID1-4 proteins have been identified as master transcriptional regulators of CSC identity, signaling to downstream pathways important for self-renewal, tumor initiation, and survival, but their role in OC CSCs and recurrence is unclear. We have previously found that ID1-3 gene expression increases following chemotherapy treatment in OC clinical samples and cell lines, and the elevated gene expression of ID1 and ID3 is associated with worse clinical outcomes. In subcutaneous xenograft mouse models, we have found that ID2 and ID4 protein expression significantly increases acutely following carboplatin treatment as compared to vehicle group, but this effect is lost over time. In OVCAR5, OVCAR8, and OV90 OC cell lines, we see a 10-40 fold increase in ID gene expression following two cycles of chemotherapy treatment. We hypothesize that ID proteins are required for OC CSC survival, self-renewal, and tumor recurrence following chemotherapy. Using a pan-ID inhibitor, AGX51, we have significantly knocked down ID expression in chemotherapy-naïve (OVCAR5, OV90) and chemotherapy-resistant (OVCAR4, OVCAR8) OC cell lines. Our data suggest pan-ID inhibition in OC cell lines reduces chemotherapy resistance, and reduces chemotherapy-dependent increases in CSC surface marker expression by flow cytometry, stemness and EMT genes by qRT-PCR, and downstream targets, including IL-6. Future studies will use siRNA silencing to further investigate the role of specific ID proteins in chemotherapy resistance, asymmetric division, spheroid formation, CSC maintenance by gene expression and flow cytometry, and signaling to downstream targets. These studies highlight a novel target important in CSC maintenance in response to chemotherapy that contributes to tumor progression and relapse. Understanding these mechanisms will allow us to develop novel therapeutic approaches to overcome chemotherapy-induced relapse, and better clinical outcomes.

#2695 TGF-β accelerates STING signaling termination in the tumor microenvironment by enhancing AP3D1-mediated STING trafficking.

Xingzhe Liu[1], Yuanjia Wen[1], Jiahao Liu[1], Guannan Li[1], Huayi Li[1], Xiaofei Jiao[1], Mengshi Luo[1], Yuewen Zhang[1], Xuejiao Zhao[1], Gorden B. Mills[2], Ding Ma[1], Guangnian Zhao[1], Qinglei Gao[1], **Yong Fang**[1]

[1]Tongji Medical College - Tongji Hospital, Wuhan, China,[2]OHSU Knight Cancer Institute, Portland, OR

Background: Activation of stimulator of interferon genes (STING) has shown great potential to enhance anti-tumor effect and reshape the tumor microenvironment (TME). Instead, the impact of TME on STING signaling remains elusive. Leveraging patient-derived samples at single-cell resolution from our clinical trial (NCT04507841), we find that TGF-β significantly attenuates STING signaling and downstream type I interferons production, which is related to the accelerated STING trafficking and degradation. Mechanistically, we identify AP3D1, a subunit of the AP-3 complex, could response to TGF-β and accelerate STING signaling termination in the TME.
Methods and results: Utilizing unique samples with HRD precision stratification and PARPi treatment information from our clinical trial (NCT04507841), and employing cutting-edge technologies such as single-cell sequencing and multiplex immunohistochemistry to reveal the complex immune microenvironment, we identified TGF-β suppresses the STING signaling pathway and the production of downstream type I IFN. Additionally, through RT-PCR, western blot, and immunofluorescence co-localization, we discovered that TGF-β promotes STING transport from Golgi to lysosome, accelerating STING degradation. To elucidate the specific mechanism by which TGF-β promotes STING transport, we employed techniques including the STING-APEX2 based proximity biotin labeling system, phosphorylation mass spectrometry and IP-MS, our analysis revealed and verified that TGF-β activates MEK to facilitate phosphorylation of adaptor related protein complex 3 (AP-3) subunit delta 1 (AP3D1) at the S9 site, thereby enhancing the interaction between AP3D1 and STING and accelerating the degradation of STING. Furthermore, we conducted validation experiments in multiple mouse models to confirm the effectiveness of peptides that target the inhibition of AP3D1-STING binding at the AP3D1 R26 site and the blockade of AP3D1 phosphorylation at the S9 site. When administered in combination with PARP inhibitors and STING agonists, these peptides demonstrated satisfactory therapeutic outcomes in upregulating STING signaling, reducing tumor burden, and inducing anti-tumor immune responses, all without evident toxicity.
Conclusions: Our work identified TGF-β as an exogenous STING regulator that accelerates AP3D1-mediated STING trafficking and degradation, providing an unprecedented insight into crosstalk between the TME and the STING signaling. Furthermore, our in-depth dissection of mechanisms offered conceptual strategies for new drug discovery and combined pharmacotherapy in cases where STING agonists fail to provide anticipated efficacy currently.

#2696 Targeting SLC7A11 creates a favorable immune microenvironment in colorectal cancer.

Jichang Li[1], **Xiaoxue Pan**[1], Kang Xia[2], Zeruo Yang[3], Xiaojing Yang[4], Pengyuan Wang[1], Shanwen Chen[1]

[1]Peking University First Hospital, Beijing, China,[2]Peking University Chengdu Academy for Advanced Interdisciplinary Biotechnologies, Chengdu, China,[3]Center of Quantitative Biology of Peking University, Beijing, China,[4]Peking-Tsinghua Center for Life Sciences, Academy for Advanced Interdisciplinary Studies, Peking Univerisity, Beijing, China

Background: Cysteine is a key immunoregulatory nutrient in colorectal cancer (CRC). Cystine uptake is primarily mediated by the cystine/glutamate transporter SLC7A11, which consists of 12 transmembrane α-helices that forming a channel through the cell membrane. Given SLC7A11's role in both metabolic competition and resistance to ferroptosis, we aim to explore whether SLC7A11 can be effectively targeted with monoclonal antibodies as a therapeutic strategy for colorectal cancer.
Methods: Using a cell-based in vivo immunoassay and standard hybridoma technology, we generated a human SLC7A11-specific murine monoclonal antibody, designated 1A4. Subcutaneous and orthotopic colorectal cancer models in mice, as well as an AOM/DSS-induced colitis-associated colorectal cancer model was established. We evaluated the effects of the SLC7A11 antibody on the immune microenvironment of colorectal cancer by multicolor immunofluorescence and flow cytometry. Furthermore, single-cell sequencing was employed to analyze alterations in immune cell subpopulations and to investigate the impact of the SLC7A11 antibody on immune cell metabolism and intercellular interactions within the tumor microenvironment. Flow cytometry was further utilized to validate the differential effects of the SLC7A11 antibody on CD4+ and CD8+ T cells.
Results: Subcutaneous and orthotopic cancer model of colon cancer showed that treatment with 1A4 significantly reduced tumor volume. Multiplex immunofluorescence analysis showed that both duel immune checkpoint blockade and 1A4 increased the number of infiltrating CD8+ T cells and the CD8+T/Treg ratio in tumor tissues, with a more pronounced increase observed in tumors treated with 1A4. Single-cell sequencing results demonstrated that 1A4 modulated the tumor immune microenvironment by increasing the infiltration of T cells, B cells, and NK cells within the tumor tissue. RNA sequencing on CD4+ T cells exhibited more pronounced alterations in metabolic pathways. The flow cytometry results showed that treatment of CD8+ T cells with 1A4 enhanced stemness and a reduction in the proportion of exhausted CD8+ T cells.
Conclusions: This study developed an antibody targeting the SLC7A11 and validated its anti-tumor effects in colorectal cancer. Targeting SLC7A11 potently creates a favorable immune microenvironment through inhibiting the activation of Tregs and increasing the stemness of CD8+ T cells.

#2697 Targeting tumor microenvironments of triple negative breast cancer with a novel adeno-associated virus-mediated virotherapy.

Md. Manirujjaman[1], Yong Ran[2], Soroor Heidari[1], Jone Garai[1], Samarpan Majumder[1], Luis Del Valle[1], Jovanny Zabaleta[1], Barbara Osborne[3], Lucio Miele[1], Todd Golde[2], **Fokhrul Hossain**[1]

[1]LSU Health New Orleans, New Orleans, LA,[2]Emory University, Atlanta, GA,[3]University of Massachusetts, Amherst, Amherst, MA

Triple-negative breast cancer (TNBC) is a group of aggressive breast cancers with a higher mortality rate due to their resistance to chemotherapy and radiotherapy. Unfortunately, there are no specific targeted therapies for TNBC, making it a critical medical need. In basal-like TNBC, Notch signaling regulates the recruitment of tumor-associated macrophages (TAMs) and the activation of cancer stem-like cells (CSCs) by TAMs through TGF-β pathways. TGFβ-responsive CSCs have enhanced resistance to T cell immunotherapy and are responsible for tumor relapse. Therefore, TGF-β pathway inhibition is a promising therapeutic target in TNBC. However, due to systemic toxicity, the FDA has not approved TGF-β investigational inhibitors. To avoid these toxicities, we use a recombinant adeno-associated virus (r-AAV) vector encoding a soluble TGF-β receptor decoy (r-AAV-TGFβRD) to inhibit TGF-β intratumorally in TNBC. r-AAVs are non-replicating viruses and, therefore, are a safe platform for in vivo gene therapy delivery. We found that rAAV-GFP transduced both human and mouse TNBC cells. Our rAAV constructs contain a C1QTNF3-derived collagen domain (CD) that facilitates the trimerization and stabilization of secreted fusion proteins. We purified these proteins from cellular supernatants of r-AAV vector-transduced cells using His-Tag affinity chromatography and found that they significantly decreased human TNBC cell's mammosphere growth. Intratumoral injection of the r-AAV-TGFβRD virus significantly reduced syngeneic mouse TNBC tumor growth and increased the tumor-infiltrating lymphocytes (TILs), including CD3 and CD8. NanoString analyses (nCounter Immunology) suggest changes in tumor microenvironments after the treatment. We found significant increases in the innate immune system, host-pathogen interactions, and chemokine signaling with increasing influx of macrophages, DC, and CD8 as TILs. Interestingly, we found decreased B cells and Tregs within TME as TILs. Notably, the r-AAV-TGFβRD virus significantly enhances the efficacy of chemotherapy (paclitaxel) in mediating the anti-tumor tumor effect in the syngeneic TNBC mouse model. These findings indicate that r-AAV-TGFβRD virus can be a promising approach for treating TNBC alone or in combination with chemotherapy for translational application in the future.

#2698 Altered collagen morphology in pancreatic cancer treated with the iRGD tumor-penetrating peptide.

Yoon Ho Choi[1], Minji Kim[1], Hotaka Kawai[2], Yukihito Kuroda[3], Norio Miyamura[3], Seock-Jin Chung[1], Kazuki N. Sugahara[3], Tae Hyun Hwang[1]

[1]Mayo Clinic Florida, Jacksonville, FL,[2]Oral pathology and Medicine, Okayama University, Okayama, Japan,[3]Columbia University, New York, NY

Background: Pancreatic ductal adenocarcinoma (PDAC) is characterized by a dense, collagen-rich stroma that impedes drug delivery. We investigated how iRGD-mediated nanoparticle delivery modifies collagen architecture using humanized mouse models. Computational analysis of Picro-Sirius Red-stained whole-slide images (WSIs) using curvelet transform-based fiber extraction method (CT-FIRE) was performed to quantitatively examine changes in collagen features, thereby understanding treatment-induced alterations in the tumor microenvironment (TME).

Methods: Humanized PDAC mice were prepared with either the human PANC-1 cell line or 0779 primary human PDAC cells and treated with or without iRGD monotherapy for two months (n=12). Primary tumors were sectioned and stained with Picro-Sirius Red to visualize collagen structures. WSIs of Picro-Sirius Red-stained tissues were analyzed with CT-FIRE to extract six morphological features of collagen, including average fiber length, waviness, and density to capture structural changes. WSIs were divided into 256×256 pixel tiles with consistent sampling through bootstrapping, followed by permutation testing for statistical validation (1,000 permutations, $p<0.01$).

Results: Computational analysis revealed significant iRGD-induced collagen remodeling with quantifiable changes in key structural and morphological features. Permutation testing showed that, compared to controls, average fiber length decreased by 3.27% ($p<0.01$), waviness reduced by 3.25% ($p<0.01$), and density diminished by 36.3% ($p<0.01$), compared to controls. The structural changes were more notable in 0779-derived tumors compared to PANC-1, with reductions in average fiber length (1.03%, $p<0.01$), waviness (8.78%, $p<0.01$), and collagen density (24.27%, $p<0.01$), demonstrating cell-line dependent stromal remodeling.

Conclusions: Our findings suggest that long-term iRGD therapy alters collagen morphology in PDAC. Further investigation is warranted to understand how these alterations contribute to enhanced penetration of drugs and immune cells observed in iRGD-treated PDAC tumors. The observed cell-line dependent variations in stromal remodeling suggest tumor heterogeneity influences treatment response, highlighting the potential for personalized therapeutic approaches in stromal-rich tumors like PDAC.

#2699 Investigating fibroblast activation protein alpha (FAPα) as a therapeutic target for delivery of pre|CISION® cancer medicines: Expression, spatial localization and functional insights.

Ruairidh Edwards[1], Curtis Rink[1], Giulia Tagliavini[2], Christopher Mills[2], David Jones[1], Michelle Morrow[1]

[1]Avacta Life Sciences, London, United Kingdom,[2]Concept Life Sciences, Edinburgh, United Kingdom

Fibroblast activation protein α (FAP) is a post-proline protease and solid-tumor target which Avacta's pre|CISION® peptide moiety linker selectively uses as a differentiated means to target the tumor microenvironment (TME). The potential of the pre|CISION® technology is highlighted by the promising clinical data from AVA6000, a pre|CISION® enabled Doxorubicin peptide drug conjugate. FAP expression is tightly regulated in normal adult tissues, with low to undetectable levels in most healthy cells. However, it becomes highly upregulated in the TME where it is expressed by cancer-associated fibroblasts (CAFs). This selective expression pattern has been observed in over 90% of epithelial tumors, including breast, colorectal, pancreatic, lung, brain, and ovarian cancer. We implemented a multi-faceted approach to further the understanding of FAP biology and the potential application for pre|CISION® medicines across a broad range of tumors. We conducted a comprehensive analysis of FAP using real-world data from Tempus AI's LENS database encompassing over 140,000 tumor samples across 30+ solid tumor types. We evaluated FAP pan-cancer RNA expression, spatial organization of FAP in the TME, as well as correlations with biomarkers. We further analyzed FAP expression pre- and post-treatment and performed in-depth analysis to evaluate FAP expression in tumor subtypes and primary or metastatic lesions. Single-cell RNA-sequencing (scRNA-seq) analysis provided insights into FAP-expressing cell populations as well as correlations between CAF abundance and FAP. FAP expression was evaluated at the protein level using IHC analysis across multiple tumor indications. Multi-immunofluorescence IHC (multi-IF) was used to evaluate the spatial localization of FAP relative to tumor cells and vasculature. Our findings reveal high FAP expression across a range of tumor indications and demonstrate a correlation with novel biomarkers of interest. IHC analysis confirms a direct relationship between FAP RNA and protein expression, while multi-IF imaging and concentric partitioning analysis for a range of solid tumor indications shows the spatial association of tumor cells, blood vessels and CAFs expressing FAP. ScRNA-seq data confirms high level FAP expression on fibroblasts in stromal-rich tumors. Finally, co-culture models were established with tumor cells and matched fibroblasts which represent tumors with differing levels of FAP enzyme activity. Avacta's preCISION® peptide-drug conjugates elicit bystander cell kill over a range of physiological FAP levels within these co-culture models. Combined, these analyses emphasize the significance of FAP as an important stromal target for focused delivery of targeted oncology therapeutics, and guide further development of the preCISION® pipeline.

#2700 AXL-positive cancer-associated fibroblasts enhance the metastatic potential of cancer cells and suppress tumor immunity in gastric cancer.

Tuyen Thanh Tran, Yulim Lee, In-Hye Ham, Hur Hoon

Surgery, Ajou University School of Medicine, Gyeonggi-do, Korea, Republic of

Purpose: Cancer-associated fibroblasts (CAFs) are key components of the tumor microenvironment (TME). Numerous studies have demonstrated a significant correlation between increased CAFs accumulation and poor outcomes in gastric cancer (GC) patients. However, no targeting agents against CAFs have been clinically applied in cancer treatments. AXL, a receptor tyrosine kinase, has emerged as a promising target to suppress cancer cell metastasis, yet AXL inhibitors have not been approved due to limited efficacy in clinical trials. However, the role of AXL upregulated in CAFs remains unexplored. In this study, we investigated the effect of AXL-positive CAFs on GC progression and explore their potential as therapeutic targets to enhance GC treatment efficacy.
Methods: We analyzed a single cell RNA-seq (scRNA-seq) dataset of human GC tissues to identify the cell types expressing AXL. Human CAFs and mouse gastric fibroblasts (MGF) expressing AXL were treated with AXL inhibitors, such as CCB3233 and 9im. Additionally, AXL knockdown (KD) was performed in CAFs and MGFs, which were subsequently co-cultured with human GC cell lines (SNU668 or MKN-1) or mouse GC cell lines (ACKPY4113) to assess the effects of AXL+ fibroblasts on GC progression. The impact of AXL-inhibited fibroblasts on T-lymphocytes or macrophages was also evaluated. Furthermore, transcriptome analysis was conducted on AXL KD and control fibroblasts.
Results: The analysis using scRNA-seq dataset revealed that AXL expression was predominantly upregulated in CAFs compared to other cell types. High expression and activation of AXL in fibroblasts were confirmed across various cell lines, including GC cell lines, fibroblasts and immune cells. AXL inhibitors, such as CCB3233 and 9im, effectively reduced AXL phosphorylation in human CAFs and MGFs. Co-culture experiments demonstrated that AXL-inhibited or KD fibroblasts significantly reduced the migration or invasion of GC cells compared to control fibroblasts. Moreover, while control CAFs and MGFs suppressed the activation of T- lymphocytes or macrophages, AXL-inactivated or KD fibroblasts were unable to inhibit immune cell activation. Transcriptome analysis of AXL KD or control fibroblasts revealed reduced expression of chemokines such as CXCL9 and CXCL13, which may explain the observed experimental results.
Conclusions: Our findings highlight the crucial role of AXL-positive fibroblasts in promoting the aggressive phenotype of GC cells and suppressing immune cell activity in the GC TME. Targeting AXL in CAFs holds significant promise as a novel therapeutic strategy for GC treatment.

#2701 iRGD peptide therapy transforms immunosuppressive microenvironment to immune-favorable state in pancreatic ductal adenocarcinoma.

Minji Kim[1], Yoon Ho Choi[1], Hotaka Kawai[2], Yukihito Kuroda[3], Norio Miyamura[3], Kazuki N. Sugahara[3], Tae Hyun Hwang[1]

[1]Department of Artificial Intelligence and Informatics Research, Mayo Clinic, Jacksonville, FL,[2]Department of Oral pathology and Medicine, Okayama University, Okayama, Japan,[3]Department of Surgery, Columbia University, New York, NY

Background: Pancreatic ductal adenocarcinoma (PDAC) exhibits a complex, immunosuppressive tumor immune microenvironment (TIME), necessitating molecular-level understanding to identify therapeutic targets. We investigated how iRGD peptide therapy remodels the immunosuppressive TIME to an immune-favorable state using single-cell spatial molecular analysis.
Methods: Single-cell level in situ molecular imaging was performed using Xenium analyzer with 5K gene panel on tumor samples from humanized PDAC mice (n=7) treated with iRGD monotherapy (n=3) or control (n=4), enabling comprehensive spatial molecular characterization of the TIME.
Results: iRGD therapy significantly transformed the immunosuppressive TIME to an immune-favorable state through T-cell composition remodeling. We observed increased populations of CD4+ memory T cells, CD4+ helper T cells, and cytokine-secreting effector T cells, indicating enhanced immune memory and effector functions. Concurrent decreases in regulatory T cells and activated CD4+ T cells reflected reduced immune suppression. Additionally, decreased TGF-β signaling in the iRGD cohort suggested TGF-β antagonism as a mechanism for overcoming immunosuppression.
Conclusions: iRGD therapy effectively converted the immunosuppressive PDAC microenvironment to an immune-favorable state by enhancing beneficial T cell populations and reducing immunosuppression through TGF-β pathway modulation. These findings support previous work by Kuroda et al. and provide mechanistic rationale for the ongoing iRGD-based immunotherapy clinical trial (iLSTA:ACTRN12623000223639).Acknowledgments: We thank DeepL for the English language editing.

#2702 A novel inhibitor targeting DDR complex to suppress pancreatic cancer growth and progression.

Chrid TP Do, Prabhakar P. Venkata, Jack Y. Prochnau, Deepika Singh, Santosh Timilsina, Panneerdoss Subbarayalu, Daisy Medina, Shahad Abdulsahib, Sajeed Khan, Manjeet K. Rao

UT Health Science Center at San Antonio, San Antonio, TX

Pancreatic ductal adenocarcinoma (PDAC) is a highly lethal malignancy, with a 5-year survival rate of 12%. The dense extracellular matrix (ECM) and cancer-associated fibroblast (CAF)-driven microenvironment contribute to tumor progression and resistance to current therapies, necessitating the development of novel treatments. This study introduces CIDD-8633, a selective small-molecule inhibitor targeting the Discoidin Domain Receptor (DDR) complex, which plays a crucial role in ECM-mediated signaling and PDAC progression. High-throughput screening identified CIDD-8633 as a potent inhibitor of DDR kinase activity. Functional assays demonstrated that CIDD-8633 significantly reduced PDAC cell proliferation, migration, and colony formation while inducing apoptosis and G1/S cell cycle arrest. RNA sequencing revealed that CIDD-8633 treatment downregulated pathways associated with DNA replication and repair, while upregulating apoptosis-related signaling pathways. In vivo, CIDD-8633 effectively suppressed tumor growth in PDAC xenograft models, reducing tumor volume and proliferation markers. Histopathological analysis showed decreased phosphorylated DDR and downstream RTKs expression, accompanied by enhanced apoptotic signaling. Furthermore, combination therapy with gemcitabine demonstrated synergistic effects, enhancing anti-tumor efficacy by reducing PDAC cell viability and metastatic potential more effectively than either agent alone. These findings position CIDD-8633 as a promising therapeutic candidate for PDAC, capable of targeting the DDR complex to disrupt tumor progression. This study highlights the potential of DDR inhibition as a novel therapeutic approach for overcoming the challenges of this aggressive cancer.

#2703 Effect of combination of calcipotriol with paclitaxel on pancreatic ductal adenocarcinoma orthotopic mouse model.

Fatima Dagher[1], Mikayla Skillman[1], Guodong Zhang[2], Lu Dai[1], Amir Mohammad Gholizadeh[1], Chun Li[2], Diana S-L Chow[1]

[1]University of Houston, College of Pharmacy, Houston, TX,[2]Cancer Systems Imaging, The University of Texas M.D Anderson Cancer Center, Houston, TX

Pancreatic ductal adenocarcinoma (PDAC) remains one of the leading causes of cancer-related mortality in the United States, with a dismal 5-year overall survival rate of less than 11%. The progression and treatment resistance of PDAC is heavily influenced by its dense stromal environment, acting as a physical and biochemical barrier, limiting the effective delivery of therapeutics to tumor tissues. This stromal barrier significantly contributes to suboptimal drug efficacy and poor therapeutic outcomes. Calcipotriol (Cal), a known modulator of tumor stroma, may disrupt this barrier and enhance drug delivery to tumors. In this study, we investigated the combination of Cal with paclitaxel (PTX), a commonly used chemotherapeutic agent, to evaluate its ability to improve therapeutic efficacy and drug distribution in a PDAC mouse model. Using an orthotopic Kras* C57bl/6 mouse model of PDAC, we assessed the pharmacokinetics, biodistribution, and antitumor effects of Cal, PTX, and the combination (Cal/PTX). Mice were randomized into four treatment groups: Cal/PTX combination therapy (3 doses of 2 mg/kg /20 mg/kg and 3 doses of 1 mg/kg/10 mg/kg) (N=3), Cal alone (2 mg/kg) (N=3), PTX alone (20 mg/kg) (N=3), and vehicle control (N=4). All treatments were administered intraperitoneally with the solvent Ethanol:Cremophore:Saline (1:1:8) as vehicle and a dosing regimen of 3 days a week (day on day off) for 2 weeks. Tumor intensity was monitored over two weeks using bioluminescence imaging with an IVIS system. Drug concentrations in blood and tumor tissues were quantified using a validated LC-MS/MS method with a lower limit of quantification (LLOQ) of 0.5 ng/ml. In the Cal/PTX group, tumor growth was effectively inhibited, with a 100% response rate observed after 6th dose. Conversely, in the groups treated with Cal or PTX alone, tumor growth continued in 2 out of 3 mice, suggesting limited efficacy of the single agents. Similarly, 3 out of 4 mice showed no signs of tumor regression in the vehicle group. Biodistribution studies further supported these findings, with significantly higher accumulation of both Cal and PTX at the tumor site in the combination group compared to single-agent groups, indicating improved tumor-specific delivery. In the tumor, the mean concentrations (ng/g) (±SD) of Cal and PTX in the combination group were 98.08 ± 55.5 and 147.4 ± 45.07, respectively, compared to 3.71±2.33 and 52.46 ± 21.25 in the alone group. These findings highlight the potential of the Cal/PTX combination therapy to overcome stromal barriers and enhance drug delivery and antitumor efficacy in PDAC. Ongoing work focuses on developing a co-formulated polymeric micelle system (M-Cal/PTX) to be tested on Kras* mouse model to enhance drug delivery further, maximize therapeutic outcomes, and overcome drugs' associated toxicity. This novel approach could pave the path for more effective treatment strategies for PDAC.

#2704 Targeting HCC tumor microenvironment interactions using an advanced HCC patient-derived on-chip model.

Orsola Mocellin[1], Abbie Robinson[1], Aleksandra Olczyk[1], Stephane Treillard[1], Thomas Olivier[1], Chee P Ng[1], Jeroen Heijmans[1], Gilles van Tienderen[2], Monique Verstegen[2], Flavio Bonanini[1], Sebastian J. Trietsch[1], Dorota Kurek[1], Henriette Lanz[1], Jos Joore[1], Paul Vulto[1], **Karla S. Queiroz**[1]

[1]MIMETAS, Oegstgeest, Netherlands,[2]Erasmus MC-University Medical Center Rotterdam, Rotterdam, Netherlands

Hepatocellular carcinoma (HCC) is the most common type of liver cancer. Its incidence is increasing and is closely related to advanced liver disease. Interactions in the HCC microenvironment between tumor cells and the associated stroma actively regulates tumor initiation, progression, metastasis, and therapy response. Current in vitro systems often fail to replicate the HCC complex microenvironment, including vascular structures, hindering accurate efficacy evaluation and limiting the translational value of preclinical studies. This study aimed to address these gaps by developing a scalable, vascularized 3D HCC model using the OrganoPlate Graft platform to enable detailed analyses of drug responses, bridging a critical gap in anticancer drug discovery Here we report a phenotypic drug screen on a HCC patient-derived comprehensive Organ-on-a-Chip setup. The vascularized patient-derived HCC models include relevant cellular players of the HCC microenvironment. These co-cultures are highly suitable for studying specific cell types as well as patient-specific responses in medium- to high- throughput fashion. We assessed the effect of 28 treatment conditions, including standard of care (SoC), single, and combination treatments with compounds targeting different molecular programs. Approximately 960 HCC patient derived cultures were grown under perfusion flow in microfluidic chips, exposed to treatments, and subsequently assessed for viability, chemokine and cytokine changes, and vascular bed responses. The screen showed known therapeutics sorafenib and lenvatinib to reduce culture viability and induce significant alterations in vascular bed organization. Compound 1 reduced viability without affecting vascular structures. All three compounds also affected chemokine and cytokine profiles. Additionally, several compounds including Compound 25, Compound 5 and Compound15 lowered IL6 in culture supernatant, whereas Compound 6 elevated IL6 levels. These findings highlight the utility of the organ-on-a-chip model in visualizing drug-induced responses at both molecular and morphological levels, providing detailed insights into drug effects on specific cellular compartments within the HCC TME. This platform holds significant potential for enabling safer and more effective drug development, offering scalability and ease of use for industrial applications. By addressing critical limitations of conventional in vitro models, this approach facilitates a more accurate understanding of HCC biology and supports the translation of novel anticancer therapies to clinical practice.

#2705 Spatial profiling of tumor microenvironment uncovers potential novel therapeutic approach in pediatric neuroblastoma.

C. Tu[1], C. Tan[1], J. Monkman[1], A. Almeida[2], G. Antonio-Carreon[1], N. Omer[1], G. Hull[1], K. Chung[1], A. Mehdi[1], A. Salerno[3], O. Vittorio[3], A. Mayer[4], C. Souza[2], F. Pinhati[2], S. Elifio-Esposito[2], W. Nicholls[5], L. Noronha[2], A. Kulasinghe[1], F. Souza-Fonseca-Guimaraes[1]; [1]Frazer Institute, Faculty of Medicine, University of Queensland, Woolloongabba, QLD, Australia, [2]Laboratorio de Patologia Experimental, PPGCS da PUCPR, Curitiba, Brazil, [3]School of Biomedical Sciences, Faculty of Medicine and Health, University of New South Wales, Sydney, NSW, Australia, [4]Enable Medicine, Menlo Park, CA, [5]Queensland Children's Hospital, Brisbane, QLD, Australia

Background: Neuroblastoma (NB) is a tumor of the sympathetic nervous system and is the most common extracranial solid malignancy in children. Patients with high-risk NB have much poorer outcomes compared with patients with low- and intermediate-risk neuroblastoma. These striking differences in clinical outcomes led us to investigate how the tumor microenvironment (TME) differs between high-risk and low-risk NB patients. We examined the cancerous and non-cancerous cells, along with other components, in the TME to determine their potential to either promote or suppress tumor growth, and to determine their association with a specific tissue spatial organization.

Methods: In this study, we profiled 27 pediatric NB patients (n = 14 high-risk and 13 low-risk samples) using GeoMx DSP Whole Transcriptome Atlas (WTA) (Nanostring Technologies) and Phenocycler Fusion (Akoya Biosciences). We analyzed a total of 67 regions of interest (ROIs) using spatial transcriptomics, guided by fluorescent markers (CD45, Synaptophysin, CD56, and DAPI). ROIs were segmented into tumor regions (CD56+Synaptophysin+CD45-) and TME regions (CD45+CD56-). We conducted spatial proteomics to phenotype cells, map their locations, and assess functional states by profiling 53 markers. This 53-plex protein panel enabled us to identify various cell types within the NB TME, covering relevant lineages (tumor, lymphoid, myeloid, and stromal), subtypes (e.g., CD4 T cells, CD8 T cells, B cells, macrophages and neutrophils), and functional states (e.g., Ki67 and PD-1). Spatially resolved signatures in the NB identified characteristics of cellular neighborhoods that are linked to NB patients' survival outcomes.

Results: Within the tumor regions, we identified an upregulation of the glutathione metabolism pathways that are involved in the suppression of ferroptosis in high-risk NB tumors, which could be targeted with GPX4 inhibitors. We also discovered that NB with macrophage-rich and stroma-secluded immune cell neighborhoods had worse outcomes. Stroma-secluded immune cells were more frequent in high-risk NB, which may contribute to the resistance mechanisms to immunotherapy and overall survival of patients with high-risk NB.

Conclusion: Our study highlights the need to combine the genomic profile of NB TME with spatially defined cellular neighborhoods to better understand tumor aggressiveness. Considering the upregulation of ferroptosis suppressive pathways and the macrophage-rich neighborhood in high-risk NB, our findings suggest that inducing ferroptosis with GPX4 inhibitors might be a promising therapy for high-risk NB. Overall, our study revealed key genes and pathways in high-risk NB and provides a new therapeutic avenue for patients with high-risk NB. This hypothesis is currently being investigated in our lab using animal models.

#2706 Engineered tumor-targeting bacteria expressing cancer-killing protein for breast cancer.

[1]University of Illinois College of Med. at Chicago, Chicago, IL, [2]University of Illinois, Chicago, IL

Despite significant advancements in the treatment of advanced breast cancer, therapies using chemotherapeutic agents still face considerable challenges. One key issue is the hypoxic tumor microenvironment (TME), characterized by insufficient blood flow and oxygen supply within tumors. This hypoxia reduces the sensitivity of breast tumors to treatment, diminishes therapeutic efficacy, and promotes resistance and metastasis. Approximately 25-40% of invasive breast cancers exhibit hypoxic tumors, which are strongly associated with increased risks of metastasis and chemotherapy resistance. Therefore, there is a pressing clinical need for novel strategies to specifically target these hypoxic tumor regions. To address this limitation, our objective is to develop an innovative approach using tumor-targeting bacteria carrying cancer-killing protein, controlled by an engineered hypoxia-inducible expression system. In this study, four *Escherichia coli* strains from the probiotic Symbioflor® 2 were isolated and characterized based on colony morphology and PCR results. These strains were transformed with luciferase gene, and luciferase activity was monitored to determine biodistributions of each *E. coli* after intravenous injection into mice. Our data showed that G5 strain preferentially colonized in xenografted triple-negative breast tumors. To specifically express cancer-killing azurin gene within the hypoxic tumor TME, we optimized the hypoxia-inducible promoter in *E. coli* G5 cells. To test its anti-tumor efficacy, TNBC cells were orthotopically injected into the mammary fat pads of immunodeficient mice. The engineered *E. coli* G5$^{Hyp*\text{-}azurin}$ strain was administered at varying concentrations (1×10^5, 1×10^6, and 1×10^7 CFU/mouse) through weekly tail vein injections over three weeks. Our results demonstrated that *E. coli* G5$^{Hyp*\text{-}azurin}$, at doses of 1×10^7 and 1×10^6 CFU, effectively inhibited tumor progression. In contrast, lower dose (1×10^5 CFU) showed no significant effect. Additionally, no noticeable side effects were observed, as there was no evidence of weight loss. Overall, our results highlight the potential of our newly designed bacterial approach to develop an innovative treatment strategy.

#2707 An *ex vivo* culture platform of invasive lobular breast cancer for the screening of novel drugs targeting the tumor microenvironment.

Konstantina Strepi, Daisy Batenburg, Martine van Miltenburg, Pim Kloosterman, Eline van der Burg, Anne Paulien Drenth, Frank van Diepen, Guido de Roo, Lex de Vrije, Mariska van Geldrop, Serge Zander, Jos Jonkers, **Julia M. Houthuijzen**

Netherlands Cancer Institute, Amsterdam, Netherlands

The study of invasive lobular breast cancer (ILC) and the development of effective ILC-specific therapies is hampered by the lack of suitable model systems that accurately reflect the human disease. Here, we present a set of four genetically engineered mouse models (GEMMs) of ILC, based on the most common genetic alterations found in human ILC. These GEMMs represent the predominant subtypes of ILC and closely mimic human ILC in growth pattern, invasiveness, tumor microenvironment (TME) composition, and subtype-specific molecular profiling. Using these GEMMs, we developed a novel *ex vivo* culture platform that maintains tissue architecture, TME composition and gene expression for up to seven days. Using this platform, we investigated whether targeting cancer-associated fibroblasts (CAFs), which are commonly found in invasive lobular carcinoma (ILC) and known to hinder therapy effectiveness, in combination with tumor cells, could enhance anti-cancer drug efficacy. To identify potential drug combinations, we conducted single-cell transcriptomics on our four ILC mouse models to investigate the complex interactions between CAFs and other cells in the TME. Building on previous research showing that immune-regulatory CAFs (iCAFs) recruit myeloid cells and promote tumor cell invasion, as well as our current findings of extensive CXCL- and complement-mediated crosstalk between iCAFs and macrophages, we hypothesized that inhibiting these iCAF functions could synergize with immunotherapy; a treatment typically ineffective in ILC. Indeed, inhibiting iCAF functions improved immunotherapy efficacy in *ex vivo* cultures, as measured by enhanced T-cell activation, a finding that was subsequently validated in mice. Furthermore, our *ex vivo* platform enabled the culture and drug screening of human ILC specimens. Overall, our ILC GEMMs effectively model a wide range of human ILC molecular subtypes, and our *ex vivo* culture platform facilitates the faster and more accurate identification of new therapeutic vulnerabilities compared to traditional 2D or 3D cultures. Taken together, these models have the potential to significantly advance ILC research.

#2708 Prediction of radiosensitivity in glioblastoma tumors after standard and low dose rates of ionizing radiation.

I. Rivera, R. Yao, K. Selting, C. Best-Popescu, B. Harley, **S. Pedron-Haba**;
University of Illinois at Urbana-Champaign, Urbana, IL

Glioblastomas (GBM) exhibit high infiltration into the brain parenchyma, impairing surgical resection and leading to recurrence. After standard of care, including tumor resection, radiation therapy (RT) and chemotherapy, most tumors recur at the tumor margins. These tumors show an increased aggressiveness and therapeutic resistance. The underlying mechanisms for these cellular transitions are unclear. Research suggests that RT paradoxically alters the GBM microenvironment promoting cancer cell survival upon recurrence. Some of these alterations in the irradiated tumor microenvironment include increased oxidative stress, hypoxia, cellular senescence, vasculogenesis and ECM compositional and structural changes.We use an *ex vivo* platform that combines the hallmarks of GBM tumors: high cellularity, the neural circuitry that surrounds tumors, a hydrogel-based ECM that mimics the biophysical and biochemical properties of GBM and the intermittent hypoxic environment present in native tumors, to characterize and evaluate the therapeutic benefits of RT and the underlying mechanisms of neurotoxicity to more effectively treat the tumor while minimizing the deleterious side effects.Our results show that radiation treatment increases glycolysis in tumor cells and that immediate response to radiation produces a more significant ATP production decrease in hypoxia environments. We have also investigated the long-term energy production and mitochondrial dysfunction in the tumor cells at different radiation rates and under low oxygen environments. Interestingly, the maximal respiration capacity in GBM cells increases with the presence of conditioned media from neuronal cultures in normoxic conditions but has the opposite effect in hypoxic environments.Proliferation ability of cells on stiffer matrices is greater than that on softer matrices. In the presence of an altered biomechanical microenvironment, a stiffer tumor tissue is more prone to immunosuppression and epithelial-mesenchymal transition. After cells are irradiated, the cell migration is different with different matrix stiffness. Moreover, softer matrices are more likely to promote cellular radiosensitivity, while stiffer matrices can inhibit cellular radiosensitivity.The use of preclinical tools that can model key features of the GBM and normal brain tissue can give a better understanding of the spatial-temporal characteristics of tumor microenvironment alterations during progression and response to therapy.

#2709 Disrupting cancer fitness and pro-tumorigenic fibroblast functions with a first-in-class Pin1 degrader.

Melvyn Chow[1], Morgan O'Shea[1], Lilly Ein[1], Julie Arnold[1], Sydney Alnemy[1], Erica Dube[1], Pradeep Kota[1], Guosen Ye[1], Ronan Hanley[1], Andrew Good[2], Kristin Brown[1], Catherine Sabatos-Peyton[1], Emily Corse[1], Sebastian Hayes[1], Krista Goodman[1]

[1]Larkspur Biosciences, Inc., Cambridge, MA,[2]CAnDiD Consulting, Wallingford, CT

Background: Pin1 plays a pivotal role in regulating cellular processes including growth and differentiation by catalyzing the cis-trans isomerization of peptidyl-prolyl bonds in phosphorylated proteins. As a key gene involved in cancer cell fitness, Pin1 promotes tumor progression and maintains the immunosuppressive tumor niche. Research has extensively documented how Pin1 acts as a catalyst in both the initiation and progression of malignancies by modulating the stability and activity of oncogenes and tumor suppressors such as p53, c-Myc and NF-κB. These interactions underline Pin1's significant role in the intrinsic biology of cancer, influencing cell cycle progression, apoptosis, and cellular senescence. Beyond its direct effects on cancer cell intrinsic pathways, Pin1's influence extends to the tumor microenvironment, the supportive niche a tumor creates to support growth and metastasis. Recent studies have identified Pin1 as a driver of cancer-associated fibroblast (CAF)-mediated suppression, particularly in colorectal cancer, breast cancer and pancreatic cancer. In this study, we present the discovery of a reversible, first-in-class Pin1 degrader. Our findings reveal how Pin1 degradation not only disrupts cancer cell fitness but also reprograms fibroblast phenotypes.
Methods: Our research employed a set of in vitro experiments with Pin1-targeting strategies applied to various colorectal cancer and fibroblast cell lines. The impact on the cancer fitness and fibroblast phenotypes was assessed through a detailed cell phenotype and protein analysis using a combination of imaging analysis, ELISA, and Western Blot techniques.
Results: We demonstrate that targeting Pin1 significantly reprogrammed fibroblast phenotypes, steering them away from a pro-tumorigenic state. We disclose a first-in-class selective Pin1 degrader which phenocopies knockout effects on CAF and cancer cell interactions. We further show that Pin1 degradation or KO has a profound impact on multiple drivers of tumor fitness and fibroblast-mediated suppression. Notably, Pin1 degradation disrupts cancer cell communication with their surrounding microenvironment, leading to reduced tumor growth and decreased survival.
Conclusions: These findings highlight Pin1's pivotal role in driving critical cellular and molecular mechanisms in cancer. Our study demonstrates the potential of a bifunctional Pin1 degrader to selectively and efficiently target Pin1 in both CAFs and cancer cells, altering CAF phenotypes and disrupting mechanisms essential for cancer cell fitness and viability.

#2710 Establishment of a co-culture model to investigate the effects of chemotherapy in pancreatic periampullary intestinal adenocarcinoma.

Panagiotis Sarametidis[1], Jojanneke Stoof[1], Laura Ivers[1], Jean Murphy[2], Niall Swan[2], Luca Benigno[2], Fiona Hand[2], Kevin Conlon[2], Paul Mullan[3], Maeve Lowery[4], Naomi Walsh[1]

[1]Dublin City University, Dublin, Ireland,[2]St.Vincent's University Hospital, Dublin, Ireland,[3]Queen's University, Dublin, United Kingdom,[4]Trinity St James Cancer Institute, Dublin, Ireland

Introduction: Periampullary adenocarcinoma (PAC) refers to cancers originating from the head of the pancreas (60%), ampulla of Vater (20%), distal common bile duct (10%), and duodenum (10%). The pancreatic tumor microenvironment (TME) plays a critical role in driving progression and therapeutic resistance in pancreatic cancer, with cancer-associated fibroblasts (CAFs) emerging as key contributors. CAFs, a heterogeneous population within the TME, are central to stromal remodeling through interactions with tumor cells and immune components. Understanding CAF phenotypes is essential to unravel their role in PAC biology and to identify novel therapeutic targets.

Methods: Patient-derived tumor organoids (PDTOs) and CAFs were isolated from primary PAC specimens. Tissue was minced, digested, and dissociated into single cells. Tumor cells were seeded into 3D domes within a basement membrane extract (BME) and cultured in supplemented medium. CAFs were seeded in 2D and allowed to attach. KRAS mutations were analyzed using Sanger sequencing, and CAFs subtypes were characterized through immunofluorescence staining for key markers. Co-cultures of organoids and CAFs were formed at a 1:4 ratio, stained with CellTracker Dyes and their growth was monitored over 2 weeks by microscopy. Flow cytometry was used to characterize T cell subpopulations from PBMCs. Advanced co-cultures were used to measure cytotoxicity and immune efficacy.

Results: PDTOs and CAFs were successfully derived and cultured from PAC specimens, both confirmed as KRAS wild type. All 3 isolated CAF lines expressed fibroblast markers Smooth Muscle Actin alpha (α-SMA) and vimentin. CAFs showed heterogeneous intensity and expression of specific myofibroblastic (myCAFs) markers like Platelet Derived Growth Factor Receptor (PDGFR) and inflammatory CAFs (iCAFs) markers, like Fibroblast Activation Protein (FAP). Co-culture of $PDGFR^{+}/FAP^{-}$ myCAFs with PDTOs at increasing concentrations of cisplatin showed a 4.0 and 6.8-fold increase in the IC_{50} of the co-culture compared to PDTOs and CAFs alone, respectively. Co-culturing a heterogenous myCAF/iCAF population with PDTOs and treatment with cisplatin, showed no induction of resistance (IC_{50} co-culture 6.6 μM) compared to organoids alone (IC_{50} 9.5 μM), and CAFs alone (IC_{50} 9.4 μM). Enrichment of T cells from PBMCs revealed 95% T cell viability, of which 26.9% were cytotoxic, 63.1% were helper T cells, 4.3% were double positive ($CD4^{+}CD8^{+}$) and 5.7% were double negative ($CD4^{-}CD8^{-}$).

Conclusion: PDTOs and CAFs serve as a useful model for studying the cellular heterogeneity of PAC *in vitro*. CAF subtypes based on protein markers exhibit both tumor-promoting effects and increased cisplatin resistance. High viability and enrichment of T cells for co-culture models will provide valuable insights into PAC biology and support testing strategies targeting the TME.

#2711 Deciphering transcriptional activity of the tumor microenvironment for robust stratification of chemotherapy response in triple-negative breast cancer.

Yaoyi Dai[1], Xiaoxi Pan[2], Shaolong Cao[3], Shuai Guo[4], Shuangxi Ji[5], Matthew Montierth[1], Yujie Jiang[6], Leming Shi[7], Gloria V. Echeverria[8], Lucy Yates[9], Johan Staaf[10], Bora Lim[11], Yinyin Yuan[2], Wenyi Wang[4]

[1]Quantitative and Computational Biology, Baylor College of Medicine, Houston, TX,[2]Department of Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston, TX,[3]Biogen inc., Cambridge, MA,[4]Department of Bioinformatics and Computational Biology, The University of Texas MD Anderson Cancer Center, Houston, TX,[5]Department of Bioinformatics and Computational Biology, Eisai Co., Ltd., Nutley, NJ,[6]AbbVie Inc., North Chicago, IL,[7]School of Life Sciences and Human Phenome Institute, Fudan University, Shanghai, China,[8]Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX,[9]Wellcome Sanger Institute, Hinxton, United Kingdom,[10]Laboratory Medicine, Lund University, Lund, Sweden,[11]Department of Breast Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX

Background: Triple-negative breast cancer (TNBC), defined by the absence of estrogen receptor, progesterone receptor, and HER2 expression, represents an aggressive subtype with poor prognosis due to limited therapeutic options beyond chemotherapy. Current molecular subtyping methods fail to predict outcomes despite known tumor-immune-stromal interactions. The tumor microenvironment (TME) influences treatment resistance, yet capturing its complex dynamics remains challenging. TNBC demonstrates distinct features between European and Asian populations, suggesting ethnicity-specific disease mechanisms. Development of biomarkers capable of delineating TME features holds promise for improving TNBC treatment outcomes across ethnic groups.

Methods: We applied our previously proposed pan-cancer biomarker TmS (tumor-specific total mRNA expression, Cao et al. Nature Biotechnology 2022) to 575 chemotherapy-treated TNBC patients from four cohorts (The Cancer Genome Atlas [TCGA], Molecular Taxonomy of Breast Cancer International Consortium [METABRIC], Sweden Cancerome Analysis Network-Breast [SCAN-B], and Fudan University Shanghai Cancer Center [FUSCC]). TmS analysis uses integrative deconvolution of matched RNA/DNA sequencing data to measure per cell per haploid total mRNA ratio for tumor versus non-tumor cells. Using recursive partitioning on survival outcomes, patients were stratified into high/low TmS groups. We performed survival analyses, gene set enrichment analysis, cell type deconvolution, and computational histology on H&E images.

Results: Across all cohorts, low-TmS patients (n=325) presented significantly faster progression of TNBC (log-rank test P value < 0.05, hazard ratio = 0.1-0.53). The high vs. low TmS dichotomization represents a novel independent biomarker distinct from Lehman's TNBCTypes. TmS stratification is independent of clinical markers including BRCA mutation status, tumor mutation burden and Ki67. Mechanistically, high-TmS tumors (n=250) showed distinct TME features with enhanced immune activation in the Western cohorts but not in the Asian cohort, while low-TmS tumors demonstrated immune exclusion with extra-cellular matrix (ECM) enrichment. These molecular distinctions were validated by computational histology showing increased stromal barriers in low-TmS tumors (Kruskal test, adjusted P value < 0.05), suggesting potential ECM-targeted therapeutic strategies.

Conclusions: TmS represents a clinically actionable biomarker capturing TME characteristics in TNBC. Its ability to summarize distinct TME states across diverse populations is ideal for patient stratification. The identification of ethnic-specific TME patterns and ECM-related targets in low-TmS tumors offers new therapeutic opportunities for chemotherapy-resistant TNBC.

#2712 Therapy-induced senescence promotes tumor immunosuppression in cholangiocarcinoma.

Binbin Li, Meina Cai, Jingchun Yang, Sumera Ilyas

Division of Gastroenterology and Hepatology, Mayo Clinic, Binbin Li (Individual), Rochester, MN

Background and Aims: Senescent cells are characterized by high expression of markers including $p16^{INK4A}$, $p21^{cip1}$, and production of a senescence-associated secretory phenotype (SASP). Therapy-induced senescence can be triggered by cytotoxic drugs and can promote resistance to further chemotherapy and immunotherapy. Cholangiocarcinoma (CCA) is a highly lethal tumor with an abundance of immunosuppressive cells such as myeloid-derived suppressor cells (MDSCs). We have demonstrated that cancer cells can leverage noncanonical proapoptotic tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) signaling to foster MDSC accumulation in murine CCA (PMID: 38219900). We hypothesize that senescent cancer cells may be an important source of TRAIL. In this study, we aim to dissect the effects of TIS on CCA tumor growth and the tumor immune microenvironment (TIME).
Methods: Sequential immunofluorescence (IF) was conducted on resected human CCA specimens. Using murine models of CCA (PMID: 29464042; 38458319), murine CCA cells (SB cells) were implanted into livers of WT C57BL/6J male mice. Mice were treated for two weeks with the potent senescence inducers, alisertib, etoposide, or doxorubicin. Mice were sacrificed and tumor and TIME characterization were conducted. *In vitro* functional studies employed murine bone marrow (BM)-derived MDSCs treated with conditioned medium (CM) from proliferating or senescent. murine (SB) cells, then co-cultured with CD8 T cells isolated from murine splenocytes.
Results: Using IF, we demonstrated the majority of $p16^+$ and $p21^+$ senescent cells in human CCA are cancer cells, rather than stromal cells. Both $p16^+$ and $p21^+$ cancer cells were increased in tumors from patients who have undergone cytotoxic therapy with gemcitabine/cisplatin (Gem/Cis). *In vivo* senescence induction led to an increase in MDSC abundance and reduced cytotoxic T lymphocyte infiltration in mice. Incubation of BM-MDSCs with CM from senescent cancer cells enhanced MDSC viability and suppressive function. scRNA seq data demonstrated that *TRAIL*$^+$ human CCA cells have higher expression of a senescence signature compared to *TRAIL*$^-$ cells. Senescence inducing therapy also significantly increased *Trail* expression in murine tumors *in vivo*. Mechanistically, incubation of BM-MDSCs with senescent murine CCA cells with deletion of *Trail* significantly decreased MDSC viability.
Conclusion: we have demonstrated that senescent cancer cells accumulate in tumors from patients treated with standard-of-care therapy with Gem/Cis. Senescent cancer cells enhance the abundance and suppressive function of MDSCs via TRAIL. Thus, senolysis has the potential to rewire the TIME, and augment response to systemic therapy.

#2713 Characterization of GM-CSF and G-CSF expressing cell subtypes in the tumor microenvironment using the Integrated MultiOmyx-RNAscope assay.

Courtney Todorov, Kevin Gallagher, Victoria Huang, Harry Nunns, Marianne Thio, Eric Leones, Flora Sahafi, Erinn A. Parnell, Qingyan Au

NeoGenomics, Aliso Viejo, CA

Granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) are cytokines known to stimulate differentiation and activation of granulocytes, monocytes, macrophages, and dendritic cells (DCs) as well as non-immune cells including endothelial, epithelial and fibroblasts. GM-CSF and G-CSF can be produced by many different cell types, including immune cells, fibroblasts, endothelial cells and have also been shown to be upregulated in multiple human cancers. Studies have further demonstrated the immune-modulatory effects of GM-CSF/G-CSF can promote both anti-tumorigenic or pro-tumorigenic activity through regulation of neutrophils/M1 macrophages/T-effectors or myeloid-derived suppressor cells (MDSCs)/M2 macrophages/Tregs, respectively. Therefore, modulators to promote or reduce the activity of GM-CSF/G-CSF have been explored for tumor therapeutic intervention, often in combination with other therapies such as chemotherapy. However, to further dissect and target anti or pro-tumor GM-CSF/G-CSF modulation requires a better understanding of the distribution and identity of GM-CSF/G-CSF secreting cells within the tumor micro-environment (TME). To characterize GM-CSF/G-CSF expression in the TME, we use the Integrated MultiOmyx-RNAscope platform. MultiOmyx^{TM} (NeoGenomics Laboratoies, Inc) is a proprietary multiplex immunofluorescence (mIF) platform for the visualization and characterization of up to 60 protein biomarkers in a single formalin-fixed paraffin-embedded (FFPE) section and offers high-resolution spatial and quantitative analysis of protein expression in tissue samples. RNAscope^{TM} (Bio-Techne) Multiplex is a highly sensitive fluorescent in-situ hybridization (ISH) assay that can detect up to 3 RNA markers in a single FFPE section. The Integrated MultiOmyx-RNAscope assay allows for simultaneous detection of both protein and RNA markers in a single sample. Herein we report the design and use of a novel panel of commercially-available RNAscope ISH probes and IF antibodies broad enough to characterize GM-CSF and G-CSF subpopulations in the TME of a variety of tumor indications including lung, prostate, melanoma, and colon cancer. Using this panel in combination with proprietary deep-learning based image analysis, GM-CSF and G-CSF expressing cells can be characterized into different immune and TME subtypes. Understanding of the variety and phenotype of GM-CSF and G-CSF expressing cells in the TME will help improve the understanding and development of targeted therapies for cancer treatment.

MOLECULAR/CELLULAR BIOLOGY AND GENETICS: Epigenetic Mechanisms and Therapeutic Implications in Cancer Poster Session

#2716 Role for KMT2C mutation in endometrial cancer pathogenesis.

Juveria Ali[1], Swornalata Pukhrambam[1], Sophia Agrusa[1], Areebah Qazi[1], Jessica Back[1], Greg Dyson[1], Michele L. Cote[2], Anna Gottschlich[1], Mike R. Wilson[1]

[1]Wayne State University, Detroit, MI,[2]Indiana University, Indianapolis, IN

Background: Endometrial cancer (EC) is the 4th most common cancer to be diagnosed in women. Although EC has reasonable survival rates, there is a disparity gap for African American (AA) women, as they are twice as likely to succumb to metastatic EC. They are also more likely to develop the more severe subtype, uterine serous carcinoma (USC), and high-grade EC. HER2-positive USC can be treated with Trastuzumab, but response varies. The KMT2C gene encodes a lysine methyltransferase involved in histone modification and transcriptional coactivation. Through a meta-analysis of multiple datasets, we identified KMT2C as highly mutated in High Grade Serous Endometrial Cancer (HGSEC) tumors from AA patients when compared to Non-Hispanic White patients. KMT2C was the top gene mutated when comparing differential mutation rates from this data.
Methods: To explore the relationship between KMT2C and EC, we transfected 12Z endometrial epithelial cells with KMT2C siRNA to induce transient knockdown and performed western blots with the transfected protein lysates. Additionally, we transfected cells with plasmids containing green fluorescent protein (GFP), Cas9, and 3 different guide RNAs targeting KMT2C to generate stable knockouts. Flow cytometry isolated the GFP+ cells. Using those isolated 12Z CRISPRCas9 knockouts, we performed a final western blot.
Results: KMT2C knockdown led to decreased HER2 expression. KMT2C knockdown increased Arid1a expression and minimally increased Snail and Slug expression. GFP expression confirmed successful transfection. CRISPR KMT2C guide 1 silenced some isoforms of KMT2C.
Conclusion: Patients who have KMT2C mutations would likely be less responsive to Trastuzumab due to reduced expression of HER2. Arid1a is mutated in about 10% of human cancers and Snail and Slug are markers of epithelial to mesenchymal transition (EMT), so their overexpression in the KMT2C knockdown may have serious implications. More testing should be done related to EC patients with KMT2C mutations and alternate treatment plans need to be explored for this vulnerable subpopulation.

#2717 Dual inhibition of PRC2 complex subunits EZH1/2 enhances DNA hypomethylation therapy in colorectal cancer.

Ashley K. Wiseman, Ali A. Chomiak, Rochelle Tiedemann, Yanqing Liu, Scott Rothbart

Van Andel Institute (VAI), Grand Rapids, MI

Aberrant DNA methylation patterning is an epigenetic hallmark of human cancers. DNA methyltransferase inhibitors (DNMTi) act by reversing these aberrant DNA methylation patterns and are clinically approved to treat hematologic cancers. However, there is limited evidence for clinical efficacy in solid tumors. Our prior work showed that compensatory transcriptional silencing through the Polycomb Repressive Complex 2 (PRC2) emerges following DNMTi to maintain epigenetic silencing of critical tumor suppressor gene networks. This provides mechanistic rationale for combining DNMTi with inhibitors of EZH2 (EZH2i), the most well studied lysine methyltransferase (KMT) subunit of PRC2 that catalyzes all three orders of lysine 27 methylation on histone H3 (H3K27me1/2/3). EZH1 is an interchangeable KMT subunit of the PRC2 complex whose role in cancer is less well studied. A small molecule screen of PRC2 inhibitors revealed that compounds targeting both EZH1 and EZH2 were more effective in combination with DNMTi than those that were selective for EZH2. Integrative proteomics and epigenomics analyses revealed a mechanism in which H3K27me1, supported by EZH1, blocks the activity of the lysine acetyltransferases p300/CBP towards the H3K27 substrate, which is critical for transcriptional activation downstream of DNMTi and EZH1/2i treatment. Collectively, these studies are defining the division of labor between the two KMT subunits of PRC2 in colon cancer cells, uncovering mechanisms of crosstalk between DNA methylation, histone methylation, and histone acetylation, and revealing therapeutic vulnerabilities that we propose are targetable with dual EZH1/2 inhibitors in combination regimens to enhance the clinical efficacy of DNMTi therapy.

#2718 Investigating the interaction of NF1 with the Polycomb Repressive Complex 2.

Asra Noor, Peng Zhang, Pinpin Sui, Feng-Chun Yang

University of Texas Health Science Center at San Antonio, San Antonio, TX

Neurofibromin 1 (NF1) is a tumor suppressor gene frequently mutated in myeloid leukemias. The encoded neurofibromin protein negatively regulates the RAS pathway in the cytosol. Inactivating mutations in NF1 lead to hyperactive RAS signaling, phenocopying activating mutations in RAS itself. This aberrant signaling drives downstream activation of pathways such as MAPK and PI3K/Akt/mTOR. *Despite the prevalence of NF1-mutated leukemia, effective therapies remain elusive, highlighting the need for a deeper understanding of NF1-mediated leukemogenesis*. To identify key dysregulated genes in NF1-driven leukemogenesis, we performed bulk RNA sequencing on hematopoietic stem cells from Nf1 knockout mice exhibiting myelodysplastic syndrome. Gene set enrichment analysis revealed significant dysregulation of pathways involved in histone methylation and RNA modification. Etv4, Id2, and Bcl6 were among the top upregulated genes, although their dysregulation is likely secondary to RAS activation. To uncover novel, non-canonical targets of NF1, we identified Phf19 as a dysregulated gene not directly regulated by RAS. PHD finger protein 19 (PHF19) is a component of the Polycomb Repressive Complex 2 (PRC2), a complex that mediates histone H3 lysine 27 trimethylation (H3K27me3) through the catalytic activity of EZH2. T*his finding is particularly intriguing as previous studies have suggested nuclear localization of neurofibromin, but its function in the nucleus has remained unclear.* To explore the potential nuclear role of neurofibromin, we employed TurboID proximity labeling to identify its interaction partners in both the nucleus and cytoplasm. We found that neurofibromin interacts with the core PRC2 components EZH2 and SUZ12 in the nucleus, a finding confirmed by co-immunoprecipitation. Ongoing studies aim to elucidate the functional consequences of Phf19 upregulation and the impact of the neurofibromin-PRC2 interaction on apoptosis, cell cycle progression, and proliferation in Nf1 knockout mouse model.

#2719 Decoding role of KMT5C-H4K20me3 in EGFRi resistance in non-small cell lung cancer.

Jihye Son[1], Alexandra Glaws[1], Christina Davidson[2], Ching-Hua Shih[2], Paula Vertino[2], Andrea Kasinski[1]

[1]Purdue University, West Lafayette, IN,[2]Wilmot Cancer Center, Rochester, NY

Epigenetic dysregulation has recently been recognized as a new hallmark of cancer, with dysregulation of chromatin remodelers estimated to affect 10-20% of cancer. Thus, understanding how epigenetic-based mechanisms contribute to cancer initiation and progression is critical. KMT5C is a histone methyltransferase that catalyzes histone H4 lysine 20 trimethylation (H4K20me3), which has historically been associated with formation and maintenance of constitutive heterochromatin regions. Perturbations in KMT5C-H4K20me3 in cancer has been extensively characterized, including our own work in which we discovered that loss of KMT5C promotes development of resistance to EGFR inhibitor (EGFRi) in EGFR-mutant non-small cell lung cancer (NSCLC) cells. Patient data further supports that the KMT5C transcript level is downregulated following resistance to osimertinib, a third-generation EGFRi. Here, we present data to support a non-canonical role for H4K20me3 where it regulates genes outside of heterochromatin. Notably, deposition of H4K20me3 in these regions occurs without the need for H3K9me3, which was thought to be a prerequisite for H4K20me3 deposition. This uniquely deposited H4K20me3 is associated with pathways such as DNA replication and cell cycle transition. H4K20me3 also co-localizes with activating histone modifications including H3K4me3, requiring additional studies to evaluate how dysregulation of H4K20me3 is involved in transcriptional programming in NSCLC to promote EGFRi resistance. Finally, we identifed the KMT5C interactome, which reveals novel interacting partners of KMT5C, potentially uncovering mediators of KMT5C dysregulation. Taken together, our findings unveil novel roles of KMT5C-H4K20me3 in regulating chromatin architecture and suggest etiological mechanism of KMT5C-driven EGFRi resistance in NSCLC.

#2720 Investigating the functional role of SUV420H1 in HPV-negative head and neck squamous cell carcinoma.

Arfa Moshiri[1], Sohyoung Kim[2], Marie Luff[1], Vassiliki Saloura[1]

[1]Thoracic and GI Malignancies Branch, National Cancer Institute, Bethesda, MD,[2]Laboratory of Receptor Biology and Gene Expression, National Cancer Institute, Bethesda, MD

Human Papilloma Virus (HPV)-negative head and neck squamous cell carcinoma (HNSCC) remains a significant clinical challenge due to limited treatment options and poor prognosis. *SUV420H1*, encoding a protein lysine methyltransferase (PMT) responsible for H4K20 trimethylation (H4K20me3), is recurrently amplified in approximately 5% of HPV-negative HNSCC tumors, indicating a potential oncogenic role. Our previous studies demonstrated that while SUV420H1 depletion using siRNAs reduced the proliferation and colony-forming capacity in HPV-negative HNSCC cell lines, enzymatic inhibition with the SUV420H1 inhibitor A-196 induced only a modest effect in these phenotypes. In this study, we generated enzymatically inactive SUV420H1 mutants with a confirmed decrease in global H4K20me3 levels and conducted proliferation and colony-forming assays which concordantly showed only a modest effect in these phenotypes. GSEA analysis of RNA-seq obtained from HPV-negative HNSCC cells treated with SUV420H1 siRNAs or the SUV420H1 inhibitor A-196 showed commonly enriched pathways, including EMT, cell cycle and proliferation, and interferon alpha response pathways. In vivo experiments using Suv420h1 knockout (KO) MOC1 mouse cell lines in a syngeneic HPV-negative HNSCC flank mouse model demonstrated a marked decrease in tumor size. Furthermore, tumor flow cytometry revealed increased CD8+ T-cell, B-cell and macrophage infiltration. These findings provide strong evidence for the role of SUV420H1 in modulating immune responses. Ongoing studies aim to evaluate the combinatorial impact of SUV420H1 depletion and anti-PD-1 therapy in vivo to determine whether SUV420H1 loss sensitizes tumors to immune checkpoint blockade. Collectively, our data supports SUV420H1 as a potential therapeutic target in HPV-negative HNSCC.

#2721 Mechanism Studies of HDACi combined with SP/KLF inhibitors in the treatment of H3K27M-mutant diffuse intrinsic pontine gliomas.

B. Wang[1], Y. Kong[2], X. Lv[2], H. Zhuang[3], X. Wu[2];
[1]UCSF, San Francisco, CA, [2]Tianjin Medical University, Tianjin, China, [3]UC San Diego, San Diego, CA

Diffuse intrinsic pontine gliomas (DIPGs) pose significant challenges in pediatric oncology with limited treatment options. Frequently harboring H3K27M mutations, these tumors are insensitive to histone deacetylase inhibitors (HDACi) in clinical trials for yet unclear reasons. Here we find that HDACi induce histone hyperacetylation including H3K27 acetylation, and increased accessibility at genomic regions linked to tumor microenvironment adaptation and invasiveness. And these regions gain occupancy of the SP/KLF family of transcription factors. Encouragingly, targeted intervention with EC-8042 effectively reverses this activated regulatory network by HDACi, thereby mitigating tumor adaptation and invasiveness. Furthermore, the combination of EC-8042 with HDACi enhances the repression of transcription in cell cycle-associated genes, leading to the inhibition of H3K27M-DIPG cell proliferation and impeding tumor progression in orthotopic xenograft models. Transcriptomic analysis further supports that the combination treatment drives transcriptional programs correlating with favorable prognosis in DIPG patients. Therefore, employing DIPG models, this study provides critical mechanistic understanding of the limited responsiveness to HDACi in solid tumors, thereby laying the groundwork for the innovation of novel combination strategies.

#2722 An added twist: drug-mediated pan-inhibition of KDM catalysis causes selective reduction of mRNAs that encode a small subset of KDM enzymes.

Hartmut Martin Hanauske-Abel[1], Mainul Hoque[1], Seema Husain[1], Sukhwinder Singh[1], Axel R. Hanauske[2], Patricia Soteropoulos[1]

[1]Rutgers New Jersey Medical School, Newark, NJ,[2]Technical University, Munich, Germany

Background: The class of 2-oxoglutarate-requiring mono-iron dioxygenases (MIDOs) that demethylate specific lysine, histidine, or arginine residues of histones is receiving attention for its role in human diseases, in particular cancer (10.1016/j.ejmech.2022.114143). The steric events during MIDO catalysis were resolved at subatomic scale in 1982 by two students at Philipps University, Marburg/Germany (HAG mechanism [10.1016/0022-5193(82)90320-4, 10.1016/0022-5193(82)90320-4]). They presented a classification of all *conceivable* inhibitors and rapidly reduced their seminal approach to practice, establishing pyridine dicarboxylates and oxalylglycines as MIDO inhibitors, now in global use. In 1995, Cornell researchers employed HAG metrics to identify, among FDA-approved drugs, deferiprone (DFP) as MIDO inhibitor, enabling control of key protein families *in vitro* and *in vivo* (e.g. US-6080766-A). In 2019, DEF was identified as pan-selective inhibitor of histone lysine demethylating MIDOs (KDMs [10.1038/s41598-019-39214-1]). KDMs have, beyond their enzymatic activity, critical non-enzymatic functions in the physical assembly of the transcriptional machinery (10.3390/ijms25136900). We noted that DFP not only inhibits key MIDOs at clinically relevant serum concentrations, but also decreases selectively their encoding mRNAs, a precondition for reducing their biosynthesis.

Hypothesis: DEF not only inhibits KDM catalysis pan-selectively, but also reduces the biosynthesis of particular KDMs via knockdown of their mRNAs.

Methods: Cell culture of ARK1; repeated, timed (12/24/48 hrs) RNA-Seq using clinical concentrations of DFP (and deferoxamine [DFOX] to test for iron depletion); flow cytometry for MIDO-dependent proteins (collagens, collectins, fibrillins) to confirm biologically effective intracellular/intracompartmental concentrations of DFP.

Results: mRNAs encoding 15 histone lysine demethylating MIDOs were detected. 11 mRNAs for KDMs were expressed irrespective of time point monitored, duration of DFOX (15 µM) or DFP (100 and 150 µM) exposure, or DFP concentration. These non-reactive mRNAs were: KDM2A, 3B, 4A, 4C, 4D, 5A-C, 6A, 7A, 7C. The expression of KBM2B, KBM3A, KBM4B, and KBM6B increased at least 1.8 fold between 12 and 48 hrs. (FDR p <0.00000) in controls, with marginal effect of DFOX. By contrast, DFP uniformly abolished this rise of expression, causing 2-fold reductions of the four mRNAs relative to controls at 48 hrs. The slopes of the dose-response curve changed markedly, e.g. from +3 in control to below -0.5 for KBM2B, KBM3A, and KBM4B on DFP. Remarkably, at 12 hrs. DFP *increased* their mRNAs distinctly above controls, e.g. doubled KDM3A expression. The disruptive DFP effects were fully evident at 100 µM.

Conclusions: Drug inhibition of KDM catalysis can reduce KDM expression, thus also affecting non-enzymatic KDM functions.

#2723 Unveiling epigenetic mechanisms driving RasGRP3 upregulation via oncogenic Gαq signaling in uveal melanoma.

Zaizhou Liu, Boris Bastian, Xu Chen

UCSF - University of California San Francisco, San Francisco, CA

Uveal melanoma (UM) is a rare but aggressive cancer originating from melanocytes within the eye. It is distinct from cutaneous melanoma (CM) and genetically defined by somatic mutations activating the Gαq signaling pathway, most commonly affecting the Gαq subunits GNAQ or GNA11. UM remains a highly lethal melanoma subtype that cannot be effectively treated by current treatment regimens, including immune checkpoint blockade and targeted therapies. RasGRP3 (RAS Guanyl Releasing Protein 3), a guanine nucleotide exchange factor (GEF) for Ras, is markedly (>100-fold mRNA levels compared to CM) and selectively upregulated in UM and serves as a critical signaling hub connecting Gαq signaling to the MAPK pathway. Elucidating the mechanisms underlying the RasGRP3 upregulation unique for UM promises to unveil alternative therapeutic targets. We compared the epigenetic landscape of the RasGRP3 locus in UM and CM cells using ChIP-seq for H3K27ac (marking active enhancer/promoters), H3K4me1 (active enhancers), and H3K4me3 (active promoter). In UM but not CM cells, the RasGRP3 locus was highly enriched for H3K27ac and H3K4me1 modifications, and two of its three transcription start sites were marked with elevated H3K4me3 levels, indicating the expression of two major isoforms in UM. Treatment of UM cells with the Gαq inhibitor YM-254890 (YM) or the PKC inhibitor LXS-196 (LXS) for 24 hours significantly reduced all three histone modifications (H3K4me3, H3K27ac, H3K4me1) at the RasGRP3 locus. No changes were observed in CM cells. Our findings indicate an active super-enhancer that regulates RasGRP3 expression in UM, which is under control of the Gαq pathway through epigenetic modifications at its promoter and enhancer regions. These findings explain the selective upregulation RasGRP3 characteristics of UM. Ongoing investigations aim to delineate the precise mechanisms by which Gαq signaling drives these epigenetic changes. Our results highlight the potential of targeting specific histone modifiers as a novel therapeutic strategy for UM treatment.

#2724 TGF-β signaling activity induces co-localization of both H4K20me3 and H3K27Ac at active enhancers during breast cancer epithelial-to-mesenchymal transition.

Bachelard Dieujuste, Christina Davidson, Ching-Hua Shih, Laura McLane, Paula Vertino

Biomedical, Genetics and Genomics, University of Rochester School of Medicine & Dentistry, Rochester, NY

In 2022, 2.3 million women worldwide were diagnosed with breast cancer, and more than670,000 breast cancer-related deaths were reported. A leading contributor to breast cancer mortality is metastatic progression driven in part by the epithelial-to-mesenchymal transition (EMT). EMT is a reversible plastic state during which cancer cells spread beyond their primary environment. This plasticity in cell states can be mediated by epigenetic factors that influence gene expression through the regulation of chromatin accessibility. Our lab and others found that inhibition of Suv420H2/KMT5C, the methyltransferase that tri-methylates lysine 20 of histone H4 (H4K20), is typically associated with gene repression that promotes EMT in breast epithelial cells, suggesting that Suv420H2-mediating H4K20me3 plays a role in regulating epithelial vs. mesenchymal identity. To further dissect the role of H4K20me3 in EMT plasticity, MCF10Aimmortalized breast epithelial cells were treated with transforming growth factor-β1 (TGF-β1); a growth factor that acts as a tumor suppressor by limiting cell proliferation but can also promote tumor progression by driving EMT. Using a TGF-β treatment, recovery, and rechallenge approach followed by RT-qPCR analysis, I confirmed that TGF-β triggers EMTs by upregulating mesenchymal marker genes, such as EMT-transcription factors (ZEB1 and SNAI1/2), and downregulating epithelial marker genes (E-cad and EpCAM). In addition, cells gain a fibroblast-like morphology. TGF-β-induced EMT was reversible in response to TGF-β withdrawal during which cells regain their baseline morphology and re-express epithelial marker genes, showing a plastic state behavior. Additionally, we performed both a Cleavage Under Targets and Tagmentation and a Precision Run-On Sequencing on MCF10A cells to identify H4K20me3 distribution and nascent transcription activity. Collected data have revealed TGF-β-induced regions that gain H4K20me3, and these regions also acquire histone H3 lysine 27 acetylation (H3K27Ac), an epigenetic mark associated with active promoter and enhancer regions in response to TGF-β. TGF-β-induced H4K20me3 and H3K27Ac co-localization sites are transcriptionally active and distal to transcriptional start sites, suggesting that they may be active enhancers. The significant accumulation and co-localization of both H4K20me3 and H3K27Ac at active enhancers in response to TGF-β suggests that H4K20me3 may have additional functions, beyond that of its known role as a repressor. A better understanding of the role of TGF-β-induced H4K20me3 sites at active enhancers in the context of EMT will provide insight to better target epigenetic modifiers to prevent breast cancer progression.

#2725 Noncanonical regulation of genes by KMT5C-H4K20me3 in EGFR inhibitor resistant non-small cell lung cancer.

Alexandra Glaws, Jihye Son, Andrea Kasinski

Purdue University Institute for Cancer Research, West Lafayette, IN

Lung cancer is the leading cause of all cancer-related deaths, with non-small cell lung cancer (NSCLC) making up ~85% of lung cancer cases. Activating mutations in the epidermal growth factor receptors (EGFR) are associated with NSCLC development, comprising ~32% of patients. Standard treatment for NSCLC patients involves targeting EGFR mutations with EGFR inhibitors (EGFRi), yet most patients develop resistance to EGFRi over time. Approximately 55% of the mechanisms involved in EGFRi resistance involve EGFR T790M secondary mutations; however, nearly 15% of these mechanisms are unknown. We have previously shown that the loss of KMT5C drives resistance to EGFRi in EGFR-mutant NSCLC cells. Patient data further supports that the KMT5C transcript level is downregulated following resistance. KMT5C is a histone methyltransferase that catalyzes the trimethylation of H4K20 (H4K20me3), a repressive modification historically known for the involvement of heterochromatin formation and maintenance. KMT5C recruitment through H4K20me3 to heterochromatic regions is a well-known mechanism occurring in H3K9me3-dependent manner. Our preliminary data also suggests KMT5C-H4K20me3 is associated with the regulation of gene-rich euchromatin regions; yet the mechanism of recruitment remains unknown. We hypothesize that recruitment of KMT5C to euchromatin is distinct from the mechanism involved in KMT5C recruitment to heterochromatin. Here, we study the interactome of KMT5C using an unbiased proximity labeling technique, BioID, and aim to identify factors that form a novel complex with KMT5C to enable the recruitment of KMT5C to its target genes in euchromatic regions that drive resistance to EGFRi.

#2726 A circadian regulator drives tumor lineage plasticity through chromatin bivalency resolution.

Y. Yang[1], X. zhang[1], h. zou[1], E. Corey[2], R. Evans[3], A. Zoubeidi[4], H. Chen[1];
[1]UC Davis, Sacramento, CA, [2]University of Washington, Seattle, WA, [3]Salk Institute for Biological Sciences, La Jolla, CA, [4]University of British Columbia, Vancouver, BC, Canada

Chromatin bivalency plays an important role in cell lineage specification during development. Cancer therapy resistance involves an extensive reprogramming of gene expression resulting in tumor lineage plasticity (LP). However, the underlying mechanisms are poorly understood. Rev-erb-alpha, a member of the nuclear receptor transcription factor family, plays a key role in regulation of circadian rhythm and metabolism primarily through repression of its target genes. We performed sequential ChIP-seq epigenome profiling of tumor tissues from the clinic and PDX models of prostate cancer and integrated analysis of tumor epigenome and transcriptome. We also treated the PDX models with small-molecule inhibitors of the receptor. We found that most of the tumor LP genes, including those in programs of neurodevelopment, neural signaling, stemness and EMT, are controlled by bivalent promoters with concurrent marking of H3K27me3 and H3K4me3. Our further studies revealed that the bivalent chromatin state resolves during the development of cancer therapy resistance. Interestingly, Rev-erb-alpha plays a critical role in promoting the bivalency resolution and activation of the LP programs. Its pharmacological targeting effectively reverses the bivalency resolution and diminishes the LP in anti-AR therapy-resistant tumors. Therefore, our study establishes that resolution of chromatin bivalency is a major epigenetic mechanism of tumor LP and demonstrates that therapeutic targeting of Rev-erb-alpha represents a novel treatment of advanced prostate cancer.
Keywords: Lineage plasticity; Bivalent chromatin; Rev-erb-alpha; Prostate cancer.

#2727 Histone deacetylase (HDAC1) and IKAROS are critical regulators of histone methylation and epigenomic landscape in T-cell acute lymphoblastic leukemia.

Jiaxing Tan[1], Yali Ding[1], Bing He[1], Daniel Bogush[1], Joseph Schramm[1], Chingakham Singh[1], Diwakar Tukaramrao[1], Charyguly Annageldiyev[2], Avinash Kudva[1], Dhimant Desai[3], Arati Sharma[3], Sinisa Dovat[1]

[1]Department of Pediatrics, Penn State College of Medicine, Hershey, PA,[2]Department of Medicine, Penn State College of Medicine, Hershey, PA,[3]Department of Pharmacology, Penn State College of Medicine, Hershey, PA

Objective: To dissect the role of IKAROS-HDAC1 complexes in global regulation of gene expression and chromatin landscape in T-ALL.

Methods: We studied IKAROS and HDAC1 role in epigenomic regulation of gene expression in primary human T-ALL, *IKZF1*-null human T-ALL, *Ikzf1*-null mouse T-ALL cells and following IKZF1-re-introduction into IKZF1-null human and mouse T-ALL cells. We used ATAC-seq and ChIP-seq of IKAROS, HDAC1, Enhancer of zeste homolog 2 (EZH2), along with CUT&Tag of histone modification markers, coupled with RNA-seq to study dynamic effect of IKAROS in *IKZF1*- null T-ALL and at several time points following *IKZF1* re-introduction.

Results: Deletion of IKZF1 results in severely reduced HDAC1 DNA occupancy and reduced H3K27me3 enrichment. Re-introduction of *IKZF1* results in the increased HDAC1 recruitment to promoters, EZH2 re-distribution, and de novo formation of H3K27me3 facultative heterochromatin. This was associated with cessation of cellular proliferation and induction of T- cell differentiation. The newly-formed heterochromatin was often located at promoters of known oncogenes and the genes that promote cell cycle progression. In contrast, IKAROS binding to DNA, without concomitant HDAC1 recruitment results in increased H3K27 histone acetylation with de novo formation of active enhancers, characterized with H3K4me1+/H3K27ac+ and super- enhancers, with a broad enrichment of histone H3K27 acetylation across the large genomic areas. Pathway enrichment analysis showed that newly-formed active enhancers positively regulate genes that are involved in cell cycle suppression and T cell differentiation.

Conclusion: Our results demonstrated that IKAROS and HDAC1 are the key regulators of histone acetylation and epigenomic landscape in T-ALL. HDAC1 recruitment by IKAROS is critical for formation of facultative heterochromatin, while IKAROS DNA binding without HDAC1 promotes of histone H3K27 acetylation. Results provide novel insight into mechanisms of regulation of histone acetylation, gene expression and tumor suppression in T-ALL.

#2728 Lysine acetyltransferase inhibitor MG149 reduces tumor recurrence in triple-negative breast cancer.

Christiana O. Appiah[1], Manjulata Singh[1], Christiane Morecock[1], Aashka Shah[1], Abigail Andrews[1], Nasser Alabdulaly[1], Akash Jagdeesh[1], Sidney Umana-Guardado[1], Jonathan Yun[1], Laura Graham[2], Carson Walker[3], Madelyn Lorenz[4], Shengzhe Shang[3], Anthony Faber[5], Andrew Souers[6], Dipankar Bandyopadhyay[7], Steve Grant[8], Gordon Ginder[3], Jennifer Kobilinski[4], Harry D. Bear[2], Joshua C. Harrell[3], Joseph W. Landry[1]

[1]Department of Human and Molecular Genetics, Virginia Commonwealth University - VCU, Richmond, VA,[2]Departments of Surgery and Microbiology & Immunology, Virginia Commonwealth University - VCU, Richmond, VA,[3]Department of Pathology, Virginia Commonwealth University - VCU, Richmond, VA,[4]VCU OVPRI, Virginia Commonwealth University - VCU, Richmond, VA,[5]Department of Oral and Craniofacial Molecular Biology, Philips Institute for Oral Health Research, Virginia Commonwealth University - VCU, Richmond, VA,[6]AbbVie Inc, Chicago, IL,[7]Department of Biostatistics, School of Population Health, VCU Massey Comprehensive Cancer Center, Richmond, VA,[8]Department of Internal Medicine, Virginia Commonwealth University, Massey Cancer Center, Richmond, VA

Triple-negative breast cancer (TNBC) is an aggressive subtype of breast cancer characterized by the absence of estrogen receptor, progesterone receptor, and HER2 expression. This lack of targetable receptors makes TNBC particularly challenging to treat. Identifying therapeutic targets which can be targeted to prevent TNBC recurrence is crucial for developing better treatments. By studying mechanisms driving recurrence we hypothesized that post-therapy changes in cancer cell epigenetics contribute to recurrence and that using epigenetic drugs to inhibit these changes could reduce the likelihood of relapse and improve patient outcomes. Thus, the aim of this study was to identify novel epigenetic regulators of tumor recurrence in TNBC. Using TNBC cell line MDA-MB-231, we generated a model of recurrence using Doxorubicin (Doxo). We performed a drug screen using commercially available epigenetic inhibitors *in vitro* and *in vivo* to identify novel epigenetic regulators of tumor recurrence. Cell count (*in vitro*) and tumor volumes (*in vivo*) were used to determine the anti-tumor effects. Weight loss was used as an index of toxicity in mice. Supporting our hypothesis, we observed notable differences in the levels of various epigenetic regulators before and after Doxo treatment and during recurrence. Additionally, we discovered that certain epigenetic drugs could prevent recurrence in culture, but only when administered sequentially following Doxo exposure, and not when used in prepriming or in combination. Sequential administration of the KAT inhibitor MG149 effectively controlled tumor growth in NSG mice with MDA-MB-231 and PDX1 tumors. MG149 was also found to enhance the effectiveness of other standard chemotherapy drugs, including paclitaxel and cyclophosphamide. *In vitro* and *in vivo* studies showed that sequential use of MG149 with Doxo increases DNA damage (gamma H2AX) and apoptosis (annexinV/7AAD) and significantly reduces the expression of cell cycle inhibitors p21, p27, and p53. These findings suggest a model where suppression of cell cycle inhibitors and persistent DNA damage post-therapy exposure with MG149 leads to increased apoptosis, reduced recurrence from therapy, and enhanced tumor growth control. Our findings indicate that new epigenetic states are formed following chemotherapy exposure, which can be therapeutically targeted to prevent recurrence in TNBC.

#2729 Investigating the interplay between RNA methyltransferase PCIF1 and DNA hypomethylating drug decitabine in *TP53*-mutated acute myeloid leukemia.

L.-Y. Shiau[1], P.-S. Ko[2], K.-J. Chang[2], S.-H. Chiou[2];

[1]National Yang Ming Chiao Tung University, Taipei City, Taiwan, [2]Taipei Veterans General Hospital, Taipei City, Taiwan

PCIF1 is an RNA methyltransferase that interacts with RNA polymerase during transcription and catalyzes N^6,2'-O-dimethyladenosine (m6Am) modification on nascent mRNA, Decitabine (DAC), a DNA hypomethylating drug treating acute myeloid leukemia (AML), would activate hypermethylated genes in a way of non-specific action, which might inadvertently promote the expression of anti-apoptosis gene, leading to drug resistance. In this study, we unveil the role of the RNA modification m6Am and its writer protein PCIF1 in modulating AML's sensitivity to DAC. Utilizing KG-1a, a *TP53*-mutated AML cell line, we confirmed that the overexpression of catalytically active PCIF1 sensitizes leukemic cells to DAC treatment. This is evidenced by a higher apoptosis rate, increased S phase arrest observed through propidium iodide (PI) staining, and significant DNA demethylation on given genes detected via methylated DNA immunoprecipitation (MeDIP). Additionally, in terms of the second role of PCIF1 in this study, we noted elevated mRNA and protein levels of p21 in PCIF1 overexpressing cells, with p21 expression becoming even more pronounced following DAC treatment. RNA immunoprecipitation (RIP) confirmed increased direct binding of overexpressed PCIF1 to p21 mRNA. Correspondingly, there was no significant upregulation of well-established upstream regulators of p21, such as the p-Akt signaling pathway, DNA damage response cascade, or Sp1 protein. To elucidate the role of elevated p21 levels in modulating DAC's cytotoxic effects, we used Annexin-V-conjugated magnetic beads to separate dead and alive cells post-DAC treatment and found a skewed distribution of p21 in live cells. Moreover, treating PCIF1 overexpressing cells with a combination of DAC and UC2288, a p21 transcription inhibitor, proved more effective at eliminating leukemic cells than DAC alone. In short, we conclude that the second role of PCIF1 is promoting p21 expression through its catalytic function and further neutralizing the cytotoxicity effect of DAC. Nevertheless, the DAC-sensitizing pathway mediated by PCIF1 ultimately prevails, resulting in increased apoptosis in the PCIF1 overexpression model. Comparing the two axes, from a prognostic perspective for AML, high PCIF1 and low p21 expression levels appear to be more favorable. Clinical data from the TCGA LAML dataset supports this, showing significantly better survival rates in patients with high *PCIF1* and low *CDKN1A* (the gene name of p21 protein) expression compared to those with low *PCIF1* and high *CDKN1A* expression. These findings pave the way for clinical research to explore whether PCIF1 and p21 protein levels influence the response rate or prognosis of AML patients receiving DAC treatment.

MOLECULAR/CELLULAR BIOLOGY AND GENETICS: Epigenetic Mechanisms of Cancer Resistance and Progression Poster Session

#2733 Super-enhancers in oncogene upregulation in high-grade ovarian serous carcinoma proliferation and platinum-resistance.

Zhongmou Jin, Kristin Adams, Kendra Wendt, Josie Wood, Sydney Olson, Jessica D. Lang

Pathology, University of Wisconsin-Madison, Madison, WI

The most common subtype of ovarian cancer, High-Grade Serous Ovarian Carcinoma (HGSC), bears an exceptionally high level of chromosomal instability including chromosomal recombination and copy number variation. Many oncogenes are amplified in HGSC, of which some of the most frequently examined ones include MYC, PAX8 and CCNE1. Although downstream pathways of those genes have been repeatedly studied, epigenetic features of many of them are relatively unknown, as they could involve mechanisms that additively and continuously promote oncogene expression that may contribute to the aggressiveness of HGSCs. In our study, we specifically focus on super-enhancers (SEs), large transcriptional hubs known to drive oncogene expression. We aim to assess whether SEs are hijacked coordinately with copy number alteration in HGSCs. We were able to apply a multi-omic approach that includes bulk RNA sequencing, histone post-translational modification CUT&Tag, and Hi-C analysis to not only identify SE regions in HGSC cell lines but link them to the genes they regulate. With integration of these layers of data, we show that there is a positive correlation between HGSC SEs and gene expression changes in HGSCs, in the context of both cancer growth as well as drug resistance acquisition. We observed that SEs are almost always statistically associated with higher gene expression of their target genes compared to enhancers. We also explored changes in SEs in the context of platinum resistance acquisition in our HGSC cell lines, with the observation that gain of new SEs are associated with increase in gene expression and vice versa. Together, these findings support the possibility that SEs could be critical for essential oncogene expression and changes that lead to drug resistance. We then explored if the copy number amplification (CNA) known associated with cancer genome also plays a role in SE regulation of oncogene expression. We found in almost all HGSC cell lines tested that compared to non-oncogene-related SEs, oncogene-related SEs are significantly more likely to be in copy number amplified regions of the genome ($p < 0.001$), rendering it a potential mechanism contributing to SE associated oncogene upregulation. Based on this result, we are launching screens for specific SE-oncogene interaction in locating functionally important epigenetic marks with CRISPRi, as well as to leverage our existing Hi-C contact data in combination with long-read sequencing to understand the chromatin architecture in the context of CNV.In summary, in this study we observed promising trends supporting SE hijacking in oncogene upregulation and CNA as a potential factor that contributes to SE regulation. We hope that understanding the mechanisms and context behind epigenetic regulation may lead to rational use of epigenetic inhibitors for cancers driven by copy number alterations to otherwise untargetable oncogenes.

#2734 Exploring epigenetic control of immunogenicity in small cell lung cancer through multi-omics analyses.

Sana Parveen[1], Ramesh Adhinaveni[1], Meijun Du[1], Neshatul Haque[2], Tianxiang Liu[3], Kun Fang[3], Raul Urrutia[2], Victor X. Jin[3], Hui-Zi Chen[1]

[1]Medicine, Medical College of Wisconsin, Milwaukee, WI,[2]Linda T. and John A. Mellowes Center for Genomic Sciences and Precision Medicine, Medical College of Wisconsin, Milwaukee, WI,[3]Data Science Institute, Medical College of Wisconsin, Milwaukee, WI

Background: Small Cell Lung Cancer (SCLC) is an aggressive neuroendocrine malignancy characterized by epigenetic dysregulation. EZH2, a key component of the Polycomb Repressive Complex 2 (PRC2), is overexpressed in SCLC and correlates with poor prognosis. Recent studies show that EZH2 inhibition enhances SCLC cell immunogenicity, though the underlying mechanisms remain unclear.

Aim: This study investigates how EZH2 function alters the epigenetic landscape in SCLC using an integrated multi-omics approach. In SCLC cell lines treated with EZH1/2 dual inhibitor valemetostat, we examine changes in chromatin accessibility (ATAC-seq), three-dimensional chromatin organization (micro-C profile), and gene expression (RNA-seq).

Key Findings: Gene set enrichment analysis of RNA-seq data revealed upregulation of genes involved in antigen processing, presentation, and inflammatory response pathways following EZH1/2 dual inhibition in SCLC cell line H146. ATAC-seq analysis showed increased chromatin accessibility of genes with increased expression, primarily in distal regulatory regions. Crucially, we addressed the limitation of ATAC-seq in providing only one-dimensional accessibility information by performing Micro-C profiling. This approach confirmed that EZH1/2 dual inhibition led to the formation of neo-loops between accessible promoters and their enhancers. Specifically, we observed gained loops leading to increased HLA-B and HLA-C expression with valemetostat treatment. Validating these findings at the transcriptional and protein levels, qRT-PCR and flow cytometry analyses confirmed increased surface expression of pan-HLA molecules following valemetostat treatment. Functional inhibition of EZH1/2 was confirmed by Western blot analyses showing decreased H3K27me3 levels. These results collectively demonstrate that EZH1/2 controls gene expression in SCLC by establishing long-range interactions between promoter and enhancer elements through modulation of chromatin accessibility, ultimately impacting the expression of key immunogenic factors.

Conclusion: Our integrative multi-omics approach reveals a comprehensive model of EZH1/2 contribution to SCLC pathogenesis, highlighting its role in chromatin reorganization and gene expression regulation. Future work will focus on identifying additional therapeutically relevant genes within the EZH1/2-regulated network for potential intervention strategies.

#2735 The role of ca2 in regulating 3d chromatin structure in tamoxifen resistant breast cancer.

Lavanya Choppavarapu, Kun Fang, Tianxiang Liu, Aigbe G. Ohihoin, Victor X. Jin

Medical College of Wisconsin, Wauwatosa, WI

Background: Estrogen receptor-positive breast cancer frequently develops resistance to tamoxifen in one third of patients, driven by various mechanisms. Our work has linked 3D chromatin alterations to this resistance. However, most of the work in 3D chromatin regulation was mostly conducted in in vitro cell culture system. It is becoming very clear that to expand the characterization of 3D genome organization in patient samples is an emerging task.
Hypothesis: We hypothesize that 3D chromatin alterations, including compartment switching, TAD reorganization, and dysregulated chromatin looping, drive tamoxifen resistance (TR) in breast cancer. Looping-mediated genes may play critical roles in resistance and serve as potential therapeutic targets.
Methods and Results: To investigate the role of 3D chromatin changes in tamoxifen resistance, we performed Hi-C profiling on normal tissues (NTs), primary tumors (PTs), and tamoxifen-treated recurrent tumors (RTs), uncovering significant chromatin alterations. These included 46.8% A-to-B and 32.8% B-to-A compartment switching from NTs to PTs, and 58.3% B-to-A flipping during PT-to-RT progression. TAD analysis identified RT-specific Neo and Fuse alterations as well as tumor-specific chromatin loops. CA2 was identified as a enhancer-promoter looping (EPL)-mediated gene with its higher expression linked to poor relapse-free survival in endocrine-treated patients. Functional studies using the CA2 inhibitor brinzolamide demonstrated its ability to reduce cell viability, loop intensity, and CA2 expression in MCF7TR and T47DTR cells. In vivo, brinzolamide significantly reduced tumor growth in tamoxifen-resistant cell-derived xenograft (CDX) models. Additionally, CRISPR deletion of CA2 EPL enhancer region in MCF7TR cells resulted in a marked reduction in cellular viability, gene expression and protein expression.
Conclusion: Our findings suggest CA2 as a key looping-mediated gene play an oncogenic role in driving tamoxifen resistance in breast cancer. Our study yields significant mechanistic insights into the role and clinical relevance of 3D chromatin architecture in tamoxifen resistant breast cancer.

#2736 Mutation of histone H2A at glutamate 121 is frequently observed in cancer patient samples and promotes cancer-associated cellular properties.

Richard L. Bennett, Jixiu Shan, Anthony J. Lamberto, Rishika Cherukuru, Kimberly Espinoza Pereira, Pierre Priam, Jonathan D. Licht

University of Florida Health Cancer Center and Department of Medicine, University of Florida, Gainesville, FL

Background: Histones are essential proteins that facilitate DNA compaction into nucleosomes and chromatin fibers. Their dynamics are crucial for various cellular processes, including regulation of gene expression, cellular differentiation, maintenance of cell identity, DNA replication and DNA repair. By surveying the cBioPortal of Cancer genomics we previously found that approximately 11% of cancer patients had alterations of histone H2A genes, primarily missense mutations of unknown significance. The most commonly mutated H2A residue was a glutamate at amino acid position 121. Prior work by others has demonstrated that mutation of H2A at E121 caused decreased ACF-dependent nucleosome sliding *in vitro* and impaired yeast growth.
Objective: To determine the effect of the histone H2A glutamate to lysine mutation at amino acid 121 (H2A-E121K) on gene expression and cell growth properties relevant to cancer.
Methods: We expressed HA-tagged wild type or mutant histone H2A-E121K at near physiological levels in the lung epithelial cell line BEAS-2B using a "minigene" construct which drove expression from a native H2A promoter and 3' UTR regulatory region. Using live cell imaging we determined the effect of H2A-E121K on cell proliferation, apoptosis and migration in normal serum free media or growth factor deprived conditions. We measured the rate of serum-induced EMT signatures by immunoblotting for proteins such as claudin and cadherins. We investigated how expression of H2A-E121K may alter chromatin accessibility and gene expression by ATAC-seq and RNA-seq.
Results: Expression of H2A-E121K promoted both proliferation and survival of lung epithelial cell line BEAS-2B when cultured in normal media or under growth factor deprived conditions. The H2A-E121K mutant promoted colony formation. Cells expressing H2A-E121K had altered chromatin accessibility and gene expression compared to cells expressing WT H2A.
Conclusions: Expression of the histone H2A-E121K mutation promotes cancer-associated cellular properties in lung epithelial cells.

#2737 Enhancing the efficacy of DNA methyltransferase inhibitors in colon cancer through dual targeting of EZH1 and EZH2.
Rochelle Tiedemann, Alison Chomiak, Ashley Wiseman, Yanqing Liu, Scott Rothbart

Van Andel Institute (VAI), Grand Rapids, MI

DNA methyltransferase inhibitors (DNMTis) have shown limited success in solid tumors, despite the prevalence of aberrant DNA methylation and associated tumor suppressor gene silencing. Colon cancer cells exposed to DNMTi accumulate lysine 27 tri-methylation on histone H3 (H3K27me3), and we and others have proposed this EZH2-dependent repressive histone modification limits DNMTi therapeutic potential. Recently we demonstrated that low-dose DNMTi treatment, which mimics solid tumor exposure in patients, sensitizes colon cancer cells to EZH2 inhibitors (EZH2is) and synergistically upregulates tumor suppressor genes and transposable elements (TEs). Importantly, the observed synergy varies among EZH2 inhibitors. Molecules targeting both EZH2 and its interchangeable catalytic counterpart, EZH1, demonstrate superior efficacy in tumor suppressor gene activation and cancer cell growth inhibition. In this study, we profiled the epigenomic landscapes that result from combination therapy with DNMTi and EZH1/2i to understand how these compounds alter the transcriptional states of solid tumors. We show that dual EZH1/2i reduces all states of H3K27 methylation (me1/me2/me3), providing additional substrates for p300/CBP deposition of H3K27 acetylation (H3K27ac) and enhancing transcriptional outcomes. Furthermore, H3K27ac is required for tumor suppressor gene activation observed with combination DNMTi and EZH1/2i treatment. These results underscore the therapeutic promise of combining DNMTi with dual EZH1/2i to reprogram the epigenetic landscape, restore tumor suppressor gene activity, and enhance the efficacy of epigenetic therapies in solid tumor treatment.

#2740 Mechanisms of phase-separation driven chromatin looping in acute myeloid leukemia.

Tooba Rashid, Zachary Drum, Doris Cruz Alonso, Gelila Petros, Yoseli Quiroga, Douglas Phanstiel

UNC Chapel Hill, Chapel Hill, NC

New therapies are desperately needed for NUP98-fusion-driven Acute Myeloid Leukemia (AML) patients as they exhibit a poor prognosis on existing therapies, with a 5-year overall survival rate of ~30%. We and others have shown that one fusion, NUP98-HOXA9 drives leukemogenesis through the formation of liquid-liquid phase separated (LLPS) condensates. Specifically, NUP98-HOXA9 binds DNA and pulls bound regions into the nuclear condensates, forming 3D chromatin loops that activate oncogenes' transcription. Mutation of the phenylalanine-glycine (FG) repeats responsible for NUP98-HOXA9 phase separation abolishes the formation of these condensates and inhibits malignant transformation. These findings suggest a new class of chromatin loops, that form via a mechanism distinct from loop extrusion and drive oncogene expression. We set out to characterize the necessary components for the formation and maintenance of these aberrant loops. Using an Auxin Inducible Degron (AID) system in HCT116 cells, we rapidly degraded loop extrusion proteins, CTCF and RAD21, followed by in situ Hi-C to observe impact on loop formation. We observe approximately 8,000 canonical loops, which are bound by CTCF and lost upon auxin treatment. Additionally, we identify approximately 60 phase-separation driven loops, bound by NUP98-HOXA9 which do not require CTCF. We additionally explore the role of ATP, BRD4, and p300 as requirements for the formation of these loops. Future work includes further characterization of loop maintenance and screening for compounds to disrupt condensate formation with the goal of using a deeper understanding of phase-separation driven loops to create new promising therapeutic avenues for NUP98-fusion-driven AMLs.

#2741 Novel murine models of epigenetic dysregulation in SWI/SNF-mutated cholangiocarcinoma.

Jayla Millender[1], Jennifer Tomlinson[2], Ryan Watkins[2], Danielle Carlson[1], Jack Sample[2], Nathan Werneburg[1], Rory Smoot[2], Keith Robertson[3], Gregory Gores[1], Caitlin Conboy[4]

[1]Department of Gastroenterology & Hepatology, Mayo Clinic, Rochester, MN,[2]Department of Surgery, Mayo Clinic, Rochester, MN,[3]Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN,[4]Division of Medical Oncology, Mayo Clinic, Rochester, MN

SWI/SNF chromatin remodeling complexes are frequently mutated across human cancers, including cholangiocarcinoma (CCA). Dysregulation of this complex due to loss of function mutations in AT-rich interaction domain-1A (*ARID1A)* and polybromo-1 (*PBRM1)* occur in up to 18% and 10% of cases respectively. SWI/SNF subunit mutations frequently co-occur alongside PI3K/AKT pathway activation. Preexisting literature suggests altered gene expression and protein synthesis contribute to CCA oncogenesis, but our understanding of these mechanisms remains immature. Genetically accurate preclinical models are needed to define the roles of ARID1A and PBRM1 in CCA and identify therapeutic targets. We developed novel murine models of CCA with either *ARID1A*, *PBRM1* or dual *ARID1A/PBRM1* (APAC) knockout in the context of AKT activation, utilizing a surgical biliary transfection method for somatic gene editing with CRISPR/Cas9. Within 8 months, mice formed numerous liver tumors, predominantly CCA and mixed CCA/HCC. Knockout of *ARID1A* and *PBRM1* was confirmed through genomic PCR, qRT-PCR, and immunoblot assays. Histologically, murine APAC tumors displayed phenotypic similarities to human CCA, including dense cancer-associated fibroblast infiltration and variable CD45+ immune cell infiltration. A novel, syngeneic CCA cell line was isolated from a dual *ARID1A/PBRM1* knockout tumor (APAC-2). RNA-sequencing of primary tumors and the APAC-2 cell line versus a non-invasive cholangiocyte cell line with AKT activation only (AC), was performed to identify differentially expressed genes (DEGs) of interest in ARID1A and PBRM1-deficient CCA. Periostin (*Postn)* was among the top upregulated genes in the APAC-2 cell line. POSTN is a secreted glycoprotein that is upregulated in human CCA and may be therapeutically targetable. Knockdown of periostin inhibited the *in vitro* growth of APAC-2 cells and a human CCA cell line with *ARID1A* mutation and periostin overexpression (HuH-28). These studies serve to characterize and validate a genetically relevant murine model of epigenetic dysregulation in ARID1A and PBRM1-deficient CCA. This model can be used for identification and validation of potential drug targets. Ongoing work focuses on studying multiple dysregulated pathways and testing dependence on genes of interest, including periostin, as potential treatment strategies for CCA.

#2743 The H2B-E76K oncohistone alters chromatin accessibility, composition, and gene expression to induce EMT.

Pierre Priam[1], Kimberly Espinoza Pereira[1], Jixiu Shan[1], Anthony Lamberto[1], Jay Sarthy[2], Wuyue Zhou[3], Ciaran Seath[3], Richard L. Bennett[1], Jonathan D. Licht[1]

[1]Division of Hematology/Oncology, University of Florida, Health Cancer Center, Gainesville, FL,[2]Seattle Childerns's Hospital, Seattle, WA,[3]Herbert Wertheim UF Health Scripps Institute for Biomedical Research, Jupiter, FL

Background: Histones are essential nucleosome components that regulate DNA accessibility and transcription. Mutations in histones, such as H2B-E76K, are prevalent in various cancers, including lung and genitourinary cancers. The H2B-E76K mutation destabilizes nucleosomes by disrupting H2A/H2B dimer binding to H3/H4 tetramers, altering chromatin structure and function.
Objectives: Investigate the effects of the H2B-E76K mutation on gene expression, chromatin interactions, signaling pathways, and cellular phenotypes, focusing on the induction of epithelial-mesenchymal transition (EMT) in lung cancer models.
Methods: CRISPR-Cas9 created BEAS-2B bronchial epithelial cell lines with heterozygous and homozygous H2B-E76K mutations in the H2BC4 gene. Phenotypic assays assessed cell growth, migration, invasion, and EMT marker expression. Transcriptomic changes were analyzed using scRNA-seq, bulk RNA-seq, and PRO-seq to evaluate pathway deregulation, transcriptional instability, and RNA polymerase activity. The µMap technique mapped protein-chromatin interactions disrupted by the mutation. Chromatin profiling with CUT&RUN and ATAC-seq examined histone incorporation and chromatin accessibility changes.
Results: H2B-E76K mutant cells showed enhanced migration and invasion, increased mesenchymal markers (N-cadherin, vimentin), and decreased epithelial markers (E-cadherin), consistent with EMT. These cells also resisted apoptosis upon growth factor withdrawal. Transcriptomic analyses revealed transcriptional instability, with increased cell-to-cell variability in gene expression, altered patterns linked to oncogenic signaling, transcript switching, and disrupted RNA polymerase activity. The µMap technique identified disrupted interactions between chromatin and RNA-processing enzyme RAVER1, correlating with altered splicing, exon skipping, and gene expression variability. ATAC-seq showed enhanced binding of EMT-related transcription factors (e.g., AP1, CEBPB, ZNF384, FOXC2) and increased chromatin accessibility at EMT-related promoters. CUT&RUN revealed diffuse genome-wide deposition of H2B-E76K histones, consistent with replication-coupled incorporation. These chromatin changes promoted transcriptional programs associated with EMT and cancer progression.
Conclusions: H2B-E76K histones are broadly distributed throughout the genome, causing transcriptomic instability, altered splicing, and transcription factor binding changes. These alterations drive EMT phenotypes, including enhanced invasion, migration, and resistance to apoptosis, contributing to aggressive cancer behavior. H2B-E76K acts as a key epigenetic driver of oncogenesis by modifying chromatin accessibility, gene regulation, and cellular plasticity.

#2744 Interrogating the functional roles of differential CTCF-binding sites in IDH-mutant gliomas using a novel CRISPR library.

Ebru Yilmaz[1], Alisan Kayabolen[2], Dogancan Ozturan[3], Tahsin E. Tekoglu[2], Ester Calvo Fernandez[1], Sedef Sarac Yalcinkaya[2], Nathan A. Lack[2], Mario L. Suva[1], Tugba Bagci Onder[2]

[1]Department of Pathology, Massachusetts General Hospital, Harvard Medical School, Boston, MA,[2]School of Medicine, Koc University, Istanbul, Turkey,[3]School of Biomedical Engineering, University of British Columbia, Vancouver, BC, Canada

Isocitrate dehydrogenase (IDH) mutations are frequently observed in gliomas, and their mutation status is accepted as a CNS tumor classification marker. IDHs are enzymes that convert isocitrate into alpha-ketoglutarate (α-KG). Mutations in IDHs cause neomorphic enzymatic activity, by which D-2-hydroxyglutarate (2- HG), the oncometabolite, is produced from α-KG. This leads to the inhibition of α-KG-dependent enzymes, such as DNA and histone demethylases, thus altering chromatin structure and gene expression profile. CTCF is a methylation-sensitive structural protein that recognizes specific DNA motifs. It dimerizes, together with cohesin, forms chromatin loops, and determines the boundaries of topologically associated domains. Previous work demonstrated that IDH-mutant gliomas have hypermethylation at CTCF-binding sites, leading to reduced CTCF binding and permitting a constitutive enhancer to interact aberrantly with a glioma oncogene. Despite the unique epigenetic features of IDH-mutant gliomas and the ever-increasing importance of IDH mutation in patient prognosis, there has been no comprehensive study on the functional roles of CTCF binding sites in these tumors.We reanalyzed publicly available CTCF ChIP-seq data of three IDH-wild type (wt) and three IDH-mutant glioma cell lines, determined differential CTCF ChIP-seq regions, and aimed to explore their functional roles in glioma survival. To investigate the effect of methylation and demethylation of a specific CTCF binding site in both IDH-wt and -mutant gliomas, we developed a novel paired gRNA library targeting the left and right sides of these differential regions, which consists of 899 paired gRNAs. The CRISPR droplet screens are being conducted using dCas9-fused DNMT3A&3 and TET1 effector proteins, causing DNA methylation and demethylation, respectively. Beyond the alterations of gRNAs in the population, the single-cell transcriptomic readout will be obtained at the end of the screen.Our library design offers advantages over available libraries as it can be utilized with different CRISPR approaches. This high-throughput epigenome editing approach will allow for identifying regulatory interactions leading to tumor cell survival in IDH-wild type and -mutant gliomas.

#2745 Identification of a selective and orally bioavailable BPTF PROTAC with anti-tumor activity in SWI/SNF mutant lung cancer.

W. Yan[1], J. Chung[1], D. E. Reyna[2], D. Sherman[2], S. Li[1], S. Linker[1], J. Lapek[1], S. Thomas[2], J. Pizzano[2], E. Bortolon[2], S. Brun[1], S. Kaiser[1], S. Sakata[1], I. Taylor[2], J. Cantley[2], A. Gilbert[1], T. Paul[1];
[1]Pfizer, Inc., San Diego, CA, [2]Arvinas, Inc., New Haven, CT

BPTF is a bromodomain and PHD finger domain-containing protein that serves as a scaffolding subunit of the ISWI family member NURF chromatin remodeling complex. Together with interchangeable catalytic subunits SMARCA1 and SMARCA5 and additional subunits RBBP4, RBBP7, the NURF complex catalyzes ATP to slide nucleosomes on DNA, exposing or occluding transcription factor binding sites, leading to transcriptional activation or repression. Dysregulation of BPTF-containing NURF complexes disrupts gene expression and contributes to oncogenesis. BPTF overexpression is observed in various cancers and correlates with poor survival. Here we report the discovery of potent and selective BPTF heterobifunctional protein degraders A123497 and A126329 utilizing BPTF bromodomain ligand NVS-BPTF-1. While BPTF bromodomain ligands are inactive across a panel of lung cancer cell lines, BPTF degraders demonstrate potent anti-tumor activity in a subset of SCLC and NSCLC models, recapitulating the genetic dependency observed in CRISPR inhibition studies. Anti-tumor activity of BPTF degraders exists in a subset of lung cancer cell line models enriched in mutations in the SMARCA2/4 catalytic subunit of SWI/SNF chromatin remodeling complex. BPTF degradation leads to loss of protein stability and chromatin binding to additional NURF complex members including catalytic subunits SMARCA1 and SMARCA5 and chromatin accessibility changes at specific genes. Unique chromatin accessibility changes observed with BPTF degraders in cell lines harboring mutant SWI/SNF suggest interplay between chromatin remodeling functions of NURF and SWI/SNF complexes. We present optimization of BPTF degraders for in vivo dosing further demonstrating the therapeutic potential for targeting BPTF-containing NURF complex in cancer.

#2746 3D genome structural alterations in biological pathway genes drive the progression of cells from normal epithelium to metastatic cancer.

Huy Nguyen[1], Shyamtanu Chattoraj[1], Jude Dunne[2]

[1]Bruker Spatial Genomics, Inc, Newton, MA,[2]Bruker Spatial Genomics, Inc, San Jose, CA

Large scale structural variation in the genome is known to be linked to cancer pathways. Breast cancer progression from normal epithelium to localized, and metastatic cancer involves genomic perturbations such as mutations, deletions, and duplications. Emerging research has shown that the structure of the 3D genome, specifically how chromosomes and genes are folded and organized in the nucleus, directly impacts gene expression and thus, may contribute to disease progression. In fact, local folding around critical genes, especially those involved in important biological pathways, may have direct impact on cancer initiation and progression. Limits in technology has restricted a more complete understanding linking 3D genome to disease. Biochemical methods require many cells and are unable to preserve single cell and sub-population level information. Previous imaging methods are limited by the number of analyzable targets, reducing the generalizability of results across other genomic loci and limited a comprehensive genome-wide understanding.

Here, we use jebFISH^{TM} and the PaintScape^{TM} platform to resolve 3D structural features of genomic loci at high fidelity. With our Biological Pathways Panel, we focus on genes that are known to play critical roles in DNA repair, cell cycle, apoptosis, chromatin modifications, and transcriptional regulation. Using breast cancer progression as the model, we apply jebFISH^{TM} to cell lines from normal epithelium, localized cancer, and metastatic cancer. We observe dramatic changes in 3D genome at both single cell and population levels. At each stage of breast cancer progression, we identify specific alterations to 3D genome features including changes in structure and switching of A/B chromatin compartments. Structural alterations are also present at whole chromosome level. We see disruption and repositioning of chromosome territories as well as interchromosomal interactions. jebFISH^{TM} single-cell, single-homolog resolution enables identification of cellular sub-populations at each stage of breast cancer progression. We observe changes in the frequency of sub-populations with disease progression. Our results suggest that genome organization, at the local gene as well as chromosome level is modulating the expression of genes important in biological pathways. The presence of sub-populations suggests that the heterogeneous nature of 3D genome organization within the population is an important feature, impacting our understanding and treatment of diseases. While this study focuses on breast cancer, we envisage that these results are generalizable and further the understanding of genome organization and gene expression.

#2748 Integrative analysis of 3D chromatin organization revealed regulation mechanisms in angioimmunoblastic T-cell lymphoma.

Makoto Iwasaki[1], Caroline MacVicar[1], Anna Baird Rider[1], Aliyah Sohani[1], Valentina Nardi[1], Josie Ford[1], Kusha Chopra[1], Eric Jacobsen[2], Jeffrey Barnes[1], Salvia Jain[1]

[1]Massachusetts General Hospital, Boston, MA,[2]Division of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA

Molecular studies have highlighted recurrent alterations in epigenetic modifier genes, including *TET2*, *DNMT3A*, and *IDH2,* in angioimmunoblastic T-cell lymphoma (AITL). However, the direct impact of gene regulatory elements on gene expression changes leading to T-cell lymphomagenesis remains poorly understood. We focus on 3D chromatin organization. Hi-C and RNA sequencing was performed on diagnostic FFPE tumor samples from seventeen patients with AITL. Two CD4+ T cells from individual donors and one follicular helper T cells (TFH) from four donors were used as controls. To annotate AITL-specific loops in association with enhancer status, we identified H3K27ac histone marks in TFH cells using CUT&Tag. Promoter-super enhancer (P-SE) loops or stripes were defined as those with non-promoter anchors containing SE predicted by ROSE. In comparison to normal CD4+ T-cell controls, recurrent AITL-specific alterations in A/B (active/inactive) compartments, topologically associating domains (TADs), and chromatin loops were identified. Principal-component analysis (PCA) of genome-wide compartment scores indicated AITL samples and normal CD4+ T cells clearly separated by the first two components. On average, there was 3.5% (range: 2.0-5.3) A-to-B compartment switch and 1.9% (range: 0.8-4.8) B-to-A switch when comparing AITL samples with normal CD4+ T cell controls ($p=5.17 \times 10^{-5}$, two-sided paired t-test). Alterations in TADs were recurrently observed in 434 of 743 cancer census genes in COSMIC, including *MYC, TCL1A,* and *RHOA*. On average, 60.1% of loops include promoters in at least one anchor. Genes within AITL-specific loops exhibited significantly higher expression than those outside of loop regions ($p=7.39 \times 10^{-88}$, Kruskal-Wallis test). Genes within P-SE loops/stripes showed significantly higher expression than those within promoter-inactive enhancer (P-IE) loops/stripes, which were defined by ENCODE as enhancers without TFH SE (loops: $p = 5.17 \times 10^{-5}$, stripes: $p=1.55e^{-15}$, Kruskal-Wallis test). Based on the differential loop analysis using diffpeakachu, significant chromatin loops were observed in the *MYC* region and genes associated with pathways related to *MYC*, such as the Wnt signaling pathway. AITL-specific loops in the *MYC* region were observed in eight of seventeen patients. Recurrent MYC promoter-TFH SE loop (chr8:127730000-127740000,chr8:127960000-127970000) was located between ME1 and ME2 of MYC enhancer in AML (Pulikkan et al., 2018). Our findings indicate that AITL exhibits unique chromatin conformations, suggesting the formation of a lymphoma-specific gene regulatory landscape. Recurrent changes in chromatin conformation involve *MYC*. Distinct gene regulatory elements associated with enhancer regions in AITL is implicated. Correlation of the regulatory candidates with their mutational signature is underway and will be reported at the meeting.

#2749 Single-cell 3D genome structure analysis reveals clonal evolution and heterogeneity in acute myeloid leukemia.

Yu Luan[1], Ye Hou[2], Yutong Lei[3], Qiushi Jin[1], Jie Xu[2], Bei Jia[4], Siwei Xu[3], Ping Wang[2], Alok Swaroop[2], Yihao Fu[2], Juan Wang[2], Qixuan Wang[2], Hong Zheng[4], Jing Zhang[3], Feng Yue[2]

[1]UT Health Science Center at San Antonio, San Antonio, TX,[2]Department of Biochemistry and Molecular Genetics, Northwestern University, Chicago, IL,[3]Department of Computer Science, University of California, Irvine, Irvine, CA,[4]Department of Medicine, Division of Hematology and Oncology, Penn State University, Hershey, TX

Alterations in the 3D genome organization have been reported in different types of cancer and have been linked with gene dysregulation and cancer progression. However, majority of the studies were performed using bulk chromatin interaction assays and therefore, cannot address the heterogeneity and clone evolution in primary human tumors. In this study, we generated single cell Hi-C and single cell ATAC-Seq data in a cohort of AML patients, comprising samples at different disease stages, including diagnosis, remission, and relapse. To our knowledge, this is first large collection of single cell Hi-C data in primary tumor. In total, we profiled 153,517 cells across 13 samples, revealing distinct contact patterns and significant heterogeneity in genome-wide contact features between different samples, as well as within the same sample. We demonstrated the impact of 3D genome alterations on AML-specific gene expression programs, highlighting the role of compartmentalization in driving AML pathogenesis. Moreover, we identified hundreds of AML-specific chromatin domains with decreased heterogeneity during the transition from initial diagnosis to post-treatment relapse, suggesting the emergence and expansion of therapy-resistant subclones. By integrating a clonal evolution model, we delineated the dynamic relationship between somatic mutation, structural variation, and 3D genome architecture alterations. Finally, we discovered a chromatin loop uniquely present in a subclone of the relapse sample, which hijacked a distal enhancer to the known chemo-resistance-related oncogene and led to its upregulation. To summarize, our findings demonstrated the heterogeneity of 3D genome structure in AML and provide insights on the disease progression and relapse mechanisms.

#2750 Alternative enhancer usage of *PER2* locus regulating 3D genome architecture in epithelial-mesenchymal states.

Yi-Chia Chiu[1], Qing You Pang[2], Tuan Zea Tan[3], Wendy W. Hwang-Verslues[4], **Ruby Y. J. Huang**[1]

[1]National Taiwan University College of Medicine, Taipei, Taiwan,[2]National Neuroscience Institute, Singapore, Singapore,[3]National University of Singapore, Singapore, Singapore,[4]Academia Sinica, Taipei, Taiwan

The regulation of epithelial (E) and mesenchymal (M) states requires orchestrated adaptation at the epigenomic level. The 3D genome hierarchical orders, together with chromatin accessibility, histone modifications, and local DNA looping, establish the architectural backbone of the genome in response to functional ques for EM plasticity during cancer progression. Here, we delved into alternative enhancer usage and the accompanied changes in 3D genome architecture which could govern the interconversion between these two states. Using ovarian cancer (OC) cells as a model, distinct enhancer usage at the circadian gene Period 2 (*PER2*) loci was identified in OC cells of epithelial-like Epi-A (PEO1 and OVCA429) and mesenchymal-like Mes (SKOVE3 and HeyA8) subtypes. Intron 6-14 of *PER2* consisted of multiple enhancers in PEO1 and OVCA429 suggesting an open chromatin state compared to a relatively closed chromatin in SKOV3 and HeyA8 marked by latent/inactive regions. OC tumors of epithelial-like Epi-A subtype with high *PER2* expression were also correlated with better overall survival, suggesting the clinical relevance of this region. CRISPR/Cas9-mediated deletion of 3 enhancers, namely A, B, and C regions, was performed to generate clones in OVCA429. Deletion of specific enhancer B and C regions of *PER2* resulted in a spindly mesenchymal morphology, compared to the cobblestone epithelial morphology of parental OVCA429 and clones with region A deletion. These changes corresponded with the altered expression of known EMT markers. RNA-seq analysis showed a significant shift in the EMT scores of OVCA429_*PER2*_B towards a Mes-like profile. Hi-C analysis was done in OVCA429_*PER2*_B to decipher the 3D genome architecture. Changes at compartments, topologically associated domains (TADs), and long-range DNA interaction loops were explored. Our findings highlighted that alternative enhancer usage is crucial in EM plasticity and subtype conversion, offering genome level insights into EMT regulatory mechanisms in cancers.

#2751 Role of transcriptional regulation in chromatin architecture and immunotherapy resistance of hepatocellular carcinoma.

Siyun CHEN[1], Yingnan LIN[1], Chengpeng Zhong[2], Yalin TU[1], Haoran WU[1], Yiling ZHANG[1], Jia WANG[3], Alfred Sze Lok CHENG[1]

[1]School of Biomedical Sciences, Chinese University of Hong Kong (CUHK), Hong Kong, Hong Kong,[2]Department of Liver Surgery, Renji Hospital Affiliated to Shanghai Jiao Tong University, Shanghai, China,[3]GMU-GIBH Joint School of Life Sciences, Guangzhou Medical University, Guangzhou, China

Introduction: Chromatin architecture is frequently altered in cancers, including one of the most prevalent cancers, hepatocellular carcinoma (HCC). Emerging evidence suggests that liquid-liquid phase separation plays a crucial role in shaping chromatin architecture and regulating gene transcription. Immune checkpoint blockade (ICB) therapy has become a new standard of care for HCC. However, the majority of HCC patients exhibit either primary or adaptive resistance to this immunotherapy, highlighting the urgent need for effective combination therapies. This study aims to uncover the differences in chromatin architecture between ICB-sensitive and resistant HCC tumors and dissect the underlying regulatory mechanisms.
Methods: Hi-C, ATAC-seq, CUT&Tag, and RNA-seq were performed on RIL175 cells from a well-established adaptive ICB-resistant mouse model to generate the multi-omics dataset. To explore the functional role of F1 in ICB resistance of HCC, RIL175-PD1-R cells with F1 knockdown were constructed using the lenti-virus infection. To explore the phase separation ability of F1, F1 protein tagged with mCherry was expressed in E. coli and purified. Droplet formation assay and fluorescence recovery after photobleaching (FRAP) assay were applied.
Results: Three-dimensional genomic analysis by Hi-C reveals comparable chromatin interactions between ICB-sensitive and resistant cells at both compartment and topologically associated domain (TAD) levels but an increase in loops within ICB-resistant cells. In accord with this, ATAC-seq results indicate upregulated chromatin accessibility in a subset of chromatin regions in ICB-resistant cells compared to ICB-sensitive cells. Motif analysis identifies F1 as the top transcription factor enriched for the open chromatin regions. CUT&Tag shows that F1 binds to those accessible regions and alters chromatin looping in ICB-resistant cells. Modulating F1 expression in HCC tumor cells significantly increases the therapeutic efficacy of ICB treatment. We also found that F1 undergoes phase separation, which may mediate the changes in chromatin architecture between ICB-sensitive and resistant cells.
Discussion and Conclusion: F1 undergoes phase separation in HCC, particularly in ICB resistant cells. This characteristic of F1 may shape specific three-dimensional chromatin architecture in HCC cells, contributing to their resistance to ICB treatment. Targeting F1 condensates may provide a novel therapeutic strategy to reprogram the genome architecture to improve ICB efficacy for patients with HCC.

Keywords: chromatin architecture, phase separation, hepatocellular carcinoma, immune checkpoint blockade (ICB) therapies

#2752 Analysis of epigenetic regulation by mutant p53 gain-of-function in anaplastic thyroid cancer.

Wataru Kawase[1], Yukihiko Hiroshima[1], Takashi Oshima[2], Katsuhiko Masudo[2], Yohei Miyagi[1]

[1]Kanagawa Cancer Center Research Institute, Yokohama, Japan,[2]Kanagawa Cancer Center, Yokohama, Japan

Thyroid cancer is one of the most common endocrine malignancies. It is primarily classified into four types : papillary thyroid cancer, follicular thyroid cancer, medullary thyroid cancer and anaplastic thyroid cancer (ATC). Among them, ATC is particularly rare, has a very poor prognosis and is insensitive to conventional treatments. Consequently, the development of effective therapeutic strategies for ATC is urgently needed. Mutations in *TP53* have been reported to play a role in the anaplastic transformation of thyroid cancer. *TP53* is the most frequently mutated gene across all human cancers. Although common *TP53* missense mutations cause loss of its tumor-suppressive function, 'gain-of-function' (GOF) mutations of *TP53* have recently been reported to promote several types of cancer. Mutant p53 (mut-p53) GOF can manipulate epigenetic regulators and alter the chromatin landscape. However, the impact of mut-p53 GOF on epigenetic regulation in ATC remains unclear. In this study, we aim to elucidate the mechanisms of epigenetic regulation underlying tumor progression driven by mut-p53 GOF in ATC. Hotspot gene mutation analysis revealed the presence of known mut-p53 GOF mutations in three out of seven ATC cell lines. Distribution analysis of ATAC-seq peaks in enhancer regions revealed that certain promising transcription factor binding motifs were enriched in ATC cell lines with mut-p53 GOF. Moreover, we demonstrated that these candidate transcription factors are involved in cell proliferation and migration of ATC cell lines with mut-p53 GOF. These results suggest that the exploration of gene expression regulatory mechanisms by mut-p53 GOF may provide a clue for a novel therapeutic strategy for ATC.

#2753 Potential novel interventions of oncohistones, epigenetic modifications, and RNA processing machinery in betel-nuts related HNSCC in Taiwan.

Jo-Pai Chen[1], Jui-Ying Chang[1], Ruey-Long Hong[2]

[1]National Taiwan University Hospital, Yun-lin Branch, Taipei, Taiwan,[2]National Taiwan University Hospital, Taipei, Taiwan

Background: Betel nut chewing leads to strong invasion & recurrence. We found betel-nuts exposed HNSCC cell line, TW2.6, caused treatment refractoriness in Taiwan with high PDL1, defective p53 mutation, p16 loss, & BCL2 overexpression. PI3K/AKT/mTOR interventions, ALK/IGF1R inhibitor, CDK4/6 inhibitor, BCl2 inhibitor, WEE1 inhibitor, ATR inhibitor, DNA-PK inhibitor, AT2AR inhibitor, Mcl-1 inhibitor, MEK1/2 inhibitor, JAK2 inhibitor, CXCR4 inhibitor, FAK inhibitor, p53 reactivator, MDM2 inhibitor, SHP2 inhibitor, PARP7 inhibitor, IAP inhibitor, GLS1 inhibitor, eribulin, & VEGFR2/ PDGFR/FGFR or VEGFR2/c-MET/Axl triple blockage might be effective on TW2.6 and reverse treatment refractoriness, through the inhibition of mesenchymal transformation, pRB, & PI3K/AKT /mTOR signaling and modulation of stemness & PD1/PDL1 pathway. Besides, PLK inhibitor & GLS1 inhibitor seemed good radiosensitizers for TW2.6(AACR2024). The genomic signature of TW2.6 was figured out(*AACR2020*) with PIK3CA H1047R mutation, high TMB/MSS, VEGF-A amplification, p53/MYC/HRAS/DDR2/ PDGFRbeta/EPHB1/ATM mutations, FAT1 loss, amplification of TERT/ FGF10/CCND3/SOX9/IL-7R/SDHA/ RICTOR/FLCN, CDK12/PTPRD loss of function, deletions of STK11/ARID1B/MITF/ TNFAIP3, & SETD2(a histone lysine methyltransferase)/KDM5A(a lysine demethylase)/CDK8 mutations. H3K36 mutation and NSD1 defects altering H3K36 methylation will block cellular differentiation and promote oncogenesis. Disrupting NSD1 in HNSCC cell lines led to CpG hypomethylation & enhanced cisplatin sensitivity.

Methods: TW2.6 used to test (1)*in vitro* drug sensitivity to (a)Chemical Modulators of Splicing; (b)PRMT5 inhibitor; (c)CDK9 inhibitor, EZH2i, DNMT3i, BRD/BET4i, and HDACi; (d)NSD1/SETD2 inhibitor; (e)METTL3 inhibitor; (2)synergistic effects with other therapies by MTT assay, colony formation, flow cytometry, & western blotting.

Results: Epigenetic modifications were tested over TW2.6. AZD4573(CDK9 inhibitor), tazemetostat(EZH2 inhibitor), azacitidine(DNMT3 inhibitor), AZD5153(BRD4/BET inhibitor), and romidepsin(HDAC inhibitor) were effective over TW2.6 and enhanced ICIs efficacy. AZD4573 can synergize with tazemetostat, AZD5153, AZD6094(c-MET inhibitor), AZD5991(Mcl-1 inhibitor), & AZD2014(TOC1/2 inhibitor); but no synergistic effects with DDR interventions, such as AZD6738(ATR inhibitor) & olaparib except AZD1775(WEE1 inhibitor). AZD4573 will cause the drop of EMT signals, pRB, & p70S6K1 and prominent elevation of p-PARP. TW2.6 was also effective towards STM2457(METTL3 inhibitor) and JNJ64619178(PRMT5 inhibitor).

Conclusions: TW2.6 was sensitive to epigenetic modifications due to CDK8/SETD2/KDM5A mutations & ARID1B loss. Novel RNA processing interventions and epigenetic modifications for radiosensitization & immuno-modulation may be future trends.

#2754 Long-read direct RNA sequencing identifies m^3C modification sites in poly(A) RNAs from pancreatic cancer cells.

Kenzui Taniue[1], Shuhei Mitsutomi[1], Anzu Sugawara[1], Kenji Takahashi[2], Yusuke Mizukami[2], Nobuyoshi Akimitsu[1]

[1]University of Tokyo, Tokyo, Japan,[2]Asahikawa Medical University, Hokkaido, Japan

Covalent modifications provide a precise and effective mechanism to regulate the biogenesis, stability, and function of biological molecules, including DNA, RNA, proteins, and lipids. More than 300 distinct chemical modifications have been identified in both coding and non-coding RNAs, forming a diverse RNA modification landscape known as the epitranscriptome. RNA modifications are mediated by three classes of proteins: writers, which add modifications; erasers, which remove them; and readers, which recognize and interpret modified RNAs. RNA modifications play critical roles in cell homeostasis and cell developmental processes by regulating gene expression, RNA metabolism, and translation into proteins. Dysregulation of RNA modifications has been linked to the pathogenesis of various human diseases, including cancer. Recent studies has shown that 3-methylcytidine (m^3C) is primarily located at position 32 on the anticodon loop of certain transfer RNAs (tRNAs). This modification is catalyzed by m^3C writers, such as METTL2A, METTL2B, METTL6, and METTL8. These writers and their cofactors have been associated with human diseases. m^3C has also been detected in polyadenylated RNA (poly(A) RNA) at levels approximately 1000-fold lower than in tRNA through LC-MS/MS analysis. However, its transcriptome-wide distribution and functions remain unknown due to its low abundance and the absence of commercially available anti- m^3C antibodies suitable for immunoprecipitation. Here, we demonstrated that METTL2A expression is upregulated in pancreatic tumor tissues and that high METTL2A levels are associated with poor prognosis in pancreatic cancer patients. To further investigate the role of METTL2A, we performed comparative direct RNA sequencing on the pancreatic cancer cell line AsPC-1 to identify potential METTL2A-mediated m^3C sites in poly(A) RNA. These m^3C sites were enriched in the CC motif and predominantly located in the coding sequences of mRNA, mitochondrial mRNA, and mitochondrial ribosomal RNA. Moreover, METTL2A downregulated m^3C RNAs and altered the balance between specific isoforms containing METTL2A-mediated m^3C sites by promoting exon inclusion and shifting isoform expression, underscoring a potential role of m^3C in poly(A) RNA in regulating gene expression. In conclusion, our approach may contribute to uncovering the functions and characteristics of previously unknown RNA modifications regulated by various factors.

#2755 The m^{6}A epitranscriptomic landscape of bladder cancer is characterized by sequential 3'UTR hypermethylation and global methylation dilution.

Jonas Koch[1], Felix Bormann[2], Vitor Coutinho Carneiro[1], Manuel Neuberger[3], Katja Nitschke[3], Malin Nientiedt[3], Philipp Erben[3], Maurice S. Michel[3], Frank Lyko[1]

[1]German Cancer Research Center, Heidelberg, Germany,[2]Bioinformatics.Expert UG, Berlin, Germany,[3]Department of Urology and Urosurgery, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany

N^6-Methyladenosine (m^{6}A) is the most prevalent internal modification of eukaryotic mRNAs and affects the regulation of its target transcripts in all aspects of the mRNA life cycle. Cancer-associated changes in the m^{6}A epitranscriptomic landscape as well as the deregulation of m^{6}A regulators have been linked to cancer development. However, most studies have focused on *in vitro* or *in vivo* models and antibody-dependent mapping techniques, which have limited resolution and lack quantitative methylation information. Here, we provide the first transcriptome-wide, base-resolution map of m^{6}A in cancer and determine methylation levels with absolute stoichiometric information by comparative sequencing of nine urothelial carcinoma of the bladder (UCB) and nine non-malignant uroepithelial control samples. Our results define key signatures of the cancer-associated m^{6}A epitranscriptomic landscape of UCB, which was characterized by differential methylation of cancer-related mRNAs. m^{6}A hypermethylation primarily occurred near stop codons and was associated with upregulation of the VIRMA subunit of the m^{6}A methyltransferase complex, and alternative polyadenylation. Furthermore, the integration of methylation data and expression data revealed a global dilution of methylation marks in UCB, which was caused by the decreased expression of highly methylated transcripts, combined with the increased expression of unmethylated transcripts. Notably, both changes appeared sequentially during the progression to muscle-invasive bladder cancer. Our study thus characterizes the systematic differences in the m^{6}A methylome of UCB and establishes the potential of m^{6}A profiling for cancer biomarker development.

#2756 Epigenetic drivers of enzalutamide resistance in prostate cancer: targeting of DNMTs and EZH2 as therapeutic strategies to overcome enzalutamide resistance in prostate cancer.

Santosh Lamichhane, Brandon E. Burow, Sweaty Koul, **Hari K. Koul**

LSU Health New Orleans, New Orleans, LA

Background: Prostate cancer results in over 35,000 deaths in USA, annually. Enzalutamide (ENZ) treatment enhances overall patient survival. The development of ENZ-R is marked by adaptive cellular mechanisms, including cellular plasticity and the emergence of CRPC-NEPC and CRPC-DNPC phenotypes. The role of epigenetic mechanisms in CRPC remains less understood. Recent studies, including those from our laboratory, have pointed to increased expression and activity of DNA methyltransferases (DNMTs) and the PRC2 component EZH2 during prostate cancer progression. However, the direct role of DNMTs in ENZ-R has not been thoroughly evaluated. In this study, we explored the potential of DNMT inhibitors and EZH2 inhibitors to sensitize prostate cancer cells to enzalutamide.
Methods: Enzalutamide-resistant (LNCaP-ENZ-R) cells were developed by maintaining the cells in a medium containing 5 μM ENZ for a minimum of six months, while Short-term treatment with ENZ was conducted for 72h. Where indicated DNMTi (5-AZA-dC) and EZH2i (GSK-126) and Enz were used at 5uM concentrations. Proliferation was assessed using Incucyte. Colony formation and cell migration were assessed. Protein and mRNA level were determined by western blot and RT-PCR techniques.
Results: We observed that treatment of PCa cells with ENZ increased levels of DNMTs in both short-term (treatment of the LNCaP cells for 72 h) and established ENZ resistant (LNCaP-ENZ-R) cells. We also observed a gradual transformation from epithelial morphology to neuroendocrine phenotype in ENZ-R cells, characterized by spindle-shaped and elongated structures in LNCaP-ENZ-R cells. Moreover, in ENZ-R cells AR levels did not change but AR target (PDEF, PSA, and KRT18) were significantly downregulated, while markers associated with EMT (Snail) and NEPC (CHGA and enolase) were upregulated. Treatment of the cells with a DNMT inhibitor (5-AZA-dC) resulted in a decrease in DNMT levels in both ENZ-sensitive and -resistant cells. EZH2 expression showed no notable changes in either ENZ-sensitive or -resistant cells, however, H3K27me3 levels were increased with ENZ treatment. Additionally, LNCaP cells were sensitive to DNMTs and EZH2 inhibitors, and inhibiting both DNMTs and EZH2 substantially inhibited the growth and proliferation ENZ-sensitive as well as of ENZ-R-PCa cells. We also observed that treatment with inhibitors of DNMT and EZH2 decreased the scratch wound closure and clonogenic activity of PCa cells.
Conclusion: Overall, our findings reveal that the DNA and histone methylation pathways play an important role in prostate cancer and development of ENZ-Resistance, and that targeting these epigenetic regulators by small molecule inhibitors, may help overcome therapy resistance in PCa.

#2757 Hypermethylation of FAT4 linked to tumor progression in colorectal adenocarcinoma.

Dalma Muller, **Balazs Gyorffy**

Semmelweis University, Budapest, Hungary

Introduction: The gene *FAT4* encodes a cell adhesion molecule of the protocadherin family. *FAT4* can be linked to cancer progression at multiple levels, including metastasis, autophagy, epithelial-to-mesenchymal-transition, and as a tumor suppressor. Aberrant methylation, a common hallmark of colorectal adenocarcinoma, disrupts normal gene regulation.
Purpose: We explored the methylation changes of FAT4 during colorectal cancer progression, using a large patient cohort with methylation microarray data.
Methods: Raw data files of a collection of 2,356 colorectal tumor, adenoma, and normal samples from two microarray platforms (Illumina HM450K and EPIC) were processed in R using the *minfi* and the *watermelon* libraries. Based on a matrix of β-values, methylated regions and CpG loci were identified using Kruskal-Wallis-test complemented with ROC analysis. For data visualization we employed www.epigenplot.com, a web platform established based on our database. False discovery rate was set at 10%.
Results: Based on UCSC RefGene data, 18 of the HM450K and 27 of the EPIC array probes were assigned to the *FAT4* gene. All the probes hypermethylated in adenocarcinoma tissues compared to normal ones belonged to the CpG island chr4:126235895-126238930 of the proximal promoter region. When comparing to normal tissues, the TSS200 region had the most prominent hypermethylation (HM450K $\Delta\beta$ =0.28, AUC 0.9; EPIC $\Delta\beta$ = 0.22, AUC 0.85, $p < 0.0001$), while the probes of the open sea CpGs in the protein coding region have shown a slight hypomethylation (HM450K $\Delta\beta$ = 0.1; EPIC $\Delta\beta$ = 0.14, $p < 0.0001$). These changes were also present in adenoma tissues compared to normal ones. Based on KEGG classification, three other genes associated to the mTOR signaling pathway were similarly hypermethylated in the TSS200 region ($\Delta\beta >= 0.2$), including *WNT2, FZD10*, and *WNT7A*.
Conclusions: *FAT4,* a tumor suppressor gene with previously reported downregulation in CRC, shows significant hypermethylation in colon cancer, including the precursor lesions. Our results suggest that detection of these methylation changes in the promoter region of *FAT4* might be utilized as a prognostic biomarker and in the early detection of CRC.

#2758 Methylome plasticity as a biomarker of treatment response in small cell lung cancer.

Danielle Benedict Sacdalan[1], Sami Ul Haq[2], Luna Jia Zhan[1], Janice J. N. Li[1], Vivek Philip[1], Scott V. Bratman[1], Geoffrey Liu[1], Benjamin H. Lok[1]

[1]UHN Princess Margaret Cancer Centre, Toronto, ON, Canada,[2]Schulich School of Medicine & Dentistry, Western University, London, ON, Canada

Background: Small cell lung cancer (SCLC) is an aggressive disease with poor treatment outcomes, in part due to epigenetic mechanisms driving tumor growth and resistance. Cell-free DNA methylome profiles in untreated SCLC can identify prognostic sub-groups, making it a useful biomarker. In this study, we hypothesize that changes in the cell free methylome of SCLC influence disease response to therapy and drive treatment resistance.

Methods: Cell free methylated DNA immunoprecipitation followed by sequencing (cfMeDIP-seq) was performed on 34 baseline-relapse paired samples belonging to a cohort of SCLC patients treated at the Princess Margaret Cancer Centre (Toronto, Canada). Matched leukocyte DNA methylation profiles were incorporated to exclude the contribution of non-cancer methylation to the cfMeDIP signal and allow focused profiling of changes in the SCLC methylome through first-line treatment. The plasticity of the SCLC methylome was determined by subtracting the reads per kilobase of transcript per million mapped reads (RPKM) at the time of progression compared to the pre-treatment timepoint. A methylome demonstrated plasticity if it showed an increase or decrease in reads compared to the median RPKM across all samples in the cohort. Associations between methylation groups and relevant clinical data were identified. Kaplan-Meier and Cox regression analysis were performed to determine if methylome changes were associated with overall survival and progression-free survival, anchored from the time of SCLC diagnosis. KEGG pathways corresponding to the top differentially methylated windows between baseline and relapse pairs were identified and characterized.

Results: Plasticity of the SCLC methylome were seen in 67% of patients (n=23/34). Methylome plasticity was found to be associated with a shorter time to progression from the end of first-line treatment (mean difference = 70 days; 95% CI 25-115, p = 0.0031). Accordingly, patients with greater methylome plasticity were more likely to be platinum resistant (57% vs. 17%; χ-squared p = 0.033). Cox regression showed that methylome plasticity was significantly associated with worse progression free survival (PFS) (adjusted hazard ratio [aHR] = 5.7, p = 0.0010) and overall survival (OS) (aHR = 1.9, p = 0.11), after adjusting for VA stage at diagnosis. Pathway analysis of differentially methylated windows mapped to genes related to neuronal polarity and axonal guidance, as well as Wnt signaling.

Conclusion: Changes in cell-free DNA methylomes serve as a biomarker for treatment response in SCLC. Increased plasticity of the methylome is associated with shorter PFS. The underlying biology of this relationship may involve changes in pathways that govern neuronal change and established cancer-associated pathways.

MOLECULAR/CELLULAR BIOLOGY AND GENETICS: Functional Genomics / Large-Scale Approaches to Cancer Gene Discovery
Poster Session

#2763 Molecular QTL analyses identify functional variants at inherited risk loci in chronic lymphocytic leukemia.

Huihuang Yan, Zhiquan Wang, Mingma Hoel, Cristine Allmer, Chantal McCabe, Daniel O'Brien, Dennis Robinson, James Cerhan, Sameer Parikh, Esteban Braggio, Susan Slager

Mayo Clinic, Rochester, MN

Most disease-associated single-nucleotide polymorphisms (SNPs) identified by genome-wide association studies (GWASs) reside in noncoding regions. There is increasing evidence that they play regulatory roles through epigenetic mechanisms by altering local chromatin state, 3D chromatin structure, and looping interactions. We and others have identified 42 CLL risk loci from GWASs. At 12 risk loci located outside of gene promoters, we previously demonstrated that functional SNPs are highly enriched in enhancers and super-enhancers that mostly target *BCL2* family genes and transcriptional regulators. However, the study was limited by using only public epigenomic data generated in lymphoblastoid cell lines (LCL) and normal immune related cell types. To gain a better understanding of how the functional SNPs alter local chromatin state and modulate target gene expression in CLL, we generated RNA-seq data (n=588) and transposase-accessible chromatin with sequencing (ATAC-seq) data (n=69) in CLL tumor B cells. We performed molecular quantitative trait loci (QTL) analysis with index and correlated SNPs (R^2 0.5) at 41 risk loci (excluding the HLA locus). The analyses identified cis expression QTLs (eQTLs), within 1Mb of genes' transcription start site, at 25 risk loci and chromatin accessibility QTLs (caQTLs, within peak) at 11 risk loci, with both eQTLs and caQTLs at 8 risk loci. We identified a total of 54 eGenes, for which the expression is affected by nearby SNPs within 1Mb, including 40 novel eGenes at 16 CLL risk loci not previously reported. Notably, based on publicly available chromosome interaction data from CLL, LCL, and normal B cells, for over 70% of the novel eGenes, their promoters showed looping interactions with the regions carrying the eQTLs. Further, 13 SNPs were identified as both caQTL and eQTL, with the associated novel eGenes including *CD81* at 11p15.5, *IPCEF1* at 6q25.2, as well as *CXXC1* and *MBD1* at 18q21.1. The result suggests that these SNPs play a role in altering chromatin accessibility contributed to gene expression variation. At 11p15.5 risk locus, SNP rs2651823 (A/G) represents a novel caQTL and eQTL. The alternative G allele is associated with increased chromatin accessibility and *CD81* expression. Hi-C data from GM12878 and CD20+ B cells supported interaction between the open chromatin region carrying rs2651823 and *CD81* promoter. CD81 facilitates the trafficking of CD19 to the surface of activated B cells, and CD81-null mice showed impaired immune response. In a mouse model, CD81 contributes to tumor progression and metastasis in Lewis lung carcinoma. In summary, our molecular QTL analysis revealed that functional SNPs, located in CLL risk loci, modulate chromatin accessibility and expression of downstream target genes that could impact CLL risk.

#2764 Cas9 cytosine base editors for precision genome editing with high specificity and activity.

Erin Brettmann[1], Stephen Beishir[1], Xiao Chen[1], Xiaokang Zhang[2], Rajagopalan Lakshmi Narasimhan[3], Ajaya Kumar Kotekar Manjunath[3], Daniel Taglicht[4], Jiajian Liu[1], Fuqiang Chen[1]

[1]MilliporeSigma, Saint Louis, MO,[2]MilliporeSigma, Shanghai, China,[3]MilliporeSigma, Bangalore, India,[4]MilliporeSigma, Jerusalem, Israel

Base editing technologies allow for the precise and efficient installation of defined nucleotide substitutions into a target genome without double strand breaks. These editing methods can be used to generate cell lines and animal models for the study of a diverse range of topics, from molecular mechanisms of pathogenesis to drug resistance and therapeutics. However, overexpression of base editors can lead to off-target editing, both genome-wide in a guide-independent fashion and enriched at sequences similar to the intended target. To counter this challenge, we have developed a suite of recombinant protein-based cytosine base editor (CBE) tools. This suite includes two separate CBE proteins with complementary editing windows, a protein format uracil glycosylase inhibitor (UGI), and a guide design tool to facilitate experimental planning and computationally predict editing outcomes. The first CBE, “Flexible,” has a wide editing window, enabling editing over a large fraction of the target sequence and facilitating flexible placement of the guide RNA relative to the target cytosine residue. The second CBE, “Precision,” has a narrowed editing window, enabling discrimination between the target cytosine and nearby, untargeted cytosines. We show that co-transfection with the UGI protein increases the proportion of substitutions that are C-to-T and the ratio of C-to-T editing to indel formation, thus reducing undesired editing outcomes. We further show that co-transfection with a transfection enhancer results in an increase in overall editing rates, and that the transfection enhancer and UGI can be combined to maximize the rate of C-to-T editing while minimizing undesired outcomes. We use *in vitro* editing experiments to characterize the editing profiles of our CBEs and identify a preference for cytosine residues preceded by thymine (TC dinucleotides) and unmethylated cytosine residues. Finally, we show that RNP delivery of Flexible and Precision CBEs results in lower rates of mismatch editing and genome-wide nonspecific editing than plasmid delivery of the same editors, demonstrating their improved specificity profiles. To facilitate use of these editors, we have developed a guide design tool that will identify candidate guide RNAs in a user-provided sequence, identify potential off-target sites, and design primers to amplify the on- and off-target sites. The tool further uses a machine learning model trained on experimental data to predict which cytosine residues are most likely to be edited, and a joint probability model to predict the potential bystander outcomes, enabling the user to predict their editing outcomes before performing the experiment. Together, these tools will facilitate precision genome editing experiments.

#2765 Extracellular vesicle (EV) RNA transcriptome analysis: An optimized RNA-Seq workflow reveals distinctive transcript structures.

Srikanth Perike, Angelica Olcott, Cissy Jiang, Linda Lingelbach, Elizabeth Dreskin

Bio-Rad Laboratories, Hercules, CA

Introduction: Extracellular vesicles (EVs) are crucial membrane-bound particles containing DNA, RNA, proteins, metabolites, and bioactive molecules, which serve as conduits for essential cell-to-cell communication. EV RNA studies often focus on miRNAs due to their prevalence, potentially overlooking non-miRNA transcripts. A wide array of RNA species are found in EVs, including long non-coding RNAs (lncRNAs), messenger RNAs (mRNAs), and small non-coding RNAs (sncRNAs); many linked to disease. To gain molecular insights into the EV transcriptome, we devised a novel protocol for isolating EV RNA, enabling comprehensive RNA-Sequencing (RNA-Seq) profiling.
Methods: We used six cell lines (A549, Jurkat, MCF-7, HeLa, HEK293, and NTERA-2) to demonstrate our workflow and results. Our protocol involves EV precipitation from a minimal volume (1.4mL) of conditioned cell culture media prepared with exosome-depleted FBS, followed by EV lysis using SingleShot Cell Lysis reagent which preserves RNAs of all sizes. In each experiment, cellular RNA from the source cells was prepared as a control. Whole transcriptome libraries were constructed using the SEQuoia Complete Stranded RNA Library Prep Kit with ten microliters of EV RNA lysate. Libraries were sequenced on the Illumina NextSeq 1000. After secondary sequence analysis, we visualized transcript differences in EV and cellular transcripts on the UCSC genome browser. Novel qPCR assays were developed as an orthogonal method to confirm the transcript structure observations.
Results: Our EV RNA-Seq workflow identified diverse RNA biotypes, including miRNAs and numerous sncRNAs in both cellular and EV transcriptomes. Notably, within EVs, our study revealed distinct structural configurations in many sncRNA transcripts that were not observed in the originating cell lines. These novel structural findings were confirmed using 1-step quantitative reverse transcription polymerase chain reaction (RT-qPCR) with custom assays designed for several transcripts. These findings are consistent across tested cell lines and other methods of EV and EV RNA isolation.
Discussion and Conclusion: Many sncRNAs which we observed to have unique transcript structures are known components of ribonucleoprotein (RNP) complexes. Given their proposed role in cell-to-cell communication, we hypothesize that the pivotal element of EVs in intercellular communication may be the incorporation of these unique RNA transcripts as components of the RNP complex. Our efficient EV RNA-Seq workflow reduces sample handling, preserves RNA samples and allows for detection of RNAs of varying sizes. This will allow researchers to uncover the complex landscape of the EV transcriptome.

#2766 Metabolic and tumor immune cell landscapes are significantly different amongst *KRAS* mutational variants in non-small cell lung cancer.

Frank D. Weinberg[1], Jen Godden[2], Denise Shieh[2], Stamatina Fragkogianni[2], Jacob Mercer[2], Melissa Stoppler[2], Daniel Principe[3], Ryan Nguyen[1], Kamya Sankar[4], Koosha Paydary[5], Mary Jo Fidler[5]

[1]University of Illinois Cancer Center, Chicago, IL,[2]TEMPUS, Chicago, IL,[3]University of Wisconsin, Madison, WI,[4]Cedars-Sinai Medical Center, Los Angeles, CA,[5]Rush University, Chicago, IL

Approximately 30% of patients (pts) with non-small cell lung cancer (NSCLC) have alterations in the *KRAS* oncogene. In NSCLC *KRAS* mutational variants are diverse and therapeutically relevant. However, it is unclear how each variant is associated with the tumor biology, including lipid metabolism and the immune microenvironment. Since perturbed tumor immune infiltration and lipid metabolism are linked to NSCLC outcomes, we evaluated and characterized *KRAS* variants and association with lipid metabolism and immune infiltration. Using the Tempus Database, 5,925 de-identified records from pts with NSCLC and *KRAS* alterations (G12A (n=464), G12C (n=2,510), C12D (n=937), G12R (n=61), G12V (n=1,251), G13C (n=244), G13D (n=185), Q61H (n=273)) were retrospectively analyzed. Samples were sequenced with the Tempus xT and xR RNA assays. Tumor microenvironment cell proportions were estimated using QuanTIseq. Single-sample gene set enrichment analysis based on 775 lipid metabolic genes was used to compute enrichment scores (ES) for each pt. We analyzed neoantigen tumor burden (NTB) and tumor mutational burden (TMB) as mutations per megabase (mut/Mb). P-values were calculated using Pearson's Chi-squared and Kruskal-Wallis rank sum test. Pairwise comparisons of median ES were performed using the Wilcoxon test and the FDR method was used to correct for multiple comparisons. Among the overall *KRAS* cohort, *KRAS* G12C and G12V represented over 60% of cases. Pts with *KRAS G12D* alterations had the highest proportion (23%) of never-smokers ($p<0.001$). We identified small but significant differences in the median lipid ES in pts with *KRAS* G12C variants compared to pts with G12V and G12D, with G12C having lower median lipid ES (0.89 versus 0.91 and 0.91 respectively, both $p<0.001$). Differences were also identified in pts with KRAS G13C compared to pts with G12D (0.9 versus 0.91, $p=0.03$). Median TMB and NTB differed amongst pts with *KRAS* variants with a higher TMB and NTB found in G12C, G13C and G13D cohorts while the lowest TMB and NTB was observed in the G12D cohort ($p<0.001$). *KRAS* G12C variant tumors had the highest median percentage of CD8 T cells while G12D and Q61H variants had the lowest median percentage of CD8 T cells ($p=0.016$). Interestingly, G12D variant tumors had the highest median percentage of infiltrating B cells ($p=0.006$). Our data show *KRAS* variants are associated with changes in the lipid and tumor immune landscape in NSCLC. There were significant differences in the proportion of tumor immune cells amongst tumors with different *KRAS* variants. Notably, pts with *KRAS* G12D variants had a less immunogenic immune microenvironment indicated by low proportion of TMB, NTB and CD8 T cells compared to G12C variants, which could affect immunotherapy efficacy. Further analysis is needed to determine if immunotherapy efficacy is altered by the distinct molecular phenotypes in pts with *KRAS* variants.

#2767 Aneuploidy-induced VHL haploinsufficiency in lung squamous cell carcinoma and clear cell renal cell carcinoma.

Joanna Kopko, Joan J. Castellano-Perez, Gayatri Bulsara, Alison Taylor

Columbia University Irving Medical Center, New York, NY

Aneuploidy is present in 90% of solid tumors, making it a hallmark of cancer. Despite its prevalence, aneuploidy has been difficult to model in human cells due to the technical challenges of generating targeted events. One high-frequency aneuploidy alteration is chromosome 3p (chr3p) deletion, which is found in 80% of lung squamous cell carcinomas (LUSC) and 90% of clear cell renal cell carcinomas (ccRCC). Cells with chr3p deletion are missing one copy of the Von Hippel-Lindau (VHL) gene, a master regulator that targets Hypoxia Inducible Factor Subunit Alpha (HIF-α) for degradation. When HIF-α is not degraded, it promotes the transcription of genes involved in cell metabolism, cell survival, and proliferation. The role of VHL has already been extensively studied in ccRCC, but only using models with homozygous VHL loss, therefore the effect of heterozygous VHL loss is not known. I hypothesize that partial VHL loss is enough to stabilize HIF and activate transcriptional targets involved in tumor progression in LUSC. To study the effects of chr3p deletion, we developed a CRISPR-based approach to generate isogenic cell lines with and without the aneuploidy event in lung airway epithelial cells. Seven of eleven chr3p deleted clones had HIF-α protein stabilization in normoxic conditions. We also generated cells with smaller regions of chr3p deleted instead of whole arm loss. If the deletion region included VHL, we observed HIF-α accumulation. To test whether VHL haploinsufficiency was sufficient for this phenotype, we used CRISPRi to reduce VHL to 50% levels and found stabilization of HIF-α. In hypoxic conditions, VHL knockdown cells had increased HIF-α protein accumulation and gene expression of HIF-α targets GLUT1 and VEGF. These preliminary data suggest that VHL haploinsufficiency is enough to cause HIF-α stabilization. Additionally, we looked at VHL knockdown in renal epithelial cells and saw no HIF stabilization. This indicates that VHL haploinsufficiency and HIF stabilization may differ in lung vs. kidney cells. To our knowledge, our research is among the first to study VHL in lung cancer, and our results could have significant implications for drug development in LUSC. HIF-α inhibitors have recently been approved by the FDA, so determining the dose dependency of VHL on HIF-α activity will increase knowledge on treatment efficacy for patients with heterozygous deletion of VHL.

#2768 Highly parallel integrated functional and sequencing analysis of single cells using the Beacon® optofluidics platform.

Leqian Liu, David Coit, Or Gadish, Julie Perreau, Andrei Rajkovic, Brandon Bruhn, Minha Park, Edward Han, **Alireza Salmanzadeh**, Vikram Devgan

Bruker Cellular Analysis, Emeryville, CA

Single-cell RNA sequencing has emerged as a powerful tool for uncovering cellular heterogeneity and its connections to disease progression and treatment efficacy, including immunotherapy. However, many critical phenotypes cannot be deduced solely from gene expression changes. To gain deeper insights, functional readouts of these cells are essential, yet current methods are limited by low throughput and restricted assay capacity. To tackle this challenge, we developed a high-throughput workflow that integrates functional and sequencing analyses at the single-cell level. This workflow combines versatile phenotypic assays with highly parallel single-cell RNA sequencing, leveraging the advanced capabilities of the Beacon® optofluidics platform from Bruker Cellular Analysis. Using this platform, we demonstrated the ability to link cell surface marker staining with gene expression profiling using single cells derived from PBMC samples. We then utilized this platform to analyze the functional and transcriptomic heterogeneity within adoptive cell therapy products. Specifically, we quantified multiple secreted cytokines (IFNγ, TNFα, and IL-2) alongside gene expression in thousands of *in vitro*-expanded T cells expressing antigen-specific T cell receptors. These non-growth-based, single live-cell functional assays were performed with minimal crosstalk, followed by cDNA capture and synthesis using barcoded beads in a highly parallel manner on the Beacon platform. Single-cell RNA sequencing data were subsequently integrated with functional assay results to uncover the molecular mechanisms underlying the functional heterogeneity of cell therapy products. We discovered that polyfunctional cells—those secreting all three cytokines—exhibit upregulated expression of genes associated with metabolic reprogramming, activation regulation, and DNA replication, hallmarks of T cell activation. Additionally, increased expression of chemokine genes in polyfunctional cells suggests ongoing immune cell recruitment beyond cytokine secretion. Validating these findings could pave the way for strategies to develop enhanced cell therapy products. Beyond uncovering the molecular drivers of functional heterogeneity in single cells, we envision this approach being further applied to advance single-cell functional genomics through integration with high-content CRISPR screening. The Beacon optofluidics platform enables direct functional profiling of gene function and regulation at single-cell resolution, making it uniquely suited to tackle previously intractable questions in cancer research and therapeutic development.

#2771 CRISPR/Cas9 essentiality screens identify stand-alone and IRF4-linked genetic vulnerabilities in melanoma cells.

Ulduz Sobhiafshar, **N. C. Tolga Emre**

Department of Molecular Biology and Genetics, Bogazici University, Istanbul, Turkey

Melanomas have poor prognosis at the metastatic stage despite impressive progress in targeted- and immuno-therapies. Therefore, identification of novel critical genes involved in melanoma biology with targeting potential is desirable.
We and others have previously demonstrated the transcription factor interferon regulatory factor 4 (IRF4) as a dependency factor in various lymphocyte-derived cancers. These findings align with the therapeutic efficacy attained by immunomodulatory drugs which indirectly target IRF4 expression in these cancers.
IRF4 also takes part in pigmentation in melanocytes, and its overexpression is prevalent in melanomas. Recently, we showed that high expression of IRF4 is linked to dependency in melanoma cells and mortality in patients. Mechanistically, we demonstrated that IRF4 regulates epigenetic silencing factors involved in DNA and histone H3K27 methylation, and consequently, controls the expression of melanoma-critical tumor suppressor genes and key downstream oncogenic pathways.
In order to identify novel genes that melanoma cells rely on for survival or proliferation, we performed CRISPR/Cas9 drop-out screens. One set of screens was aimed at identifying single individual genes necessary for cell fitness. The other set of screens was aimed at uncovering genes, when knocked-out, compromised cell fitness synthetically with IRF4 deficiency. For each set, we screened in replicate two publicly available sub-genomic guide RNA libraries, one targeting genes involved in gene expression and the other targeting genes involved in apoptosis and cancer processes. In order to detect drop-outs between the start and the end of the experiments, we analyzed samples quantitatively via next generation sequencing of guides and the MAGeCK algorithm. Depletion of guides targeting core essential genes verified the screens' ability to detect dependency genes. We then defined all significant dependency genes in their respective screens. We observed that, in addition to core essential genes, several genes that are deemed druggable show up as essential for melanoma cell fitness, some of which not previously reported. Several additional genes show up only in IRF4-knock out state, suggesting synthetic dependency. We followed up with pathway enrichment analyses to identify the prominent cellular pathways with dependency genes. Here, we observed gene transcription and translation, and cell cycle/mitosis as pathways enriched for melanoma dependency genes, among others. In addition, RNA processing and protein degradation are among the pathways enriched for dependency genes in the IRF4-knockout setting.
The dependency genes uncovered in these CRISPR/Cas9 drop-out screens are expected to pave the way for novel targeting approaches in melanoma by themselves or in combination with IRF4.

#2772 Comparison of three single-cell CRISPR-Seq protocols on the 10X Genomics platform.

Donato Tedesco, Tianbing Liu, Mikhail Makhanov, Nadya Isachenko, Dongfang Hu, Paul Diehl, **Alex Chenchik**

Cellecta, Inc., Mountain View, CA

Different methodologies exist for single-cell CRISPR (scCRISPR) screens, each with its own requirements concerning sgRNA scaffold, sgRNA library vector design, instrumentation, and reagents. This study compares the performance of three distinct scCRISPR protocols: 10X Genomics 3' scCRISPR, CROP-Seq (using a modified 10X 3' scCRISPR protocol), and 10X Genomics 5' scCRISPR. 10X 3' scCRISPR relies on the CS1 capture sequence inserted in the sgRNA tracr to detect expressed sgRNAs. CROP-Seq protocol requires the sgRNA sequences to be embedded in an expressed mRNA for detection. 10X Genomics 5' scCRISPR detects sgRNAs without the need for scaffold modifications or inclusion in a mRNA transcript. A modification of the 10X 5' scCRISPR protocol also allowed us to incorporate sc-targeted RNA-seq, decreasing NGS costs and potentially leading to better transcriptional profiling data. The findings of the study showed that while the CROP-Seq and 10X-CS1 approaches are equally effective for single-cell sgRNA detection and gene expression profiling, the CROP-seq approach was superior in the sgRNA's ability to induce the expected phenotype. The 10X 5' scCRISPR protocol proved to be superior to both CROP-Seq and 10X-CS1 in sgRNA detection, and comparable if not better to CROP-seq in gene expression profiling and sgRNA activity. Also, the 5' scCRISPR targeted RNAseq approach proved to be technically successful, although it did not provide the expected transcriptional profiling improvement. Given the ease of use, the quality of the results, and the lack of need for specialized sgRNA scaffold or library design, 10X 5' scCRISPR should be the protocol of choice for scCRISPR screens utilizing the 10X Genomics platform.

#2773 The Gundersen Precision Oncology Cohort: a biospecimen resource for mutation characterization and target discovery.

Peter Feiszt, **Paraic A. Kenny**

Gundersen Medical Foundation, La Crosse, WI

Background: The generation and widespread sharing of large somatic mutation datasets has revolutionized our understanding of genetic mechanisms driving cancer initiation and progression. For well-understood mutations, this has created the opportunity for individualized therapeutic intervention in a wide range of malignancies. Beyond these well-characterized mutations, there exists a wide range of alterations that remain poorly understood and which require some kind of functional genomics analysis to determine whether such patients are eligible for the targeted therapy used for more typical mutations in that gene, whether these alterations are passenger mutations that don't affect throughput on the associated signaling pathway, or reflect another more nuanced phenomenon. Whether using ectopic overexpression in cell lines or generation of genetically modified mice, addressing this problem at scale using functional genomics approaches is challenging. A key limitation is the absence of the original tissue context in which that variant co-evolved with other genetic alterations as well as data on the clinical response of the patient to successive lines of therapy. This can be addressed, in part, by the banking of tissue from patient cohorts who have had comprehensive genomic profiling as part of their routine clinical care. For this purpose, we have established the Gundersen Precision Oncology Cohort.
Methods: The Gundersen Precision Oncology Cohort is a retrospective collection of tissue specimens, NGS reports and associated clinical data from deceased patients who received cancer care at the Gundersen Health System. The cohort is updated twice per year and banked tissue specimens are available for collaborative research studies. High resolution digital pathology whole slide images are available for artificial intelligence and machine learning studies.
Results: At November 26, 2024 there were data from 908 patients (913 tumors) in the cohort, with specimens tested between 2015 and 2024. 55 tumor types were represented, of which lung (n = 225), colorectal (n = 101), pancreas (n = 69), esophageal (n = 62) and breast (n = 56) were most common. The most common diagnostic companies were STRATA Oncology (n = 533) and Tempus (n = 332). Most patients had testing at a single timepoint, but longitudinal testing is available for 40 patients. We present data from some of the studied subgroups, including atypical point mutations in BRAF as well as fusions affecting BRAF and ROS1.
Conclusions: This cohort, available for collaborative studies via the Gundersen Cancer Biobank, illustrates the value of banking well-annotated biospecimens to address outstanding questions in oncology.

#2774 Pan-cancer chromatin state profiling suggests enhancer-heterogeneity and precision medicine approach.

Mayinuer Maitituoheti, Emre Arslan, Ayush T. Raman, Christopher Terranova, **Kunal Rai**

Genomic Medicine and MDACC Epigenomics Therapy Initiative, The University of Texas MD Anderson Cancer, Houston, TX

Epigenetic aberrations are a hallmark of cancer; however, systematic chromatin state maps of cancer cells are unavailable. We generated and analyzed 803 histone mark profiles in 142 cancer cell lines and 114 human tumors belonging to 9 solid tumor types. Irrespective of their cell-of-origin, cancer cells segregate from normal tissues based on their enhancer patterns, suggesting enhancer deregulation is a fundamental epigenetic feature in cancer. Enhancer based clustering defined 5 distinct subgroups of cancer cells (EpiC1-5) with unique developmental trajectories, molecular features and dependencies. Importantly, we define a set of core TFs that are critical for EpiC-specific enhancer patterns and survival. Notably, EpiC4 represented a predominantly epigenetic, pan-cancer subtype that displays poor survival, activation and dependence on a FN1-CAV1-SRC-PI3K-AKT signaling network. Together, these data uncover enhancer heterogeneity in pan-cancer systems with identification of a novel enhancer-based subtype and identify potential new therapeutic targets associated with unique epigenetic features.

#2775 High-resolution mapping of oncogenic structural changes in osteosarcoma.

Andrew Scott Clugston

Pediatric Oncology, UCSF - University of California San Francisco, San Francisco, CA

We have leveraged long-read and spatial sequencing modalities to identify cancer-specific oncogenic alterations for treatment of osteosarcomas.

Osteosarcoma is archetypal of cancers driven by aneuploidy and structural rearrangement rather than point mutations. The functional consequences of many SVs stem from their effect on multidimensional genome organization. SVs can enable enhancer hijacking, alter boundaries of topologically associated domains (TADs), and move gene loci to different regulatory compartments to affect gene expression. SVs can also lead to the formation of extrachromosomal DNA amplicons (ecDNA), which can be megabases in size and can incorporate both genes and regulatory elements to result in substantial increases in gene transcription and intratumor heterogeneity. Complex SVs may have profound implications for prognosis and treatment in OS and other cancers yet they remain poorly understood. By incorporating long-read optical genome mapping (OGM) and chromatin conformation capture sequencing (HiC), we studied SVs in osteosarcoma with the goal of elucidating their contribution to cancer development.

We studied a unique panel of 11 OS patient-derived xenograft (PDX) cell lines which have been previously characterized regarding response to targeted therapies as well as genomically via whole genome (WGS), RNA (RNA-seq), and chromatin accessibility (ATAC-seq) sequencing. To understand the complex genomic reorganization that occurs in osteosarcoma, we integrated OGM and WGS data for all 11 cell lines to describe detailed genome-wide SVs including ecDNA formation. PDX lines assayed using OGM exhibited between 106 and 704 translocations each (versus zero detected in germline controls) and we identified dozens of potential ecDNA amplicons, including one that may explain exceptionally high expression of YAP1 and BIRC3 transcripts. Further, we use HiC to determine which ecDNA amplicons appear to be free-floating based on their genome-wide interaction scores, noting significantly greater interaction in between 33% and 67% of ecDNA detected using OGM and break point graph-based methods. We also used HiC to describe the topological environment resulting from genome-wide SVs and observed potential enhancer hijacking events affecting dozens of known oncogenes including MYC and CDK4. HiC interaction maps among six cell lines reveal genomic compartments and TAD boundaries in detail, with 4,167 unique TAD boundaries identified among six cell lines using 50kb genomic bins. Changing TAD boundaries are associated with numerous SVs and/or copy number discrepancies, and are associated with genomic regions that contain genes with dysregulated RNA transcript levels. Overall, OGM and HiC modalities add considerably to our ability to detect oncogenic SVs and the genes they affect.

#2776 Leveraging HiChIP to assess chromatin interactions of lung cells upon smoking-related BaP exposure and identify target genes of lung cancer risk-associated variants.

Elelta Sisay, Thong Luong, Chia-Han Lee, Mai Xu, Jinhu Yin, Jiyeon Choi

NIH-NCI, Rockville, MD

Lung cancer is the leading cause of cancer-related deaths in the United States, with lung adenocarcinoma (LUAD) and lung squamous cell carcinoma (LUSC) as the most frequent subtypes. These subtypes have distinct biological origins and risk loci, as identified through genome-wide association studies (GWAS), which are influenced by environmental exposures such as smoking. GWAS variants, largely found in non-coding regions, are hypothesized to function as cis-regulatory elements (CREs) that influence gene expression. However, CREs do not always regulate the nearest gene and can act over megabase distances. Chromatin conformation capture (Hi-C) assays can link GWAS variants to their target genes over long ranges, but these datasets are scarce and often derived from lung cancer cell lines, which may not recapitulate early tumor development. To address this gap, we performed HiChIP, which combines Hi-C and chromatin immunoprecipitation (ChIP) to profile chromatin interactions at active enhancer regions (marked by H3K27ac) in two non-tumorigenic lung cell lines: HPL1-D and BEAS-2B. These cell lines model the alveolar and bronchial tissues where LUAD and LUSC originate, respectively. To determine molecular effects of smoking on chromatin interactions, we exposed cells to the tobacco smoke carcinogen benzo[a]pyrene (BaP). We tested multiple time points to establish acute (48-hour) and chronic (10-day) BaP protocols, evaluating transcriptional responses, DNA damage, and viability. Acute exposure induced DNA damage marked by γ-H2AX and dose-dependent *CYP1A1/CYP1B1* responses by 48 hours, while chronic exposure elicited stronger nuclear metabolic and inflammatory responses measured by *RRM2* and *IL1R1* expression, respectively. The IC_{20} dose of BaP, determined as 0.10 µM after 10- and 20-day treatments, guided the selection of 0.10 µM and 0.25 µM BaP for chronic exposure and 0.25 µM and 0.50 µM for acute exposure, with DMSO as a control. Notably, BEAS-2B cells showed significant responses to BaP, while HPL1-D did not. Critical optimization steps in HiChIP to ensure ChIP efficiency, sensitivity, and specificity include complete cell lysis and efficient DNA shearing by sonication. Incorporating a FACS filter successfully reduced clumped cells and improved cell lysis. Optimizing lysis time and sonication power achieved the desired chromatin fragment distribution range. With an optimized workflow, we use the Arima-adapted MAPS and FitHiChIP pipelines to perform quality control, identify interacting regions, and analyze differential loops between conditions. By integrating GWAS data with chromatin interaction profiles, we aim to pinpoint functional variants and their regulatory genes influenced by cell type and BaP exposure. This work will further our understanding of lung cancer etiology while providing a unique dataset for the public.

#2777 Smoking, clonal evolution, and lung cancer risk.

Edward J. Evans[1], Fabio Marongiu[2], Emilia Lim[3], Faiz Jabbar[4], Ferriol Calvet[5], Shi Biao Chia[1], Amy Briggs[1], Nuria Lopez-Bigas[5], Moumita Ghosh[1], Mariam Jamal-Hanjani[6], York Miller[1], Charles Swanton[4], James V. DeGregori[1]

[1]University of Colorado Anschutz Medical Campus, Aurora, CO,[2]University of Cagliari, Cagliari, Italy,[3]University of British Columbia, Vancouver, BC, Canada,[4]The Francis Crick Institute, London, United Kingdom,[5]Institute for Research in Biomedicine Barcelona, Barcelona, Spain,[6]University College London, London, United Kingdom

Lung cancer is the leading cause of cancer mortality in the U.S. and in the world. Although tobacco use has steadily declined with a corresponding decrease in lung cancer incidence, the impact of smoking on the progression to lung cancer and its mechanisms are largely unresolved. This is further highlighted by the fact that the presence of oncogenic mutations persists in histologically normal tissue for years, even decades. Therefore, we sought to understand the mechanisms by which smoking exposure alters the somatic mutational landscape to result in lung oncogenesis. To observe somatic mutations, we used a rare-mutation detection technique, DuplexSeq, to analyze somatic variants across a 50kb panel of 31 genes associated with lung cancer from 400+ lung samples. We acquired DNA from lung cells from bronchoscopy brushings (BDRE cohort) and surgical samples of histologically normal tissue (PEACE and TRACERx cohorts) from people who currently, formerly, or never smoked cigarettes. We characterized mutations using bioinformatic pipelines and various databases. For each cohort, we analyzed the mutational landscape at the panel, gene, and nucleotide level. Across the panel, we observed higher summations of the variant allele frequencies (VAFs) from those with a smoking history than those who abstained from smoking, indicating that smoking selected for larger clones in cancer-associated genes. Despite the different nature of the samples across cohorts, numerous genes showed increased VAFs and altered dN/dS measures of selection independent of smoking status when compared to the control *TIAM2* gene, suggesting that selection is already at play in histologically normal tissue. When looking at the nucleotide level, the most deleterious and cancer-associated mutations and drivers (based on the Cancer Genome Atlas and COSMIC) are most prevalent in the people who smoked. We also conducted Principal Component Analysis on the mutations from multiple lung regions of the same individual. Here, we observe higher intra-lung similarity of mutational landscape than similarity based on smoking status, highlighting the uniqueness of mutational landscapes to each individual. Using CRISPR technology, we recapitulated mutations observed in the human tissue samples in air-liquid interface and mouse models of the lung, where we observed disruptions in cell proliferation and differentiation. With the duality of characterizing the mutational landscape in the lung and modeling the observed mutations, we can begin to elucidate the mechanisms by which smoking can induce oncogenesis and understand the intermediate phenotypes in the progression of lung cancer. Altogether, these results show that while lung tissue exhibits mutation-driven clonal expansions independent of smoking history, that smoking enhances selection for particular cancer-associated mutations consistent with the increased risk of lung cancers, emphasizing the value of precision diagnoses and prevention.

#2778 Large-scale multi-omic analysis identifies noncoding somatic driver mutations and nominates *ZFP36L2* as a driver gene for pancreatic ductal adenocarcinoma.

Jun Zhong[1], Aidan O'Brien[1], Minal Patel[1], Daina Eiser[1], Michael Mobaraki[1], Irene Collins[1], Li Wang[2], Konnie Guo[2], ThucNhi TruongVo[2], Ashley Jermusyk[1], Maura O'Neill[3], Courtney D. Dill[1], Andrew D. Wells[4], Michelle E. Leonard[4], James A. Pippin[4], Struan F. A. Grant[5], Tongwu Zhang[1], Thorkell Andresson[3], Katelyn E. Connelly[1], Jianxin Shi[1], H. Efsun Arda[2], Jason W. Hoskins[1], Laufey T. Amundadottir[1]

[1]Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Rockville, MD,[2]Center for Cancer Research, National Cancer Institute, National Institutes of Health, Rockville, MD,[3]Frederick National Laboratory for Cancer Research, Leidos Biomedical Research Inc, Rockville, MD,[4]Center for Spatial and Functional Genomics, Children's Hospital of Philadelphia, Rockville, MD,[5]Division of Human Genetics and Center for Applied Genomics, Children's Hospital of Philadelphia, Rockville, MD

Pancreatic ductal adenocarcinoma (PDAC) is predicted to become the second leading cause of cancer-related mortality in the U.S. by the end of this decade. Due mainly to a late stage at diagnosis and lack of effective treatment, PDAC is a highly lethal malignancy with an overall 5-year survival rate of 13%. This highlights an urgent need for further research into the etiology of PDAC to improve outcomes for this cancer of unmet need. Cancer develops due to somatic and germline genetic factors exerting their influence within the cellular context of environmental factors. Most somatic mutations are in noncoding regions of the genome, but identification of noncoding somatic driver mutations remains challenging. To comprehensively characterize noncoding driver mutations for PDAC, we first created genome-scale maps (2,929,610 elements) of accessible chromatin regions (ACRs) (using ATAC-Seq) and histone modification marks (HMMs) (using ChIP-Seq for H3K27Ac, H3K27me3, H3K4me1 and H3K4me3 marks) in pancreatic cell lines and purified pancreatic acinar and duct cells. Integration with whole-genome mutation calls from 506 PDACs revealed 314 ACRs/HMMs significantly enriched with 3,614 noncoding somatic mutations (NCSMs). Although a majority of these were only observed in a single patient, using enrichment analysis, we identified 988 NCSMs located to ACRs/HMMs where at least two PDAC patients had a mutation within a 31bp window (selected as the longest ENCODE transcription factor (TF) motif). On one hand, to identify the potential target genes for the 988 NCSMs highlighted by our enrichment analysis, chromatin interactions between promoter and enhancer regions by high-resolution promoter-focused capture C (in-house datasets) and HiChIP revealed 416 target genes putatively implicated by these NCSMs, and differential expression analysis revealed six significant NCSMs/target gene pairs by RNA-seq. One the other hand, to functionally assess if the 988 NCSMs alter gene regulatory activity, the functional assessment using massively parallel reporter assays (MPRA) (in-house datasets) identified 178 NCSMs impacting reporter activity (19.45% of those tested) in one or more cell lines. Focused luciferase validation confirmed negative effects on gene regulatory activity for NCSMs near *CDKN2A* and *ZFP36L2*. For the latter, CRISPR interference (CRISPRi) further identified *ZFP36L2* as a target gene (16 - 24% reduced expression, $P = 0.0230\text{-}0.0047$) with disrupted KLF9 binding likely mediating the effect. Our integrative analysis provides a catalog of potentially functional noncoding driver mutations, nominates *ZFP36L2* as a PDAC driver gene and highlights potential therapeutic targets. Moreover, our approach provides a paradigm for employing a multi-omics approach to decipher complex noncoding mutations related to tumorigenesis.

#2779 Whole transcriptome spatial exploration of cultured tumor cells at subcellular resolution.

Yi Cui, **Shanshan He**, Margaret Hoang, Rachel Liu, Tushar Rane, Rustem Khafizov, Haiyan Zhai, Christine Kang, Michael Rhodes, Joseph Beechem

Bruker Spatial Biology, Seattle, WA

Cancer research has long sought to understand the complex tumor microenvironment and the molecular underpinnings of tumor progression. Traditional methods often fail to capture the spatial organization and cell-cell interactions within tumors. The CosMx® Spatial Molecular Imager (SMI) with its CosMx Whole Transcriptome (WTX) panel offers a transformative solution, providing spatially resolved, single-cell transcriptomics with nanometer-scale precision. This platform enables the mapping of RNA molecules within their native tissue context, which is essential for uncovering critical biological insights related to cancer cell behavior, tumor microenvironment interactions, and therapeutic responses.

We developed and optimized a tailored protocol for in vitro cell-based assays using the CosMx WTX platform. Key steps, including permeabilization and enzymatic digestion, were fine-tuned to preserve RNA integrity and cellular morphology, ensuring high-quality transcript detection. Cancer cell lines, U2OS (osteosarcoma) and SH-SY5Y (neuroblastoma), were cultured and analyzed using CosMx WTX to map the spatial distribution of RNA transcripts. The data were compared to bulk RNA-seq results to validate reproducibility and accuracy. The assay's spatial resolution allows for precise mapping of individual RNA molecules within their spatial context, facilitating phenotype-associated spatial transcriptomics.

In our analysis, the CosMx WTX platform successfully quantified approximately 7,300 transcripts per cell in U2OS cells and 1,900 transcripts per cell in SH-SY5Y cells, showing high reproducibility and strong agreement with bulk RNA-seq data. This high-throughput capability allows for robust transcriptomic profiling of diverse cancer cell types. By correlating gene expression data with morphological and functional phenotypes, we were able to visualize the spatial organization of transcripts within cells. The platform's nanometer-scale resolution also supports mapping of cancer organoids, offering insights into intratumoral heterogeneity, treatment resistance, and metastatic processes.

The CosMx WTX cell-based assay represents a significant advancement in spatially resolved transcriptomics. By enabling high-resolution analyses, this platform provides valuable insights into cancer biology and offers a powerful tool for drug screening and companion diagnostic development. The integration of spatial transcriptomics with protein-level data holds the potential to transform our approach to cancer diagnostics and therapy, advancing precision medicine and improving patient outcomes.

#2780 Topoisomerase IIb binding underlies frequently mutated elements in cancer genomes.

Juri Reimand[1], Christian A. Lee[1], Robin H. Oh[2], Zoe P. Klein[1], Nina Adler[1], Sana Akhtar Alvi[3], Ellen Langille[2], Elisa Pasini[4], Kevin C. L. Cheng[1], Diala Abd-Rabbo[1], Huayun Hou[3], Ricky Tsai[2], Mamatha Bhat[1], Daniel Schramek[2], Michael D. Wilson[3], Liis Uuskula-Reimand[3]

[1]Ontario Institute for Cancer Research, Toronto, ON, Canada,[2]Lunenfeld-Tanenbaum Research Institute, Toronto, ON, Canada,[3]Hospital for Sick Children, Toronto, ON, Canada,[4]University Health Network, Toronto, ON, Canada

Type-II topoisomerases resolve topological stress in DNA through controlled double-strand breaks. While TOP2A is a chemotherapy target in proliferating cells, the ubiquitously expressed TOP2B is a potential off-target. Here we explore roles of TOP2B in mutagenesis by generating DNA-binding maps of TOP2B, CTCF, and RAD21 in human cancer samples and analyzing these maps for driver mutations and mutational processes in 6500 whole cancer genomes. TOP2B-CTCF-RAD21 and TOP2B-RAD21 sites are enriched in somatic mutations and structural variants (SVs), especially at evolutionary conserved sites displaying high transcription and long-range chromatin interactions. TOP2B binding underlies SVs and hotspot mutations in cancer-driving genes such as TP53, MYC, FOXA1, and VHL, and many cis-regulatory elements. We show that the TOP2B-bound mutational hotspot at RMRP drives tumor initiation and growth in vivo. These data highlight TOP2B as a protector of the genome from topological challenges whose aberrant activity promotes driver and passenger mutations in cancer genomes.

#2781 Enabling low cell input and high throughput processing of cell fixation for single cell RNA profiling using combinatorial barcoding.

Olivia Kaplan, Sarah Schroder, Vuong Tran, Simone Marrujo, Alec Salvino, Ajay Sapre, Ian Dowsett, Zeynep Sayar, Alex Koriath, Alex Sova, Gary Geiss, Charles Roco, Alex Rosenberg

Parse Biosciences, Seattle, WA

Single cell analysis is a critical approach to tease out nuanced information in any biological system. Combinatorial barcoding is an extremely efficient method for scRNA-seq at scale, achieving both sensitivity in gene detection and flexibility in sample input. This approach, however, is challenging when starting with sample inputs of less than 100,000 cells. To address this, we have developed a modified fixation and cell capture method for low sample inputs that is compatible with the combinatorial barcoding approach. This allows researchers working with low sample inputs to fix, store and barcode their cells efficiently without the need for costly or specialized instruments. Low Input Fixation can be used to fix and profile up to 384 samples in parallel, results in a shorter workflow, and enables consistent handling (which minimizes both experimental error and burden on scaling). This method maintains the stability of fixed samples at -80℃ and capture efficiency remains consistently high for inputs as low as 10,000 cells. The workflow maximizes sample recovery while providing accurate and comprehensive results of transcriptional changes from experimental perturbations. As proof-of-concept we screened a cancer drug panel with cell input amounts between 10,000 - 20,000 cells per treatment. Robust cell capture minimizes loss during drug perturbations resulting in consistent gene detection. Whole transcriptome analysis using Evercode WTK identifies changes in gene expression associated with each drug class and cell type. Results of the screen validate putative drug targets in the panel. Additionally, panel-based perturbation allows for detection of off-target impacts at scale. This work demonstrates the combination of low input fixation with combinatorial barcoding to enable high throughput cancer drug and compound screening.

#2785 Effects of melatonin and 17β-estradiol on the miR-222-3p's expression and activity in IDCs cells.

Bruna Cristine De Almeida, Kelly Pedrozo Ferreira, Jose Maria Soares-Junior, Juciara Costa Silva, Katia Candido Carvalho, Edmund Chada Baracat

Departamento de Obstetricia e Ginecologia, Faculdade de Medicina da Universidade de Sao Paulo, Sao Paulo, Brazil

Background: The *DICER* gene encodes a protein that is required for RNA interference and microRNA (miRNA) synthesis. It is known that miRNAs have a substantial impact on cancer origin and progression, and they are deeply involved in the posttranscriptional regulation of genes expression. A growing body of evidence indicates that the oncomiR *miR-222-3p* overexpression promotes proliferation, migration, invasion, and metastasis of breast cancer (BC) cells as well as chemoresistance, by the regulation of its target genes. However, in this circuit, the *miR-222* negatively regulates the expression of *DICER*, which can be involved with tumor malignant behavior. In an attempt to modulate the *miR-222* expression, we treated invasive ductal carcinoma (IDC) cells with melatonin (Mel), which exerts anti-tumor actions by regulating miRNA expression and may protect against BC. In addition, we stimulated the IDC cells with 17β-estradiol (E2) to mimic the hormonal conditions. Hence, our goal was to evaluate the *miR-222* expression under the effects of Mel and E2 treatments in IDC cells and to assess the expression of its target gene *DICER*.
Methods: MCF7 and MDA-MB231 cell lines treatments were performed with 3000 µM Mel and 100 nM E2, and the two drugs were combined (M+E2) and were replaced daily. After the treatment, the RNA was extracted and the reverse transcription was performed. Expression of *miR-222* and *DICER* were assessed by RT-PCR. Data analysis was performed with ExpressionSuite Software v1.3.
Results: *miR-222* showed a significant decrease with Mel (fold: 0.701) and M+E2 (fold: 0.829) treatments in MCF7 cells, compared to control. However, the E2 treatment did not significantly affect the *miR-222* expression. Inversely, *DICER* expression was increased with suppression of *miR-222* after the treatments, both Mel (fold: 1.436) and M+E2 (fold: 1.368). After the E2 treatment, *DICER* presented low expression levels (fold: 0.720), compared to control. In MDA cells, the expression levels of *miR-222* were increased after Mel (fold: 1.095) and M+E2 (fold: 1.109) treatments, compared to control. *miRNA-222* showed a slight reduction in expression with E2 treatment (fold: 0.856). Nonetheless, *DICER* did not present differences of expression. Although Mel and M+E2 led to a greater expression of *miR-222*, these treatments also increased the expression of *DICER* (Mel fold: 2.011 and M+E2 fold: 1.979).
Conclusion: These data revealed that *miR-222* contributes to the tumorigenicity of IDC through the down-regulation of *DICER* in MCF7 cells. In addition, the anticancer effect of Mel modulates the critical expression of *miR-222-3p* and its target *DICER* in IDC cells.

#2786 Investigation on the role of tumor suppressive microRNAs in angiosarcoma.

Bozhi Liu, Jillian Stachon, Annaleigh Powell-Benton, Sagar Utturkar, Nimod Janson, Anthony Murphy, Nadia Lanman, Jason Hanna

Purdue University, West Lafayette, IN

Angiosarcoma (AS) is an aggressive tumor resulting in a very poor prognosis for patients. MicroRNAs (miRNAs) regulate gene expression and play important roles in a variety of diseases including cancer. Our previous studies demonstrate miRNA loss leads to AS in mice. To further understand the role of miRNAs that function as critical tumor suppressors in AS, we performed a miRNA-focused CRIPSR-Cas9 screen. The gRNA library was transduced into a human AS cell line expressing doxycycline (dox)-inducible Cas9. After passaging the cells for 28 days, sgRNA amplicon sequencing was performed to determine the change in the frequency of gRNAs. We anticipated that the loss of function of tumor suppressing miRNAs would lead to gRNA enrichment in the cells. Indeed, three miRNAs were identified as hits with significant enrichment of multiple gRNAs, including miR-200b, miR-181b, and miR-410. We hypothesize these miRNAs act as tumor suppressors and reduce proliferation and cell viability in AS. Based on our RNA-seq data, all three miRNAs are expressed in normal endothelial cells. Additionally, miR-410, miR-181b and a miR-200 family member are significantly downregulated in a human AS cell line and miR-410 is frequently deleted in AS patient samples. We are currently conducting functional validation studies by overexpressing these miRNAs in a panel of AS cell lines by lentiviral based expressing the pre-miRNAs. In preliminary results, the overexpression of miR-410 consistently inhibits cell proliferation and colony formation ability in both human and mouse AS cell lines. Additionally, to gain mechanistic insights for these miRNAs, a novel technique called AgoTRIBE was used to identify important mRNA targets regulated by miRNAs. In AgoTRIBE, the miRNA effector Ago2 is fused to ADAR's RNA editing domain, directing ADAR activity to miRNA natural targets. The ADAR editing events on miRNA targets can be detected by RNA seq. We used a dox-inducible lentiviral vector expressing human ADAR (hADAR) or hADAR-Ago in a mouse AS cell line. In preliminary data, we validated the protein expression of ADAR and ADAR-Ago upon dox treatment and the cellular localization of these complexes in cytoplasm. We are working on validating the function of AgoTRIBE by RNA seq and utilize this tool to identify targets regulated by our screen hits. This project represents the first global screen on miRNAs in AS. Functional validation of the hits from the screen in combination with the mechanistic insights from AgoTRIBE can provide fundamental evidence for the role of tumor suppressive miRNAs in AS.

#2787 Effect of miR-494 modulation in colorectal cancer (CRC): Clinical outcome, target expression and cell characteristics.

P. Mittal[1], J. Millstein[1], S. Soni[1], F. Battaglin[1], K. Ashouri[1], S. Algaze[1], P. Jayachandran[1], Y. Yang[1], L. T. Gonzalez[1], U. H. Shah[1], W. Zhang[1], F.-S. Ou[2], A. P. Venook[3], I. K. Singh[4], H. J. Lenz[1];

[1]USC - University of Southern California, Los Angeles, CA, [2]Mayo Clinic Rochester, Rochester, MN, [3]University of California, San Francisco, CA, [4]University of Delhi, New Delhi, India

Background. MicroRNAs are small, single-stranded non-coding RNA molecules that play major role in gene regulation. miRNAs have been reported as both tumor suppressive and oncogenic and are promising candidates for cancer prognosis and treatment. miR-494 is known to promote cell migration and invasion in CRC. Our study aimed to further explore the role of miR-494 modulation (inhibition and overexpression) in CRC.

Methods. We evaluated the impact of tumor gene expression of *MIR494* on outcomes (overall survival: OS; progression-free survival: PFS) in data for 433 metastatic CRC (mCRC) patients (pts) (bevacizumab [bev] (N = 226) vs cetuximab [cet] (N = 207)) enrolled in randomized phase III CALGB/SWOG 80405 trial obtained from Alliance for Clinical Trials in Oncology. RNA extracted from FFPE tumor samples was sequenced using the HiSeq 2500 (Illumina). Gene expression was divided into high, medium and low. Associations were assessed by log-rank test and multivariable Cox proportional hazards regression model. Treatment-gene interactions were analyzed using the likelihood ratio test. CRC cell lines HCT116 and HT29 were transfected with miR-494 inhibitors and mimics for 48 hours and total RNA was collected, followed by RT-qPCR (miR-494 and target genes *BMAL1*, *PAK1*, *CDH1*, *CDH2*, *SNAI1*, *TWIST*) and clonogenic assays.

Results. High miR-494 was significantly associated with worse PFS in overall (median survival: high vs low: 9.3 vs 11.3 months, $P<0.025$) and cet-treated (median survival high vs low: 9.2 vs 9.6 months, $P<0.025$) mCRC cohorts, while no significance was observed in bev-treated mCRC. Multivariable Cox model showed significant association between high miR-494 and worse PFS and OS in the cet-treated cohort; however, treatment-gene interaction was not statistically significant. Expression analysis revealed miR-494 was significantly reduced and increased following inhibitor and mimic transfection, respectively. Differential gene expression of the target genes analyzed was observed between the miR-494 inhibitor and mimic-treated HCT116 and HT29 samples. In HCT116 cells, inhibition of miR-494 significantly ($P < 0.01$) reduced expression of *PAK1*, while increased the expression of *CDH1*. The number of colonies formed relatively increased after transfection with miR-494 inhibitor compared to miR-494 mimic.

Conclusion. Our findings showed that high miR-494 expression correlated with worse PFS overall and in cet-treated mCRC pts. It would be interesting to check for potential associations with EGFR signaling (direct or indirect). Further studies are warranted for efficient targeting and to gain better understanding of the associated signaling involved in miR-494 modulation in CRC. Support: U10CA180821, U10CA180882; U10CA180888 (SWOG): Genentech. https://acknowledgments.alliancefound.org; P30CA014089, UG1CA180830 [HJL]. Clinicaltrials.gov Identifier: NCT00265850

#2788 Targeting miR-92b reduces neurosphere formation in glioblastoma cancer stem cells.

Annelis O. Sanchez-Alvarez[1], Diego Garcia-Ortiz[2], Misael Rivera-Garcia[3], Alanis M. Labeaga-Sainz[3], Pablo E. Vivas-Mejia[2]

[1]Clinical & Translational Research, University of Puerto Rico Comprehensive Cancer Center, San Juan, Puerto Rico,[2]Biochemistry, University of Puerto Rico Medical Sciences Campus, San Juan, Puerto Rico,[3]Interdisciplinary Studies of Natural Sciences, University of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico

Glioblastoma (GBM) is a grade IV brain tumor with a dismal prognosis, driven by aggressive brain tumor-initiating cells (BTICs). This study focuses on targeting microRNA-92b-3p (miR-92b-3p), a microRNA aberrantly overexpressed in GBM that correlates with poor patient outcomes. We utilized primary BTIC neurospheres M1123 and GBM1A, derived from GBM patients, to investigate miR-92b-3p's role in tumor progression and therapeutic resistance. Our findings revealed a striking 40-fold higher basal expression of miR-92b-3p in GBM1A compared to M1123. Functional studies showed that miR-92b-3p inhibition significantly disrupted neurosphere formation in both cell lines up to 96 hours post-transfection, highlighting its essential role in maintaining GBM stemness. Additionally, the IC50 values for temozolomide, the standard GBM chemotherapeutic agent, were 27 µM for M1123 and 30 µM for GBM1A, suggesting similar baseline resistance. Ongoing experiments are exploring whether miR-92b-3p inhibition sensitizes BTICs to temozolomide, potentially enhancing its efficacy. These results underscore miR-92b-3p’s critical role in neurosphere maintenance and chemoresistance in GBM cancer stem cells. Its overexpression may serve as a biomarker for aggressive tumor behavior, and its inhibition represents a promising therapeutic strategy to target BTICs, disrupt GBM progression, and improve patient outcomes.

#2789 miR-6794-3p inhibits human pancreatic cancer metastasis by regulating the RBBP4/GRHL2 signaling pathway.

H. Kim, E.-T. Oh, Y. Cho, H. Park;
Inha University College of Medicine, Incheon, Korea, Republic of

Metastasis is a major cause of treatment failure in patients with pancreatic cancer, highlighting the urgent need for effective therapeutic strategies. Here, we focused on identifying novel miRNAs with key roles in metastasis of pancreatic cancer. Microarray analysis of miRNA expression in metastatic and non-metastatic pancreatic cancer samples revealed significantly lower expression of miR-6794-3p in the metastatic tumor group. Gain- and loss-of-function approaches using the pancreatic cancer cell lines MIA-PaCa-2 and HPAF-II expressing low and high levels of miR-6794-3p, respectively, indicated a role of miR-6794-3p in suppression of cell invasion, migration, and EMT signaling. Importantly, our results showed that miR-6794-3p exerts its effects by inhibiting expression of the chromatin remodeling factor, RBBP4. The resulting suppression of RBBP4 induced an increase in the levels of GRHL2 involved in regulating invasion, migration, and EMT signaling in metastatic pancreatic cancer cells. Consistent with these findings, low miR-6794-3p expression levels correlate with poor pancreatic cancer patient survival. Additional preclinical experiments on nude mice clearly demonstrated inhibitory effects of miR-6794-3p on pancreatic cancer cell metastasis. The collective results highlight the functional significance of miR-6794-3p as a suppressor of metastasis and support its predictive utility as a prognostic biomarker and therapeutic target in pancreatic cancer.

#2790 Identification of tumor suppressor miRNA to regulate FXYD3 in pancreatic cancer cells.

Ke Xin Yee, Kuen-Haur Lee

PhD program of Cancer Biology and Drug Discovery, College of Medical Science and Technology, Taipei Medical University-Shuang Ho Campus, New Taipei, Taiwan

Pancreatic cancer (PC) continues to be one of the deadliest cancers globally, ranking among the top causes of cancer-related mortality. Despite significant progress in medical research, effective methods for early diagnosis and treatment remain challenging, contributing to poor survival rates. MicroRNAs (miRNAs), small non-coding RNA molecules that consist of 18-25 nucleotides, have emerged as critical regulators of gene expression as therapeutic agents and diagnostic biomarkers. Recently, the oncogene FXYD3 has gained attention as a candidate for early detection, offering a promising result for research. In this study, we applied bioinformatic analyses to identify potential interactions between tumor-suppressing miRNAs and the oncogene FXYD3. Our findings revealed that several miRNAs directly target FXYD3, highlighting their role in regulating its expression. To validate these predictions, we performed immunohistochemistry (IHC) analysis. The results confirmed that these miRNAs were significantly overexpressed in normal pancreatic tissues compared to PC tissues. These observations suggested that the loss of specific miRNAs could contribute to the upregulation of FXYD3, promoting tumor progression. Interestingly, our study also found differential expression patterns of these miRNAs across various pancreatic cancer cell lines, indicating cell-type-specific regulatory mechanisms. The findings of the functional assays using miRNA mimics or inhibitors provide a foundation for developing miRNA-based therapeutic strategies targeting FXYD3. In summary, this study emphasizes the importance of miRNAs that target FXYD3 in pancreatic cancer. Our research supports their role as tumor suppressors and underscores their therapeutic potential in combating one of the most aggressive and challenging cancers.

#2792 PiRNA as a novel therapeutic in hepatocellular carcinoma: insights from population screening.

Rui Han[1], Qin Qin[1], Ran Liu[1], Tianshu Wu[1], Yaya Guo[1], Peyton Cook[2], Kinsey Garofalo[2], Yujuan Guo[2], Bolni Nagalo[2], **Yong Zhu**[2]

[1]Yale University School of Public Health, New Haven, CT,[2]University of Arkansas for Medical Sciences, Little Rock, AR

Hepatocellular carcinoma (HCC) ranks as the third leading cause of cancer-related death globally and is the fastest-growing cause of cancer-related deaths in the United States. Current therapies, such as chemotherapy and radiotherapy, are largely ineffective in advanced HCC due to tumor-specific characteristics, resistance to drugs and radiation, and substantial adverse effects. Despite breakthroughs in immunotherapy, approximately 80-85% of American patients with advanced HCC fail to respond to treatments. These challenges underscore the urgent need for more effective therapeutic strategies to treat HCC. One emerging therapeutic strategy involves the use of small non-coding RNAs (ncRNAs), which have shown promising efficacy in both preclinical and clinical studies for various cancer types. Piwi-interacting RNAs (piRNAs) are an abundant of small non-coding RNAs (ncRNAs) involved in maintaining genomic stability and represent a promising but largely unexplored avenue for cancer treatment. The current study identified a piRNA candidate and examined its therapeutic implication for the treatment of HCC. First, we performed piRNA arrays for small RNAs isolated from 12 pairs of HCC tissues and normal liver tissues and detected significantly downregulated piRNAs in HCC tissues compared to normal liver tissues. Downregulation of piR-37213 was confirmed using the TCGA small RNA-seq data of HCC tissues (N=331) and normal liver tissues (N=48). Lipid nanoparticles (LNP) were used as a delivery vehicle to capsulate piR-37213 in functional tests. Significant tumor-suppressing effects of piR-37213 were observed in a series of *in vitro* assays ($P<0.01$), including cell proliferation assays, colony formation assays, 3D formation and invasion assays. Systemic delivery of LNP-piR-37213 was administered in animal experiments. Mice (N=44) were treated twice a week for four consecutive weeks via tail vein injection. Tumor signals were significantly reduced by 90% $P<0.001$) after 2 weeks of treatment. Survival was significantly improved ($P<0.05$). Both *in vitro* and *in vivo* experiments suggest that the identified piRNA candidates, which are downregulated in HCC tissues, play a tumor-suppressing role. A genome-wide expression profiling analysis was further performed and found that genes involved in cell cycle proliferation, replication, and DNA repair were significantly downregulated, which further provided molecular mechanisms accounting for the anti-tumor effect of under-expressed piR-37213. This preclinical study represents the crucial initial step in developing a novel, piRNA-based therapeutic strategy for liver cancer and provides proof of principle for the use of piRNAs in future clinical treatment. Future studies are needed to explore the transformative potential of this early-stage, highly innovative, piRNA-based technology in cancer treatment.

#2793 LncRNA CRNDE facilitates head and neck cancer progression by modulating the tsmiRs-oncogenes network regulating multiple oncogenic signaling pathways.

T. Lin, A. Cheng, Y. Chen, H. Huang;
Chang Gung University, Taoyuan, Taiwan

Recent studies have emphasized the pivotal role of long non-coding RNAs (lncRNAs) in tumorigenesis, with CRNDE identified as dysregulated in several cancers. This study explores the role of CRNDE in head and neck cancer (HNC), a globally prevalent malignancy. We demonstrate that CRNDE drives key malignant phenotypes in HNC, including enhanced cell migration, invasion, proliferation, and chemoresistance. RNA sequencing identified numerous downstream effectors, with 195 oncogenes significantly enriched in cancer-related pathways, such as focal adhesion, actin cytoskeleton organization, and PI3K-AKT, Ras, and Rap1 signaling. To elucidate the regulatory mechanisms of CRNDE, we observed that it predominantly localizes in the cytosol of HNC cells, suggesting its primary role in miRNA modulation. Bioinformatic analysis identified 14 miRNAs with strong regulatory potential. Among these, three tumor-suppressive miRNAs (TsmiRs)—miR-181c-5p, miR-29a-3p, and miR-29b-3p—were prioritized based on their clinical relevance from the TCGA-HNSC dataset. Further analysis revealed that these miRNAs potentially regulate 391, 417, and 137 target genes. Integrative analysis demonstrated that these hub miRNAs co-regulate 69 oncogenes, significantly influencing five cancer-related pathways. We constructed a comprehensive CRNDE-TsmiRs-Oncogenes regulatory network, uncovering a complex cross-regulatory mechanism. Moreover, we validated the CRNDE-miR-181c-PI3K/AKT3 axis as a critical pathway in HNC progression. Overexpression of miR-181c-5p markedly suppressed CRNDE-driven cancer progression by downregulating PI3K/AKT expression and mitigating malignant phenotypes, including migration, invasion, and chemoresistance. This study presents a novel CRNDE-TsmiRs-Oncogenes molecular network and highlights the CRNDE/miR-181c-5p/AKT axis as a promising biomarker and therapeutic target for improved HNC management.

#2797 N-linked and O-linked glycosylated RNA enrichment in human prostate cell lines with low/no malignancy.

Esther Jones, Samantha McGuire, Spencer Moen, **Aurora Esquela Kerscher**

Biomedical & Translational Sciences, Eastern Virginia Medical School at ODU, Norfolk, VA

Our lab is the first to characterize glycosylated RNA in the context of human prostate cancer (PCa). PCa is the 2nd leading cancer-related cause of male deaths in the United States. As high-grade forms of PCa often lead to poor prognoses, it is imperative to improve patient stratification screening tools and treatment options to increase patient survivorship. Noncoding RNAs are widely misexpressed in clinical PCa tissues and many act as key tumor suppressors, oncogenes, and metastatic factors in the prostate. Noncoding RNA harbor a range of post-transcriptional modifications (m6A, pseudouridine, uridine tailing) important for RNA folding, stability, transport, and localization. Dysregulation of these RNA modifications is often associated with malignancy, disease aggressiveness, and drug resistance. Noncoding RNA carrying a newly discovered class of glycosylation modifications was recently discovered in cultured human and mouse cells metabolically labeled using bioorthogonal chemistry methods normally employed for glycosylated protein and lipid enrichment. Nothing is known about the existence/significance of prostate glycoRNA or its role in disease. We hypothesized that RNA requires carbohydrate modifications to maintain prostate homeostasis and predicted that the glycosylated state of RNA would correlate with disease progression. We first confirmed that prostate glycoRNA exists in the human prostate. Our studies employed a stringent RNA isolation workflow and were tested using two independent approaches; metabolic labeling with azide click chemistry for biotin-tag detection & lectin northern blot analysis. Using metabolic azidosugar reagents that preferentially labeled N-linked (Ac4ManNAz) or O-linked (Ac4GalNAz) modifications, we detected small (<200 nt) noncoding RNA (but not large RNA) carrying N-linked and O-linked sugars that showed sensitivity to endoglycosidases (PNGase F, O-glycosidase) and glycosylation inhibitors. GlycoRNA expression correlated with PCa progression with preferential enrichment in human prostate cell lines and syngeneic panels with low/no malignancy compared to metastatic lines. Lectin northern blot studies (WGA, PNA, ConA) verified that prostate RNAs carry N-linked and O-lined sugars. Subcellular fractionation studies indicated glycoRNA localization predominantly at the plasma membrane of prostate cells. Results from our RNAseq and glycomics studies are ongoing and will also be discussed. Furthermore, we verified that *C. elegans* grown on Ac_4GalNAz plates expressed glycoRNA, indicating conservation across species. This work will provide novel insight into how RNA modifications impact PCa progression and identify first-in-class clinical tools to improve patient outcomes.

#2798 Long non-coding RNA DUXAP10 regulates mediators of endoplasmic reticulum stress-induced epithelial-to-mesenchymal transition in anaplastic thyroid cancer.

Nicole R. DeSouza[1], Kate Nielsen[1], Danielle Quaranto[1], Michelle Carnazza[1], Tara Jarboe[1], Kaci Kopec[1], Robert Suriano[1], David Garber[2], Steven Hemmerdinger[2], Augustine Moscatello[2], Humayun K. Islam[1], Raj K. Tiwari[1], Jan Geliebter[1]

[1]New York Medical College, Valhalla, NY,[2]Westchester Medical Center, Valhalla, NY

Anaplastic Thyroid Cancer (ATC) is a fast-growing, metastatic and lethal carcinoma with mortality rates reaching ~100%. Understanding the molecular landscape that separates ATC from other slow-growing, highly survivable thyroid carcinoma subtypes is key to biomarker detection, therapeutic successes, and increased patient survival. Long non-coding RNAs (lncRNA) use their extensive DNA, RNA, and protein-binding domains to orchestrate cell function. These multi-ranged regulatory capabilities make their study in ATC salient. LncRNA DUXAP10 is overexpressed in NCBI GEO datasets by 40-fold and 20-fold (GSE33630, GSE85457) in ATC patient tissue and primary ATC cell lines compared to normal thyroid tissue. DUXAP10 expression is higher in samples taken from primary ATC sites (cBioPortal) and its overexpression is correlated with distant metastasis and lower patient survival (cBioPortal, GEPIA).

Our data supports DUXAP10 overexpression in ATC cell line T238, and the transcriptional reduction of its expression was achieved using CRISPRi technology. Supporting experiments show a significant role for DUXAP10 at the interface of metastatic phenotypes driven by the convergence of the Unfolded Protein Response (UPR) and Wnt/β-catenin-induced epithelial-to-mesenchymal transition (EMT). Hypoxia is a central issue at ATC tumor sites, resulting in an unremitting survival adaptation that by-passes ER-stress induced apoptotic branches of the UPR. Our data showed that ER-stress induced upregulation of EMT phenotypes was ameliorated by CRISPRi-reduced DUXAP10 expression- functioning via β-catenin-driven rapid growth induction of PERK-mediated EMT.

DUXAP10 was determined to have strong nuclear localization in T238. Current work includes investigation of its protein-scaffolding role in the nucleus, and how this specific function is impacting mediators of the UPR and Wnt/β-catenin regulation. Other supporting data confirms a role for DUXAP10 in T238 proliferation, clonogenicity, apoptosis, cell-cycle regulation, invasion, migration and rate of RNA synthesis. These data reveal the novelty of DUXAP10, and that its over-expression may increase the negative consequences of ATC metastasis.

#2799 SNORD80-guided 2'-O-methylation stabilizes the lncRNA GAS5 to regulate cellular stress responses.

L. Xu, X. Zhao, Y. Zhang, L. Jin, X. Zhang;
University of Newcastle, Australia, Newcastle, Australia

The introns of the gene encoding the long noncoding RNA (lncRNA) GAS5 host up to 10 C/D box small nucleolar RNAs (snoRNAs). However, whether there is a regulatory and functional relationship between these snoRNAs and GAS5 is unknown. Here, we show that the expression of SNORD80, but not the other snoRNAs, parallels GAS5 expression and is regulated alongside GAS5 in response to cellular stress. The 2′-O-methylation at the A496 site, located within a segment of GAS5 complementing the conserved RNA binding region on SNORD80, promotes GAS5 stability and consequent upregulation. This methylation requires SNORD80, as it is diminished by knockdown of SNORD80 and increased by SNORD80 overexpression, similar to the effects of manipulating the expression of fibrillarin, the methyltransferase of the box C/D small nucleolar ribonucleoprotein particle (snoRNP). The upregulation of SNORD80 in response to cellular stress is due to an enhancement in its stability, which is associated with an increase in its interaction with fibrillarin. Collectively, these results identify a novel role for SNORD80 in guiding 2′-O-methylation to stabilize GAS5. This uncovers a feedforward regulatory loop at the GAS5 gene locus in response to cellular stress and sheds new light on posttranscriptional mechanisms governing lncRNA expression.

#2800 Unraveling long non-coding RNA dynamics in uveal melanoma: Insights into pathogenesis, biomarkers, and targeted therapies.

Vasileios Alevizos[1], Nikitas Gerolimos[2], Sabrina Edralin[3], Clark Xu[4], Akebu Simasiku[5], Georgios Priniotakis[6], George A. Papakostas[7], Zongliang Yue[8]

[1]Karolinska Institutet, Solna, Sweden,[2]University of Aegean, Syros, Greece,[3]University of Illinois Urbana-Champaign, Champaign, IL,[4]Artificial Intelligence & Discovery, Mayo Clinic, Rochester, MN,[5]Zambia University, Lusaka, Zambia,[6]University of West Attica, Attica, Greece,[7]Department of Informatics, Democritus University of Thrace, Kavala, Greece,[8]Auburn University, Auburn, AL

Uveal melanoma (UM), a rare yet aggressive intraocular cancer with an estimated 5 cases per million people annually, presents a high metastatic risk and poor prognosis, highlighting an immeasurable need for novel diagnostic and therapeutic strategies. Not only is UM characterized by complex genetic and epigenetic aberrations, but it is also prone to deregulation of non-coding RNAs that could be used as therapeutic targets of diagnostic markers. In this study, we analyzed whole exome sequencing data from tumor and control samples of patients diagnosed with both uveal and cutaneous melanoma, focusing on a patient with a germline mutation in MBD4. Our framework, made up to work with long non-coding RNAs (lncRNAs), aims to flesh out these molecules' novel roles in disease etiology and progression. We identified several lncRNAs significantly associated with UM progression and computationally validated them in conjunction with microenvironmental factors in existing literature. LncRNAs are instructive in maintaining cellular homeostasis and, when deregulated, contribute to oncogenesis. Our results implied that the interaction between lncRNAs and other non-coding RNAs might be one of the most relevant mechanisms influencing UM pathogenesis. More interestingly, microenvironmental factors and lncRNA interplay are crucial in disease progression. The clinical relevance of our findings was tested using radiation treatment to evaluate potential therapeutic implications. Over and above that, we assessed the potential of lncRNAs as biomarkers and therapeutic targets in personalized medicine for UM patients to address ineffective treatments. The new lncRNA panels could serve as a new avenue for targeted therapy. With an in-depth understanding of the descent of molecular alterations and how lncRNAs interact within the tumor microenvironment, we can better size up potential strategies to cast off the challenges UM poses. Our work provides instructive insights into lncRNAs underpinnings of UM, emphasizing the significance of lncRNAs in tumor biology and their interactions within the microenvironment. We believe our findings will lay the groundwork for future therapeutic strategies and underscore the necessity for continued research to unravel the complex mechanisms in UM pathogenesis.

#2801 Functional characterization of long non-coding RNA *PAINT* and mechanistic insights into its crosstalk with splicing factor hnRNPM in cancer progression.

Subhoja Chakraborty[1], Kavya Ganapathy[1], Angela Rodio[1], Manasi Joseph[1], Mitchell Campbell[1], Julia Soulakova[1], Domenico Coppola[2], Ratna Chakrabarti[1]

[1]University of Central Florida, Orlando, FL,[2]Florida Digestive Health Specialist, Lakewood Ranch, FL

Long non-coding RNAs (lncRNAs) modulate crucial cellular processes in nexus with miRNAs, transcription factors and RNA-binding proteins (RBPs) whose dysregulation is often linked with cancer progression and drug resistance. In aggressive, recurrent and often fatal invasive cancers, there is an unmet need to identify newer targets and their mechanistic roles in cancer progression for improved therapies. Previously, we reported an association of lncRNA *PAINT* with aggressive prostate cancer (PCa) and its involvement in dysregulated expression of several cancer hallmark genes including genes in WNT and AKT signaling pathways. In this study, we tested our hypothesis on the general involvement of *PAINT* in cancer. Our study showed an oncogenic role of lncRNA *PAINT* in metastatic breast cancer (BCa) cells. GSE database-based expression analysis showed *PAINT* upregulation in tumor samples compared to normal patient samples. *In-situ* hybridization (ISH) of tissue microarrays revealed differential upregulation of *PAINT* in aggressive BCa subtypes. *PAINT* inhibition decreased proliferation and migration of triple negative BCa (TNBC) cell lines MDA-MB-231 ($BRCA^+$) and MDA-MB-436 ($BRCA^-$), and improved the sensitivity of MDA-MB-231 cells to Doxorubicin, Docetaxel and Carboplatin. *PAINT* over-expression in an inducible MDA-MB-231-*PAINT* stable subline augmented cell proliferation and migration and increased S-phase cell population. Mass spectrometry of *PAINT*-bound proteins using *in-vitro* transcribed biotinylated *PAINT* and PC-3 cell extracts revealed hnRNPM as an interactor of *PAINT*, which was validated by RNA immunoprecipitation in both BCa and PCa cell lines. Ectopic expression of *PAINT* in an inducible PC-3-*PAINT* PCa subline showed an increased hnRNPM concentration upon induction, promoting CD44 exon-skipping function of hnRNPM in PC-3-*PAINT* and C4-2B-*PAINT* PCa stable sublines. *In-silico* analysis showed prospective hnRNPM-interacting sites on *PAINT*, overlapping with its stem-loop structure forming regions. hnRNPM knockdown in induced MDA-MB-231-*PAINT* cells diminished the effect of *PAINT* over-expression on cell proliferation and migration. Our study demonstrates that the oncogenic role of *PAINT* is partly mediated by the stabilization of its interactor hnRNPM, in turn exerting its tumorigenic and epithelial-mesenchymal transition effects on cancer progression. This study establishes the benefit of *PAINT*-silencing on enhancing the antitumor effects of hnRNPM knockdown, that can be utilized in combination with chemotherapeutics for treating aggressive forms of BCa and PCa.

#2802 Circular RNA variants of the*NUMB* gene modulate the oncogenicity of oral squamous cell carcinoma.

C.-H. Chou, P.-Y. Chen, S.-C. Lin, **K.-W. Chang**;
National Yang Ming Chiao Tung University, Taipei, Taiwan

NUMB adaptor protein confers pleiotropic biological and pathological functions by binding with ubiquitin ligases to break down targeted molecules and other activities. Our previous studies have identified that NUMB protein suppresses oral squamous cell carcinoma (OSCC) oncogenicity, and it binds monocarboxylate transporters to elicit the degradation and the associated metabolic disruption. Besides, several oncogenic miRNAs co-target *NUMB* to abrogate its activity. However, in the TCGA head and neck squamous cell carcinoma (HNSCC) dataset and our OSCC cohort, *NUMB* expression is slightly unregulated. Despite several isoforms of *NUMB* owing to alternative slicing, our studies have disclosed the resemblance in oncogenic potential from different *NUMB* isoforms. Circular RNAs deriving from exons' back-splicing are new RNA entities mediating versatile biological functions. This study identifies several uncharacterized circular RNA variants of the *NUMB* gene (*circNUMB*s) in OSCC cell lines and tissues. Following the induction of *NUMB* promoter activity using the Crispr SAM activation system, the endogenous linear and circular *NUMB*s are upregulated similarly. The *NUMB*-null cell subclones, devoid of linear and circular *NUMB* transcripts, exhibit decreased oncogenicity. However, *circNUMB*s expression increases the oncogenicity of parental OSCC cells, and it profoundly reverses oncogenic phenotypes of cell subclones as being repressed by *NUMB* deletion. Analysis using transcriptomic algorithms reveals that *circNUMB*s modulate cancer, cell development, cell injury, and cell movement genes. The MYC and WNT/β-catenin are the leading signals affected by *circNUMB*s. This study concludes that *circNUMB*s mediate oncogenic functions opposite to linear *NUMB* transcript. Illuminating the interplay of linear *NUMB*, *circNUMB*, and their effectors would enable mechanistic insight into HNSCC/OSCC pathogenesis associated with *NUMB* expression.

#2803 Genome-wide CRISPR-Cas9 functional screens map long noncoding RNA dependencies in triple-negative breast cancer.

N. M. Alajez;
Qatar Biomedical Research Institute (QBRI), Doha, Qatar

Long noncoding RNAs (lncRNAs) are increasingly recognized as crucial regulators of gene expression, significantly influencing complex biological processes and disease progression, including cancer. Their transformative potential was underscored by the awarding of the 2024 Nobel Prize in noncoding RNA research, spotlighting lncRNAs as powerful modulators of biological regulation and therapeutic innovation. However, the precise functions of most lncRNAs remain largely unexplored. While GENCODE has cataloged over 20,000 lncRNA genes, the true diversity of lncRNAs is likely much greater. To address this, we constructed an expanded lncRNA reference by integrating GENCODE, BIGTranscriptome, and MiTranscriptome databases. This enhanced reference enabled a comprehensive mapping of lncRNA dependencies in aggressive triple-negative breast cancer (TNBC) using a genome-wide CRISPR-Cas9 screen. Our screen specifically targeted the transcription start sites of over 1,000 TNBC-associated lncRNAs, encompassing both annotated and novel transcripts. By employing a dual-excision CRISPR strategy in two TNBC cell models, we identified lncRNAs that are essential for TNBC cell growth and chemoresistance, validating several candidates using antisense oligonucleotides (ASOs). In total, 102 lncRNA hits were identified across both MDA-MB-231 and BT-549 TNBC models. Of these, three novel lncRNAs were found to be indispensable for TNBC survival in both two-dimensional and three-dimensional cultures. Analysis of a large TNBC cohort (n=360) further associated the expression of these lncRNAs with more aggressive TNBC subtypes. Loss-of-function studies with ASO Gapmers underscored the roles of these novel lncRNAs in regulating key cellular processes, including extracellular matrix organization, lipid metabolism, and GTPase signaling. Our study provides the first comprehensive map of lncRNA vulnerabilities in TNBC, highlighting their potential as therapeutic targets. This approach, while focused on TNBC, is adaptable for exploring lncRNA functions in other biological settings, paving the way for novel RNA-based therapies and clinical applications.

#2804 Long non-coding RNA LINC01614 regulates ferroptosis-mediated carcinogenic phenotypes in papillary thyroid cancer.

Danielle Quaranto[1], Michelle Carnazza[1], Nicole R. DeSouza[1], Sina Dadafarin[2], Augustine Moscatello[3], Humayun K. Islam[1], Codrin Iacob[4], Raj K. Tiwari[1], Jan Geliebter[1]

[1]New York Medical College, Valhalla, NY,[2]University of Washington, Seattle, WA,[3]Westchester Medical Center, Valhalla, NY,[4]New York Eye and Ear Infirmary of Mount Sinai, New York, NY

Papillary thyroid cancer (PTC) is the most common endocrine malignancy and is increasing annually in incidence by about 3%. PTC has a significantly higher prevalence in females of childbearing age and aggressiveness increases among males. Despite a high survival rate, disease recurrence and metastasis remain prominent issues-even decades after diagnosis. Therefore, the identification of prognostic biomarkers and actionable therapeutic targets remains a critical need. A newer class of epigenetic and regulatory molecules, known as long non-coding RNAs (lncRNAs), have demonstrated differential expression patterns in a variety of cancer types. lncRNAs modulate gene expression and drive carcinogenic behavior- making them attractive biomarkers and/or therapeutic targets for investigation. Bioinformatic analysis of our PTC vs. normal thyroid genomic repository identified the lncRNA LINC01614 transcript as significantly 12-fold upregulated in PTC. Thus, we are studying LINC01614 as a potential PTC biomarker. LINC01614 was found to be upregulated in thyroid cancer cell lines. Two PTC cell lines, TPC1 (~5 fold upregulated; RET/PTC rearrangement; female) and K1 (~2 fold upregulated; BRAFV600E; male), were selected for in vitro study. For phenotypic evaluation, CRISPRi technique was employed to achieve transcriptional repression of LINC01614 in TPC1and K1. LINC01614 knockdown in TPC1 and K1 resulted in decreased migration (~20%), clonogenicity (~50% and ~34%, respectively), and proliferation (~55% and ~45%, respectively). RNA sequencing analysis of CRISPRi knockdown cell lines vs. CRISPRi controls demonstrated reduced expression of key ferroptosis-related genes-SLC7A11 and SLC3A2. Both genes encode for the xCT system (cystine/glutamate reverse transporter) that regulates the uptake of cystine - a key precursor for glutathione (GSH) synthesis. GSH is a critical antioxidant defense against lipid peroxidation, further preventing ferroptosis. Total cell iron levels were quantified and found to be significantly higher in our LINC01614 knockdowns, signifying increased ferroptosis induction. Studies are currently underway to identify the impact of LINC01614 on lipid peroxidation levels, reactive oxygen species production, as well as identification of ferroptosis-related protein expression in our PTC in vitro model. Elucidation of LINC01614's carcinogenic mechanism of action through ferroptosis regulation is a promising and novel avenue of exploration for PTC prognosis and therapy.

#2805 A lncRNA-specific CRISPRi screen identifies an essential role of *PDCD4-AS1* in colorectal cancer growth and survival.

Vida Kufrin[1], Silvia Schafer[1], Silke Brilloff[1], Maria Gabriela Pereira dos Santos[1], Elahe Rahimian[1], Sandra Kuchler[1], Denis M. Schewe[2], Claudia R. Ball[1], Hanno Glimm[1], Marius Bill[2], Alexander A. Wurm[1]

[1]National Center for Tumor Diseases Dresden, Dresden, Germany,[2]University Hospital Carl Gustav Carus, Dresden, Germany

Colorectal cancer (CRC) ranks as the third most commonly diagnosed cancer worldwide and is the second leading cause of cancer-related mortality. Recent studies have highlighted the critical role of long non-coding RNAs (lncRNAs) in CRC development, influencing processes such as proliferation, invasion, and therapy resistance. However, the functional roles of most annotated lncRNAs in CRC remain poorly understood, underscoring the need to uncover novel lncRNAs that may impact CRC initiation, progression, and treatment response.

To identify lncRNAs involved in CRC cell growth, we conducted a comprehensive lncRNA-specific CRISPR interference (CRISPRi) dropout screen targeting 675 lncRNAs highly expressed across various cancer entities. We utilized four CRC models with diverse molecular backgrounds, including two patient-derived 3D models. As a control, we included HEK293T cells to filter out common essential lncRNAs. This approach revealed 11 lncRNAs significantly depleted across all CRC models, indicating a shared regulatory role in CRC. To validate these findings, we inhibited expression of selected top-hit lncRNA candidates using CRISPRi and antisense oligonucleotide-mediated knockdown. In both approaches, we observed reduced cell growth compared to control conditions, closely aligning with the dropout screen findings. Among the candidates, *PDCD4-AS1* was prioritized for further characterization, as it is not located near an oncogenic or common essential protein-coding gene, minimizing the likelihood of off-target effects. By generating loss-of-function patient-derived spheroid models, we showed that *PDCD4-AS1* silencing significantly reduced cell growth, induced G2/M cell cycle arrest, and promoted apoptosis. To evaluate the therapeutic potential of targeting *PDCD4-AS1*, we performed knockdown experiments in a panel of patient-derived organoids (PDOs) both *in vitro* and *in vivo*. In a PDO xenograft mouse model, *PDCD4-AS1* knockdown significantly suppressed tumor growth and prolonged overall survival. To explore the molecular mechanisms underlying the *PDCD4-AS1* knockdown phenotype, we performed transcriptomic analysis by RNA sequencing. Here, we identified significant alterations in amino acid metabolism, suggesting a *trans*-regulatory role of *PDCD4-AS1* in CRC. However, further analyses are required to identify the interaction partners of *PDCD4-AS1* and gain deeper insights into its mechanism of action.

Collectively, our findings highlight the potential of CRISPRi screens in uncovering novel molecular vulnerabilities in patient-derived CRC models. We present the previously uncharacterized lncRNA *PDCD4-AS1* as a mediator of CRC progression and provide strong evidence for lncRNAs as promising therapeutic targets and/or biomarkers for personalized oncology.

#2806 The putative role of the lncRNA (*SOCS3 DT*) as a potential biomarker for ovarian cancer diagnosis and progression.

Yahya Tamimi[1], Safa Al-Battashi[1], Shika Hanif Malgundkar[2], Sidika Sevde Yenigun[1], Hamad Al Riyami[1], Mohammed Al Toubi[1], Moza AL Kalbani[1], Aikou Okamoto[1], Ikram Burney[1]

[1]Sultan Qaboos University, Muscat, Oman,[2]Biochemistry, Sultan Qaboos University, Muscat, Oman

Ovarian cancer (OC) is a major global health challenge due to its high rates of cancer-related morbidity and mortality. The majority of OC cases are diagnosed at advanced stages, leading to poor survival outcomes. Thus, the identification of effective screening methods for early detection is crucial. The emergence of long non-coding RNAs (lncRNAs) as key regulators of gene expression has opened new avenues for investigating cancer biology. Previous *in-silico* analyses have indicated elevated expression levels of the lncRNA *SOCS3-DT* in OC, suggesting its potential as a biomarker. However, the exact functional role of *SOCS3-DT* in OC remains elusive. In this study, we conducted bioinformatic analysis using R software to identify differentially expressed lncRNAs in recurrent OC samples compared to primary ovarian tumor samples. Our analysis revealed increased expression of *SOCS3-DT* in recurrent OC samples compared to primary samples. To validate these findings, we utilized qRT-PCR to monitor *SOCS3-DT* expression in OC cell lines and human tissue samples. The qRT-PCR analysis revealed the overexpression of *SOCS3-DT* in the high-grade OC cell line OVSAHO, with a gradual increase in expression across early and late stages of OC tissue samples compared to healthy individuals. This suggests its potential as a promising marker for OC detection.Moreover, we suppressed *SOCS3-DT* expression in OVSAHO cells and assessed its impact on proliferation, colony formation, and wound healing. Additionally, to assess the effect of *SOCS3-DT* knockdown on crucial markers associated with cancer pathways, we conducted qRT-PCR and western blotting. Compared to the negative control, silencing *SOCS3-DT* in OVSAHO cells resulted in reduced cell proliferation and colony formation abilities, decreased expression of apoptotic markers (CASPASE-3, BCL-2), downregulation of autophagy markers (ATG5 and BECLIN), and mesenchymal markers (VIMENTIN and CDH2). In conclusion, this study provides new insights into identifying an effective early detection biomarker (*SOCS3-DT*) implicated in the early stages of the disease. This biomarker shows promise as a novel therapeutic target, presenting new approaches for the effective treatment of OC.

#2807 Determining a role for a long noncoding RNA involved in the DNA damage response of lung adenocarcinoma.

Michele Ramos Correa[1], Jonathan Castillo[2], Patrick Pirrotte[3], Crystal N. Marconett[4]

[1]Surgery, University of Southern California, Los Angeles, CA,[2]Integrative Translational Sciences, Beckman Research Institute of The City of Hope, Glendale, CA,[3]Department of Immuno-Oncology, Beckman Research Institute, Duarte, CA,[4]Integrative Translational Sciences, Beckman Research Institute, Duarte, CA

Lung adenocarcinoma (LUAD) is the most common histological subtype of the deadliest cancer in the United States. This cancer accounts for 40% of cases that can arise from a high rate of mutations that is exaggerated by dysregulation in the DNA damage and repair signaling pathways that cause genomic instability. Historically, the role of protein coding genes in regulation of these pathways has been extensively studied but developments in new technology has identified noncoding RNAs as critical regulators involved in physiological and pathological processes related to DNA stability. Specifically, long noncoding RNAs (lncRNAs) have been implicated as critical regulators of gene expression in the DNA damage response; controlling the repair mechanism response's magnitude, duration, and resolution, but very few have been characterized and ascribed a function. We have previously identified the lncRNA, *LINC00261*, that acts as a tumor suppressor in LUAD by regulating the activation of the DNA damage repair system. However, its exact mechanisms of action in the signaling pathway remain unknown. We found that reintroduction of *LINC00261* in LUAD is associated with G2/M cell cycle arrest and phosphorylation-mediated activation of key DNA damage response pathway components. We hypothesize that *LINC00261* maintains DNA fidelity through direct interaction with repair components. To gain critical insights into the essential functions that *LINC00261* plays in the DNA damage response, a mediation analysis including *LINC00261* and tumor mutational burden was conducted on the TCGA LUAD dataset. Results of this mediation analysis suggested a role for *LINC00261* in nucleotide excision repair (NER) pathway in lung adenocarcinoma. To mechanistically characterize the function of *LINC00261* in NER, we have conducted ChIRP-MS in the A549 LUAD cell line. Our preliminary results indicate LINC00261 direct interaction with mitochondrial translation (p=1.34E-13), rRNA processing in the nucleolus and cytosol (p=3.76E-10), and branched-chain amino acid catabolism, (p=5.68E-09) pathways. Further validation of the relationship between *LINC00261* and NER was performed on RNA isolated from A549 cells upon UVC DNA damage. *LINC00261* was subcellularly localized to both cytoplasm and nucleus, inferring that *LINC00261* can function in cis and trans. We are currently investigating *LINC00261* direct binding partners that mediate DNA damage and repair responses. Our findings provide evidence for the role of *LINC00261* in the DNA damage response and will lead to a further understanding of how lncRNA-mediated dysregulation of DNA repair leads to genomic instability and oncogenic activation.

#2808 LUCAT1 facilitates areca nut-induced cell invasion and therapeutic resistance in head and neck cancer through STAT1 transcriptional modulation.

H.-H. Huang, A.-J. Cheng;
Chang Gung University, Taoyuan, Taiwan

Areca nut is a significant carcinogen associated with head and neck cancer (HNC) in Southeast Asia, but the mechanisms, particularly those involving long non-coding RNAs (lncRNAs), remain unclear. We previously identified the lncRNA LUCAT1 as induced by arecoline, a key areca nut component, and this study explores its crucial role in HNC progression. Silencing LUCAT1 reduced several arecoline-induced malignant features. These include cell invasion through epithelial-mesenchymal transition (EMT) modulation and chemo-radiotherapy resistance via reactive oxygen species (ROS) scavenging and autophagy regulation. RNA sequencing (RNA-seq) of LUCAT1-silenced cells revealed 2,326 downstream effectors enriched in oncogenic pathways, including EGFR, VEGF, HIF-1, and extracellular matrix-receptor interactions. This underscored LUCAT1's pivotal role in cell motility and survival. LUCAT1 predominantly localizes in the nucleus, suggesting transcriptional regulation. Bioinformatic analysis of its promoter revealed 491 transcription factors binding to a DNase hypersensitivity site (DHS). Integrative proteomic analysis of areca nut-treated HNC cells narrowed this to three key transcription factors (IRF6, CUX1, and STAT1). Among these, STAT1 was confirmed as the primary factor induced by arecoline to activate LUCAT1 transcription. Silencing STAT1 or inhibiting its phosphorylation using fludarabine suppressed LUCAT1 expression, reduced ROS-scavenging, and reversed arecoline-induced malignancy. Thus, this study demonstrates that areca nut upregulates LUCAT1 via STAT1 activation, contributing to cell invasion and therapeutic resistance in HNC. Additionally, fludarabine shows potential as a therapeutic agent to counteract areca nut-induced malignancy, offering a promising avenue to improve survival outcomes for HNC patients with areca nut-chewing.

#2809 Targeting the LINC00355-MENIN interaction with CDK4/6 inhibitors to reduce proliferation in late relapse breast cancer.

Richa Mishra[1], Brianna Duhart[1], Dhanusha Duraiyan[1], Prasanth Thunuguntla[1], Kyla Gelev[1], Debbie C. Crans[2], Cynthia X. Ma[3], Jessica Silva-Fisher[3]

[1]Division of Oncology, Department of Internal Medicine, Washington University School of Medicine in St. Louis, St. Louis, MO,[2]Department of Chemistry, Colorado State University, Fort Collins, CO,[3]Division of Oncology, Department of Internal Medicine, Washington University School of Medicine in St. Louis and Siteman Cancer Center, St. Louis, MO

Breast cancer is the most common cancer diagnosed among women in the United States, with approximately 310,720 new cases estimated in 2024. Late relapse refers to disease recurrence after being disease-free for at least five years following the initial curative treatment. Late relapse is particularly relevant to ER+/HER2- breast cancer as it accounts for over 50% of recurrences for patients with this subtype of breast cancer. Cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitors in combination with endocrine therapy are standard first-line therapy for metastatic relapse. While these therapies initially show promise, resistance to endocrine therapy and CDK4/6 inhibitors inevitably develops, presenting a major clinical challenge and unmet medical need for late relapse. Long non-coding RNAs (lncRNAs) are key regulators of cancer-related processes, including cell cycle progression. Our lab has identified deregulated lncRNAs in metastatic late relapse breast cancer patient tumor samples, but their role in CDK4/6 inhibitor resistance remains unclear. To investigate this, we treated the ER+ primary breast cancer cell line MCF7 (wild-type) and the long-term estrogen-deprived (LTED) cell line - mimicking late relapse with CDK4/6 inhibitors, including Abemaciclib, Palbociclib, and Ribociclib. Wild-type cells were more sensitive to these inhibitors than LTED cells. Further, the analysis identified that *LINC00355*, the topmost upregulated lncRNA in late relapse breast cancer binds to the MENIN protein. This was demonstrated using RNA pulldown assays and multiplexed RNA in situ hybridization in LTED cells and patient samples. The *LINC00355*-MENIN interaction decreases CDKN1B expression, promoting cellular proliferation. Notably, MENIN has been shown to regulate the CDK4/6 pathway and inhibit cell proliferation. To explore the therapeutic potential, we reduced *LINC00355* expression using GapmeRs, locked nucleic acid-based antisense oligonucleotides (LNA ASOs), which significantly decreased cell proliferation. In contrast, treatment of LTED cells with Palbociclib or Ribociclib alone for 72 hours showed no significant changes in proliferation. However, combination treatment with *LINC00355* LNA ASOs and Palbociclib or Ribociclib resulted in a notable reduction in cell proliferation. These findings highlight the critical role of lncRNA-protein interactions, such as *LINC00355*-MENIN, in promoting cellular proliferation and provide proof-of-concept for targeting lncRNAs that can cause resistance to CDK4/6 inhibitors for late relapse breast cancer.

#2810 Investigating the oncogenic function of the long noncoding RNA KCNQ1OT1 in rhabdomyosarcoma.

Ara Jo[1], Alex Kovach[1], Christian Stackhouse[1], Samantha Weitzel[1], Brian Masters[1], Justina McEvoy[2], Wenyue Sun[3], Frederic G. Barr[3], Mauro Calabrese[4], Xiang Chen[5], Corinne M. Linardic[1]

[1]Pediatrics, Duke University, Durham, NC,[2]St. Jude Children's Research Hospital, Memphis, TN,[3]National Cancer Institute, Bethesda, MD,[4]Pharmacology, University of North Carolina, Chapel Hill, NC,[5]Computational Biology, St. Jude Children's Research Hospital, Memphis, TN

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma in children and adolescents, with survival for high-risk cases stagnant at less than 30%. Contemporary molecular classification of RMS is into fusion-positive (FP) and fusion-negative (FN) groups, based on expression of fusion oncogenes. Although the majority of FN-RMS tumors exhibit mutations in protein coding genes, especially in the RAS pathway, about 25% instead show only copy number alterations and LOH at chromosome 11p15.5, which harbors tumor suppressor genes (TSGs) *CDKN1C*, *PHLDA2*, and *SLC22A18*. The 90kb long noncoding RNA KCNQ1OT1 (OT1) is a known *cis* silencer of this locus. We hypothesize that OT1 is upregulated in RMS, contributes to RMS tumorigenesis by repressing critical TSGs, and that targeting OT1 could provide a novel therapeutic approach. Using qPCR and epigenomic interrogation of available RMS tissue, we find OT1 highly expressed in FN-RMS cell lines and banked tumor samples. Complementary genomic methylome data of RMS tumors shows silencing and activation of the *CDKN1C* and *OT1* promoters, respectively. Suppression of *OT1* using shRNA against various sites along the transcript, or a dual excision CRISPR knockout (DECKO) of the promoter, inhibits RMS cell proliferation, induces apoptosis, and recovers TSG expression. In a candidate approach, using both gain and loss of function approaches, the Hippo pathway YAP1 transcriptional co-activator was found to modulate OT1 expression. Unbiased genomic screens are planned. Finally, using *in silico* binding prediction models, we designed OT1-directed anti-sense oligonucleotides (ASOs), demonstrating they can be delivered to RMS cell lines. These ASOs, designed to degrade or inhibit OT1 function, will be tested in RMS cell-based and xenograft models to determine their efficacy and specificity. To generate additional information about regions of OT1 that might be therapeutically tractable, antisense DNA capture probes will be applied to OT1 in RMS cells to generate higher nucleotide resolution maps of OT1 structure and protein binding. This study not only deepens our understanding of OT1's role in RMS but also advances the development of innovative RNA-based treatments, addressing a critical need for effective therapies in this aggressive childhood cancer.

#2811 Mapping the eRNAs regulatory networks associated with clinical traits in gastric cancer.

Yanxin Yao, Xiangnan Zhang, Lijie Ji, Mengyue Qiu, Huahuan Liu, **Kexin Chen**, Ben Liu

Tianjin Medical University Cancer Institute and Hospital, Tianjin, China

Gastric cancer (GC) is one of the top five common malignancies worldwide and the fourth leading cause of cancer-related death. Enhancer RNA (eRNA) is a type of non-coding RNA transcript originating from enhancers. In different tumors, eRNAs exhibit significant tumor specificity. In different tumors, eRNAs showed significant tumor specificity. However, the expression characteristics of eRNAs and their potential transcriptional regulatory functions still need to be further explored. More than two hundred local gastric adenocarcinoma samples were included in this study. We define two classes of eRNAs, the shorter bi-directionally transcribed 2D eRNAs and the longer 1D eRNAs. We identified about 30,000 eRNAs expressed in gastric cancer or normal gastric cancer tissues, and most of these eRNAs are located in intergenic and antisense strands of genes. Some of the eRNAs showed strong tissue specificity, aberrant activation or silencing of eRNAs leads to tumorigenesis in gastric cancer. Previous reports have demonstrated that eRNAs play a complex scaffolds role in maintaining chromatin ring stability and regulating the expression of target genes. HiC and HiChIP data were collected as evidence of spatial proximity of enhancers and promoters. Anchors annotation was performed using previously quantified eRNAs to obtain eRNA-targe gene pairs. Co-expression analysis of eRNAs and their target genes, combined with the above 3D genomic results, total of about 30,000 eRNA-target gene pairs were identified. Using edge perturbation in the gene interaction network, the edge-perturbation matrix of eRNA-target gene interaction pairs was obtained, and a value was assigned to each interaction pair. About 30,000 of these action pairs were associated with clinical characteristics. It is noteworthy that a large proportion of the action pairs were associated with the degree of differentiation of gastric cancer. To further explore the role that eRNAs play in tumor proliferation, we selected representative eRNAs and constructed CRISPRa and CRISPRi screening libraries to explore the potential role of eRNAs in gastric cancer proliferation. Bulk screening results showed that gastric cancer cells proliferated faster after activating or knocking down eRNAs. In addition, CROP-seq was used to verify the changes in target genes after activation/knockdown of eRNAs expression. Taken together, these results demonstrate that eRNAs can regulate the progression of gastric cancer by modulating the expression of their target genes, and that eRNAs can be used as potential targets for gastric cancer therapy. In summary, we have provided an in-depth characterization of the eRNAs expression landscape and its regulatory functional network in gastric cancer, and validated the eRNA-target gene action, demonstrating the possibility of eRNAs as a potential target for gastric cancer therapy.

#2812 Prognostic implications of gastric cancer-specific tsRNA subtypes and functional validation.

Yuan Liu, Xin Hu, Ye Tian, Wei Wang, **Kexin Chen**, Hongji Dai, Ben Liu, Fengju Song

Tianjin Medical University Cancer Institute and Hospital, Tianjin, China

Background: Gastric cancer is a global malignant disease of the digestive tract. The marked heterogeneity of gastric cancer leads to prognostic and therapeutic challenges. tRNA-derived fragments (tsRNAs), a novel class of small non-coding RNAs closely associated with tumor progression, have an imperfect role in prognostic assessment and treatment of gastric cancer. We aimed to identify specific tsRNA isoforms associated with the tumor microenvironment of gastric cancer, establish a tsRNA-based prognostic model for gastric cancer, and screen-specific factors that may inhibit gastric cancer to guide prognosis and treatment.
Methods: We performed matrix score analysis and consensus clustering analysis using tsRNA expression profiles from the tsRFun database and gastric cancer sample information from the TCGA database. Ten machine learning (Lasso, Enet, plsRcox, CoxBoost, StepCox, GBM, Ridge, RSF, survival-SVM, and SuperPC) were used to construct tsRNA-related prognostic models (TRS). In-house development of an R package called 'GCtsRNAscore' for calculating tsRNA score (RS) in gastric cancer patients. TMB and IMvigor210 cohorts were evaluated for immunotherapy efficacy. Pandora sequencing screened for gastric cancer-specific tsRNAs for functional validation in cellular, organoid, and animal models for functional validation.
Results: We classified 80 gastric cancer-specific tsRNAs into three immunological subtypes, Stromal_L, Stromal_M, and Stromal_H, based on stromal cell infiltration analysis, with Stromal_L having the best prognosis. A multi-omics approach revealed significant differences in biological characteristics, CNVs, and mutation patterns among the subtypes ($P < 0.05$). The TCGA and GEO gastric cancer cohorts validated that TRS was the best prognostic model for tsRNA-associated tsRNAs in gastric cancer ($P < 0.0001$, AUC = 0.967). Gastric cancer patients were categorized into high-risk and low-risk based on their respective RS. High-risk patients responded well to axitinib, bexarotene, and dasatinib, while low-risk patients responded well to immunotherapy. In addition, we identified six subtype-specific tsRNAs, which were combined with Pandora sequencing to screen for the gastric cancer-specific suppressor Gly-tsRNA-4. Overexpression of Gly-tsRNA-4 was found to inhibit tumor growth in cellular, organoid, and animal experiments.
Conclusion: In this study, tsRNA-related indicators accurately predicted the prognosis of gastric cancer and provided insight into the response of GC patients to therapeutic drugs. Gly-tsRNA-4 may act as a tumor suppressor to inhibit gastric cancer progression. The above study can help to explore new targets for gastric cancer treatment, but further comprehensive validation is needed.

MOLECULAR/CELLULAR BIOLOGY AND GENETICS: Non-Apoptotic Cell Death
Poster Session

#2816 Lipid composition differentiates ferroptosis sensitivity between in vitro and in vivo systems.

Vivian S. Park[1], Lauren E. Pope[2], Justin Ingram[1], Grace A. Alchemy[2], Julie Purkal[1], Eli Y. Andino-Frydman[2], Sha Jin[1], Sanjana Singh[1], Anlu Chen[3], Priya Narayanan[3], Sarah Kongpachith[3], Darren C. Phillips[1], Scott J. Dixon[2], Relja Popovic[1]

[1]AbbVie Inc., North Chicago, IL,[2]Stanford University, Stanford, CA,[3]AbbVie Bay Area, South San Francisco, CA

Ferroptosis is a regulated non-apoptotic cell death process characterized by iron-dependent lipid peroxidation. This process has recently emerged as a promising approach for cancer therapy. Peroxidation of polyunsaturated fatty acid-containing phospholipids (PUFA-PLs) is necessary for the execution of ferroptosis. Ferroptosis is normally suppressed by glutathione peroxidase 4 (GPX4), which reduces lipid hydroperoxides to lipid alcohols. Some evidence indicates that GPX4 may be a useful target for drug development, yet factors that govern GPX4 inhibitor sensitivity *in vivo* are poorly understood. We find that pharmacological and genetic loss of *GPX4* function was sufficient to induce ferroptosis in multiple adherent ("2D") cancer cell cultures. However, reducing GPX4 protein levels did not affect tumor xenograft growth when these cells were implanted in mice. Furthermore, sensitivity to GPX4 inhibition was markedly reduced when cells were cultured as spheroids ("3D"). Mechanistically, growth in 3D versus 2D conditions reduced the abundance of PUFA-PLs. 3D culture conditions upregulated the monounsaturated fatty acid (MUFA) biosynthetic gene stearoyl-CoA desaturase (SCD). SCD-derived MUFAs appear to protect against ferroptosis in 3D conditions by displacing PUFAs from phospholipids. Various structurally related long chain MUFAs can inhibit ferroptosis through this PUFA-displacement mechanism. These findings suggest that growth-condition-dependent lipidome remodeling is an important mechanism governing GPX4 inhibitor effects. This resistance mechanism may specifically limit GPX4 inhibitor effectiveness *in vivo*.

#2817 ATR-mediated phosphorylation of RIPK1 inhibits DNA damage-induced necoptosis and chemosensitivity in ovarian cancer.

Q. Xu[1], S.-n. Shi[1], X. Jiao[1], X. Zhao[1], G. B. Mills[2], Q. Gao[1], Y. Fang[1];

[1]Tongji Hospital, Tongji Medical College, Wuhan, China, [2]Department of Cell, Development and Cancer Biology, Oregon Health and Sciences University, Portland, OH

Background: Cell death under DNA damage induced by chemotherapy is considered a highly significant and effective treatment for epithelial ovarian cancer. Nevertheless, ovarian cancer to date persists as the leading cause of death among all gynecological malignancies, as the majority of patients eventually obtain chemotherapy resistance. chemotherapy-resistant patients, while the underlying mechanism remains unclarified. When tumor cells are undergoing persistent DNA damage, ATR is activated, yet the cell fate mediated by ATR remains unknown. RIPK1 is the crucial regulatory protein for cell death, which is activated by upstream signals and mediates RIPK1-dependent cell apoptosis and necroptosis. However, the mechanism through which RIPK1 regulates cell death in DNA damage still requires further exploration.

Methods and results: Western blot and flow cytometry were employed to detect the cell death induced by etoposide-induced DNA damage, which revealed this mode of cell death was dependent on RIPK1 activation-induced necroptosis. Through Co-immunoprecipitation, it was determined that RIPK1 and ATR had an obvious interaction. Subsequently, by using ATR inhibitors or si-RNA to knockdown ATR, the activation of RIPK1 increased, the necroptosis induced by DNA damage was enhanced, and the downstream Necrosome formed within a shorter period. Furthermore, a kinase-specific phosphorylation site-prediction program, GPS 6.0, and a mass spectrometry analysis were employed to determine that RIPK1 is phosphorylated at Ser335 by ATR. Additionally, the WT and S335A mutant plasmids were complemented in RIPK1 knockout tumor cells, which revealed that in the case of the S335A mutation, the repression of RIPK1 was released, and downstream necroptosis was also augmented. Finally, RIPK1 was knocked out with the complementation of WT and S335A in ovarian cancer cell lines. The results demonstrated that ATR phosphorylation of RIPK1 at S335 led to chemoresistance, while the acquisition of the S335A mutation significantly enhanced chemosensitivity, as indicated by the intense activation of the necroptosis pathway, decreased cell viability, and increased apoptotic cells.

Conclusions: Our study reveals a pathway that governs ATR-mediated RIPK1 regulation and RIPK1-dependent cell death under DNA damage, suggesting for the first time that the ATR-RIPK1 axis plays an unrecognized role in integrating DNA damage checkpoints and cell death. Parallel to its other substrates, ATR directly inhibits RIPK1 and downstream necrosome formation by phosphorylation at Ser335, thereby suppressing RIPK1-dependent cell death triggered by DNA damage. This work broadens our comprehension of the interplay between DNA damage and cell death regulation, which could facilitate the development of therapeutic drugs aimed at enhancing DNA damage-induced tumor cell death and promoting chemosensitivity.

#2818 Targeting PIKfyve sensitizes gastroenteropancreatic neuroendocrine tumor to mTOR inhibition by disrupting ferritinophagy and lipid homeostasis.

Yizhi Cao, Yitong Yin, Caleb Cheng, Shannon VanAkon, Sarah Nicole Yee, Jacinda Jiali Liu, Yang Zheng, Andrej Coleski, Radha Paturu, Somnath Mahapatra, Fan Yang, Rupam Bhattacharyya, Rahul Mannan, Yuanyuan Qiao, Arul Chinnaiyan

University of Michigan, Ann Arbor, MI

Gastroenteropancreatic neuroendocrine tumors (GEP-NETs) have shown a significant global increase over the past decade. The mTOR signaling pathway is a positive regulator of cell cycle progression, with its activation playing a key role in the pathogenesis of NETs. Since 2011, the FDA-approved mTOR inhibitor everolimus has been used as an anti-tumor agent for treating progressive NETs, and its clinical efficacy is limited due to rapid disease relapse and progression. In this study, we investigated the role of autophagy, specifically ferritinophagy, in mediating resistance to mTOR inhibition in GEP-NETs. Enhanced ferritinophagy followed by mTOR inhibition increases intracellular iron availability, supporting tumor cell energy production and survival. Genetic or pharmacological inhibition of PIKfyve, a lipid kinase integral to lysosomal functioning, disrupted ferritinophagy, reducing the intracellular iron pool elevated by mTOR inhibition. Interestingly, mTOR inhibition also restored cholesterol and fatty acid biosynthesis resulting from PIKfyve inhibition. Notably, dual inhibition of mTOR and PIKfyve exhibited a strong synergistic antitumor effect in vitro and significantly prolonged survival in an orthotopic GEP-NET preclinical model. Together, our findings highlight the therapeutic potential of combining mTOR and PIKfyve inhibitors in the treatment of GEP-NETs.

#2819 Metabolic determinants of ferroptosis in B-cell malignancies.

Etienne Leveille[1], Eden Bramson[1], Mark Robinson[1], Thierry Bertomeu[2], Andrew Chatr-Aryamontri[2], Shalin Kothari[1], Markus Muschen[1]

[1]Center of Molecular and Cellular Oncology, Yale University, New Haven, CT,[2]The ChemoGenix pooled CRISPR screening platform of the Institute for Research in Immunology and Cancer, Universite de Montreal, Montreal, QC, Canada

Although the development of targeted approaches has been effective for the treatment of B-cell malignancies, outcomes remain poor in the relapsed and refractory settings. To expand the portfolio of B-cell-selective drugs, we developed an interactive computational tool (lymphoblasts.org) and identified ferroptosis, a form of cell death driven by iron-dependent membrane lipid peroxidation, as a previously unrecognized selective vulnerability in B-cell malignancies. Although ferroptosis has shown potential in therapy-resistant tumors, no potent ferroptosis inducers are available clinically, and a better understanding of the factors regulating ferroptosis is required to allow its therapeutic targeting and the development of clinical grade ferroptosis inducers. Our comparative analyses of CRISPR dependency (DepMap) and drug (CTD, GDSC) screens revealed that B-cell malignancies are particularly sensitive to ferroptosis and depend on several anti-ferroptotic molecules that notably include components of the glutathione synthesis machinery (GCLC, GCLM, GSS) and selenoprotein synthesis (SEPHS2, LRP8). Strikingly, this analysis also identified pro-ferroptotic genes involved in iron (*TFRC*) and polyunsaturated fatty acid (PUFA; *ACSL4*) metabolism as selective B-cell dependencies, suggesting that addiction to these pro-ferroptotic processes makes B-cell malignancies intrinsically vulnerable to ferroptosis. Accordingly, iron chelation treatment showed a much higher toxicity in B-cell malignancies compared to solid tumors, and Cre-mediated ablation of *Tfrc* in murine models of B-cell acute lymphoblastic leukemia (B-ALL) and B-cell lymphoma induced rapid cell death. Cre-mediated loss of ACSL4, while making cells almost completely resistant to ferroptosis, significantly compromised murine B-ALL cell viability, suggesting a key role of ACSL4 and PUFA in B-cell malignancy survival. An important role of ACSL4 and PUFA metabolism in B-cell malignancies was also suggested by analysis of clinical data from the diffuse large B-cell lymphoma MMMLNP trial, which revealed that greater than median expression of *ACSL4* is associated with significantly worse survival ($p = 0.0007$).To uncover new ferroptotic regulators in B-cell malignancies, we performed whole-genome CRISPR knockout screens under the selective pressure of the ferroptosis inducers RSL3, Erastin, and $FINO_2$, which highlighted several known ferroptosis regulators and uncovered new ferroptosis-related genes and pathways including sphingolipid metabolism (*KDSR*), phosphatidylcholine synthesis (*FLVCR1*, *PCYT1A*), inositol metabolism (*ITPK1, IPMK*), and lipid membrane remodelling (*ATP8B2*). Taken together, our findings uncover iron and PUFA metabolism as selective B-cell dependencies that likely contribute to their exquisite sensitivity to ferroptosis and identifies novel regulators of ferroptosis in B-cell malignancies.

#2820 Intracellular calcium dynamics affect ferroptosis sensitivity.

Veronica T. Brooks[1], Ronan Talty[2], Simon F. Roy[2], Marcus W. Bosenberg[3]

[1]Department of Dermatology, Yale University, New Haven, CT,[2]Department of Dermatology, Pathology, Yale University, New Haven, CT,[3]Department of Dermatology, Pathology, Immunobiology, Yale University, New Haven, CT

Background: Melanoma is the deadliest form of skin cancer, and its incidence continues to rise. While advances in immunotherapy, in the form of anti-PD-1, anti-CTLA-4, and anti-LAG-3 immune checkpoint inhibitors, have led to extended cancer-free outcomes for many patients with advanced disease, most patients do not have durable responses. Therefore, improvements in long-term treatment of melanoma will depend on the identification of methods to enhance existing immunotherapy regimens. Recent studies highlight ferroptosis, an iron-dependent form of regulated cell death, as a necessary component of immunotherapy-induced tumor clearance. Cytosolic calcium influx is a key aspect of ferroptosis, preceding cell bursting and linking increased plasma membrane permeability with the activation of membrane repair mechanisms.
Design: This study investigated the ability of calcium modulators to alter sensitivity to ferroptosis in cancer cells. SKF96365, an inhibitor of calcium release-activated channel (CRAC) activity and store-operated calcium entry (SOCE) channels, was selected for its effects on cellular calcium homeostasis and its limited exploration as an anti-melanoma agent and ferroptosis regulator. The ability of SKF96365 to sensitize melanoma cells to ferroptosis induction was assessed by evaluating key ferroptotic hallmarks, including cell death, lipid peroxidation and reduced glutathione levels. To further elucidate the underlying mechanism, three additional calcium modulators—GSK7975A, 2-Aminoethoxydiphenyl borate (2-APB), and Ruthenium Red (RR)—were tested.
Results: SKF96365 enhanced sensitivity to ferroptotic cell death, but not apoptosis or autophagy. Melanoma and colon adenocarcinoma cells treated with SKF96365 had increased levels of lipid peroxides and decreased reduced glutathione levels. GSK7975A similarly sensitized cells, supporting the role of store-operated calcium entry (SOCE) channels in ferroptosis. In contrast, 2-APB, which shows a dose-dependent bimodal effect on SOCE, increased resistance to ferroptosis despite elevating lipid peroxides and reducing glutathione. RR, a mitochondrial calcium uniporter inhibitor, also sensitized cells to ferroptosis.
Conclusion: SKF96365, GSK7975A, and RR enhance ferroptosis sensitivity, whereas 2-APB confers resistance. These results provide a foundation for further exploration of calcium signaling pathways in ferroptotic cell death.

#2821 Regulation of autophagy by the DDI2-CCN1 axis.

Nayyerehalsadat Hosseini, Ahmed M. Elshazly, Holly A. Byers, Janakiram R. Vangala, Senthil K. Radhakrishnan

School of Medicine, Virginia Commonwealth University, Richmond, VA

Background: The two primary mechanisms of protein degradation in cells are the ubiquitin-proteasome system (UPS) and the autophagy-lysosome pathway (ALP). In cases of UPS dysfunction, compensatory autophagy is activated to alleviate proteotoxic stress. This phenomenon can influence the efficacy of cancer treatments. Despite significant progress in understanding these systems, the specific molecular pathways linking proteasome dysfunction to the activation of compensatory autophagy remain poorly understood. DDI2 (DNA Damage Inducible 1 Homolog 2) functions as both a protease and a ubiquitin shuttle factor. Its loss sensitizes cancer cells to proteasome inhibition through the accumulation of polyubiquitinated proteins. However, these cells may activate autophagy to clear ubiquitinated protein aggregates. This study investigate how DDI2 depletion promotes autophagy in cancer cells to improve the efficacy of cancer treatments.

Methods: Autophagy activity was assessed in various cell lines, including non-cancerous (NIH-3T3 murine fibroblasts, MRC5 human fetal lung fibroblasts) and cancerous (EW16 and ES1 human Ewing sarcoma, MIA PaCa-2 human pancreatic cancer) cell lines, either with or without DDI2 depletion. Proteomic analysis revealed an upregulation of cellular communication network factor 1 (CCN1) in DDI2-deficient cells, suggesting its potential role in autophagy activation. Then, siRNA and viral constructs were used to examine CCN1's role in autophagy induction. Moreover, Co-immunoprecipitation (Co-IP) and confocal microscopy were applied to investigate the possible interactions between DDI2 and CCN1.

Results: Autophagy flux analysis showed increased LC3B-II levels, a key marker of autophagy, in DDI2-deficient cells compared to controls. Furthermore, western blotting confirmed elevated levels of CCN1 protein in DDI2-deficient cells. Downregulation of CCN1 by siRNA resulted in reduced autophagy activity in DDI2-deficient cells, demonstrating that CCN1 is essential for the autophagic induction. In contrast, overexpression of CCN1 in wild-type cells led to an increase in LC3B-II levels, confirming that CCN1 alone can trigger autophagy activity. Co-IP analysis revealed a direct interaction between DDI2 and CCN1, and confocal microscopy further confirmed their colocalization.

Conclusion: Autophagy plays a critical role in effectiveness of cancer treatments. Our findings show that the loss of DDI2 leads to the accumulation of CCN1, which consequently activates autophagy. This research highlights the interaction between protein degradation pathways, UPS and autophagy, suggests that targeting both DDI2 and autophagy could provide a promising strategy to improve cancer therapy outcomes.

#2822 AdipoRon suppresses breast cancer growth through autophagy-mediated ferroptosis.

Yong-Han Su, Yi-Zhen Wu, Hsin-Yi Yang, Tzu-Yi Chia, Jou-Fang Hsu, Ching-Ying Kuo

National Taiwan University College of Medicine, Taipei City, Taiwan

Excess adipose tissue and the release of large amounts of adipokines are recognized as contributing factors in the development of various cancer types. Adiponectin, distinct from other adipokines, is negatively correlated with cancer progression. Low serum levels of adiponectin have been correlated with dysregulated cellular metabolism, including lipid and glucose metabolism, as well as increased cancer cell aggressiveness. Additionally, elevated adiponectin has been characterized as an anti-tumor factor with potential as a therapeutic target. However, due to its large size and protein instability, the development of adiponectin as a drug has been challenging. Recently, an oral adiponectin receptor agonist, AdipoRon, has been identified and is currently under investigation as a potential cancer treatment. Given that breast cancer is known to be highly influenced by surrounding adipose tissue, we utilized the breast cancer cell models to further evaluate the effects of AdipoRon on cancer progression. Cell viability of various breast cancer cell lines across subtypes was reduced by AdipoRon supplementation, and autophagy was induced in a dose-dependent manner, with significant LC3 lipidation and autophagosome formation. In addition, AdipoRon led to the accumulation of free radicals in mitochondria, accompanied by morphological changes and functional disruption, which in turn caused mitophagy. Lipid metabolism of cancer cells was also impaired by AdipoRon, with a decline in fatty acid storage capacity. The increased free fatty acids were further oxidized, resulting in lipid peroxide accumulation, a hallmark of ferroptosis. Other characteristics of ferroptosis, including ferritinophagy, iron accumulation and a decrease in glutathione peroxidase 4 level, were also observed in AdipoRon-treated cells. Moreover, AdipoRon-induced cell death could be rescued by a ferroptosis inhibitor, ferrostatin, suggesting that ferroptosis was induced by AdipoRon in breast cancer cells. Mechanistically, we identified BECN1, the key regulator of autophagy, as a critical factor in AdipoRon-associated ferroptosis. Knockdown of *BECN1* significantly rescued the ferroptotic cell death and related characteristics in breast cancer cells. Collectively, our data demonstrate that AdipoRon induced cell death in breast cancer cells by disrupting cellular metabolic capacity and triggering ferroptosis, a mechanism that has not been previously reported. These findings suggested the therapeutic potential of AdipoRon in inhibiting breast cancer progression.

#2823 CHAC1 regulates paraptosis by promoting glutathione degradation in cancer cells.

Ling-Chu Chang[1], Shih-Kai Chiang[2], Shuen-Ei Chen[2]

[1]China Medical University Hospital, Taiwan, Taichung, Taiwan,[2]Department of Animal Science, National Chung Hsing University, Taichung, Taiwan, Taichung, Taiwan

Paraptosis is a type of programmed cell death characterized by cytoplasmic vacuolation, merging as a potential therapeutic strategy for cancer treatment. Paraptosis has been associated with disruption of proteostasis and redox homeostasis, however, the detailed mechanisms remain to be explored. CPYPP, a known paraptosis inducer, was employed to investigate the underlying mechanisms in breast cancer and melanoma cells. CPYPP significantly increased the production of reactive oxygen species (ROS). Treatment with *N*-acetyl-$_L$-cysteine (NAC) and glutathione (GSH), but not oxidized glutathione (GSSG), mitigated CPYPP-induced cytoplasmic vacuolation and cell viability inhibition. CPYPP significantly decreased the intracellular GSH/GSSG ratio. Next-generation sequencing analysis indicated that CPYPP upregulates the expression of genes related to the cystine metabolism pathway, including SLC3A2, SLC7A11, cystathionine-γ-lyase (CTH), glutamate-cysteine ligase (GCLC, GCLM), and ChaC glutathione specific γ-glutamylcyclotransferase 1 (CHAC1). CPYPP increased the uptake of cystine. Cystine deprivation attenuated CPYPP-induced protein ubiquitination, cytoplasmic vacuolation, and cell viability inhibition. Furthermore, CHAC1 knockdown ameliorated CPYPP-induced endoplasmic reticulum stress, unfolded protein response, protein ubiquitination, cell viability inhibition, and ROS production. CHAC1 is transcriptionally upregulated by CPYPP via the PI3K-mTOR-CDK7/CDK9 axis. Taken together, these results suggest that the upregulation of CHAC1 mediates paraptosis. CHAC1 enhances the degradation of GSH, resulting in a decline in the GSH/GSSG ratio, a more oxidized intracellular state, and increased ROS production. This leads to the disruption of proteostasis, ultimately inducing paraptosis.

#2824 Physiologic regulation of lipid oxidation and ferroptosis by vitamin E, high-density lipoprotein and scavenger receptor class B type 1.

Jonathan S. Rink[1], Andrea E. Calvert[1], Adam Y. Lin[1], SonBihn T. Nguyen[2], Leo I. Gordon[1], C Shad Thaxton[1]

[1]Northwestern Univ. Feinberg School of Medicine, Chicago, IL,[2]Chemistry, Northwestern Univ. Feinberg School of Medicine, Evanston, IL

Introduction: Ferroptosis is a form of cell death caused by oxidative (-OOH) damage to phospholipids (PL) in the cell membrane. Understanding mechanisms of ferroptosis is important because of the role it plays in cancer. Previous work has focused on the intracellular antioxidant enzyme glutathione peroxidase 4 (GPx4), which detoxifies PL-peroxides (PL-OOH) and prevents ferroptosis. Studies show that alpha-tocopherol (α-toc), the active form of Vitamin E, is an exogenous lipophilic antioxidant that inhibits ferroptosis in cancer cells in vitro. The mechanisms by which α-toc engages cells to manipulate PL redox balance and ferroptosis are unknown. Lipoproteins, like high- and low-density lipoproteins (HDL and LDL), carry α-toc in the circulation. Using diffuse large B cell lymphoma (DLBCL) and clear cell renal cell carcinoma (ccRCC) models, two malignancies sensitive to ferroptosis, we show that lipoproteins, particularly HDL, deliver α-toc by binding the cell membrane receptor scavenger receptor class B type 1 (SR-B1) to prevent ferroptosis.
Methods: Ramos (lymphoma), SUDHL4 (lymphoma) and 786-O (ccRCC) cell lines were used in these experiments. Ferroptosis was induced using ML210 and erastin. α-toc loading of native HDL and LDL was increased by incubation with free α-toc and spin filter purification. To isolate α-toc as the component responsible for modulating ferroptosis, we developed synthetic α-toc-loaded HDLs (sHDL). siRNAs were used to reduce SR-B1 and LDL Receptor (LDLR) expression. Blocker of lipid transport-1 (BLT-1) was used to inhibit uptake of lipoprotein cargo via SR-B1. Cell viability was measured by MTS assay and lipid peroxidation was measured by C11-BODIPY.
Results: The α-toc level was higher in LDLs compared to HDLs (6.0 ± 0.1 α-toc/ apoB-100 vs. 1.0 ± 0.1 α-toc/ apoA-I) and increased in both HDL and LDL following incubation with free α-toc (α-toc LDL, 10.1 ± 0.1; α-toc HDL, 1.6 ± 0.3). HDL, α-toc HDL and α-toc LDL, but not LDL, rescued DLBCL and ccRCC cells from ferroptosis induced by the addition of ML210 and erastin, with a corresponding decrease in PL-OOH accumulation. Similarly, α-toc sHDLs, but not empty sHDLs, prevented ferroptosis in DLBCL and ccRCC. Knockdown of SR-B1 resulted in down-regulation of GPx4 expression and ferroptosis in ccRCC cells, requiring the use of BLT-1 to investigate SR-B1's role in α-toc delivery. Addition of BLT-1 prevented α-toc lipoprotein rescue from ferroptosis. Knockdown of LDLR expression did not alter the ability of HDL and α-toc HDL to prevent ferroptosis and enhanced the ability of α-toc LDL to prevent ferroptosis.
Conclusion: We reveal a tunable cellular redox axis whereby HDLs containing α-toc target SR-B1 to reduce PL-OOH and prevent ferroptosis. Accordingly, this work reveals that the α-toc / HDL/ SR-B1 axis of ferroptosis prevention must be accounted for when targeting ferroptosis in vivo.

#2825 Oncosis-inudcing hydrazones complexes with selective anticancer activity.

Alzbeta Srovnalova[1], Robert Kakplanek[2], Zdenek Kejlik[2], Jan Hajduch[2], Pavel Martasek[2], Josef Srovnal[1], Sona Gurska[1], Katerina Jecmenova[1], Petr Dzubak[1], Marian Hajduch[1], Milan Jakubek[2]

[1]Palacky Univ. Faculty of Medicine, Olomouc, Czech Republic,[2]Charles University, Prague, Czech Republic

INTRODUCTION: The molecular hybridization of three pharmacophores—benzothiazole, cyclobut-2-ene-1,2-dione, and hydrazone—has led to the development of novel compounds with diverse biological activities, including anticancer, anti-inflammatory, and antiviral properties. Among these, certain derivatives demonstrated potent and selective anticancer activity, particularly in CCRF-CEM and HCT116 cell lines. Some derivatives also emitted green fluorescence, enabling organelle-specific imaging by fluorescence microscopy. In U2OS cells, these fluorescent derivatives induced cytoplasmic vacuolization within 24 hours, suggesting a non-apoptotic cell death mechanism consistent with oncosis, characterized by energy depletion, increased membrane permeability, organelle swelling, and protein denaturation.

METHODS: Various microscopy techniques were employed to explore the fluorescent features of target organelles in U2OS cells. Compound 6, with its stable green fluorescence, was selected for detailed analysis. Mitochondria were visualized using MitoTracker dye, with colocalization assessed via Pearson correlation. Mitochondrial membrane potential was evaluated using TMRM dye, which accumulates only in cells with intact membrane potential. Endoplasmic reticulum colocalization with cytoplasmic vacuoles was analyzed using mCherry-tagged calreticulin in a recombinant U2OS cell line. Lysosomal integrity and vacuole colocalization were examined with LysoTracker dye. To determine if cytoplasmic vacuolization is depended on caspase activation, cells were treated with compound 6 in the presence or absence of the pancaspase inhibitor Z-VAD-FMK, and caspase-3/PARP-1 cleavage was assessed by Western blot. The FUCCI reporter system was used for cell cycle analysis.

RESULTS: Compound 6 strongly colocalized with mitochondria and induced mitochondrial dysfunction, ER vacuolization, and oncosis-like non-apoptotic cell death. This suggests that compound 6 exerts anticancer effects by targeting multiple cellular compartments, involving ER stress and mitochondrial disruption. The oncosis-like pathway is significant as it may bypass apoptosis resistance, a key hurdle in cancer therapy. Additionally, compound 6 reduced LysoTracker staining, indicating lysosomal dysfunction. Cell cycle analysis revealed a concentration-dependent G2/M arrest, further supporting its anticancer efficacy.

ACKNOWLDEDGEMENT: This work was supported by the Technology agency of the Czech Republic project PERMED: T2BA (TN02000109) and the National Institute for Cancer Research (Programme EXCELES, ID Project No. LX22NPO5102). Infrastructure was supported by projects CZ-OPENSCREEN (LM2023052) and EATRIS-CZ (LM2023053). #2826 Celastrol-Cu nanoparticles induce self-amplified cuproptosis augmented cancer immunotherapy.

Huawei Pan, Liuxian Meng, Yifan Li, **Tj (Tiejun) Bing**

ICE Bioscience, Inc., Beijing, China

Cuproptosis, a recently identified copper-dependent programmed cell death pathway, has emerged as a promising strategy in cancer therapy. Its effectiveness is closely linked to intracellular copper accumulation but is mitigated by elevated levels of glutathione (GSH) in tumor cells. A significant barrier to its clinical application lies in the challenge of facilitating the cellular uptake of copper ions. Additionally, intracellular copper ions rapidly bind with GSH, further complicating the induction of tumor cell death. Notably, no existing ionophore drug simultaneously acts as both a copper ionophore and a GSH scavenger to effectively induce cuproptosis.
In summary, we have developed a celastrol-based nanomedicine that, upon complexation with copper ions, effectively promotes cuproptosis in a self-amplifying manner, as validated in both 4T1 subcutaneous and metastatic breast cancer models. This Cel-Cu NP platform provides a novel option with significant translational potential for the integrated programmed therapy of triple-negative breast cancer (TNBC) in immunologically “cold” tumors.

#2827 Heat shock factor 1 regulates the cellular toxicity-induced autophagy in pancreatic ductal adenocarcinoma.

Rejina Shrestha, Shruti Ghai, Ahmad Hegazi, Kuo-Hui Su

Department of Cell and Cancer Biology, The University of Toledo, Toledo, OH

Background: Heat shock factor 1 (HSF1) is a master transcriptional regulator of the proteotoxic stress response and has been known to be hyperactivated in pancreatic ductal adenocarcinoma (PDAC). Recent research has shown that ion-induced cellular toxicity (ferroptosis or cuproptosis) triggers autophagy—a critical mechanism that maintains cellular homeostasis. HSF1 has been established to mediate autophagy in a context-dependent manner. It has been reported that HSF1 prevents copper-induced toxicity in PDAC; however, it remains unclear whether HSF1 mediates autophagy as a mechanism of stress adaptation in response to aforementioned cellular toxicity.
Objective: The objective of this study is to investigate the molecular mechanism of the role of HSF1 in cellular ion toxicity-induced autophagy.
Methods: Human PDAC cell line MIA PaCa-2 was used for this study. A CellTiter Blue Cell Viability Assay was used to determine the IC50 of Erastin, a well-known ferroptosis inducer, and Elesclomol/copper, a copper ionophore, in human PDAC cells. An HSF1 overexpressed (HSF1_WT) MIA PaCa-2 cell was used to test ion-induced toxicity in comparison to the control (LacZ) MIA PaCa-2 cells. Western blotting was used to detect the protein HSF1, autophagy markers, and internal loading control.
Results: In human MIA PaCa-2 cells, Elesclemol/copper and Erastin induced cell death. Elesclomol/copper and Erastin induced increased autophagy marker microtubule-associated protein 1A/1B-light chain 3β (LC3β) lipidation and decreased the expression of total HSF1 protein in a dose-dependent manner. The overexpression of HSF1 prevented the Erastin-induced LC3β lipidation.
Conclusion: HSF1 plays a role in the induction of autophagy, which functions as a stress-adaptive mechanism in the tumor cell in response to the toxicities induced by ferroptosis and cuproptosis inducers.

#2828 Anthocyanin-induced autophagosome accumulation and mitochondrial dysfunction drive apoptosis in liver cancer cells.

Anyssa Rodriguez[1], Samantha Tamayo[1], **Aarya Tripathi**[1], Sumeet Chauhan[1], Subash Chauhan[2], Nirakar Sahoo[1]

[1]School of Integrative Biological and Chemical Sciences, The University of Texas Rio Grande Valley, Edinburg, TX,[2]Medicine and Oncology, School of Medicine, The University of Texas Rio Grande Valley, Edinburg, TX

Introduction: Liver cancer remains one of the most lethal malignancies worldwide. Hepatocellular carcinoma (HCC) accounts for most cases. Existing therapies provide limited efficacy, especially in advanced stages, highlighting the urgent need for alternative treatments. Recent studies have demonstrated that anthocyanins, a natural plant-derived compound, show anticancer potential. Dracorhodin Perchlorate (DP), a synthetic analog of anthocyanin found in *Daemonorops draco* fruit, exhibits cytotoxic effects in cancer cells. This study investigates the mechanisms underlying DP's cytotoxicity in HCC.
Methods: We examined the effect of DP on human liver cancer cells (SK-HEP1). We employed an integrative experimental approach combining cell viability assay, death pathway analysis, autophagy monitoring, lysosomal function evaluation, oxidative stress assessment, and mitochondrial integrity. Western blot, immunocytochemistry, and live cell imaging were employed.
Results: Our result shows that DP significantly reduced SK-HEP1cell viability in a time- and dose-dependent manner. The IC50 values decreased from 60 µM at 24 hours, 26 µM at 48 hours, and 18 µM at 72 hours, reaching 12 µM at 96 hours. We observed decreased pro-caspase-3 levels in DP-treated cells, confirming apoptosis. We found no change in phosphorylated MLKL levels, ruling out necroptosis. Interestingly, we observed a significant increase in LC3II/I ratios and LC3 puncta, indicating autophagosome accumulation. However, we noted no increase in lysosomal activity-based DQ-BSA and Lysotracker assays, suggesting autophagic flux inhibition. Furthermore, we detected a significant rise in reactive oxygen species (ROS) levels following DP treatment, accompanied by elevated HO-1 expression. We found evidence of mitochondrial dysfunction, as Mitotracker assays revealed fragmented mitochondria and reduced cytochrome c release. We observed that Bafilomycin A1 amplified DP-induced apoptosis, supporting the role of autophagic flux inhibition in driving cell death.
Conclusions: Taken together, these findings reveal that DP induces apoptosis in liver cancer cells by driving autophagosome accumulation, oxidative stress, and mitochondrial damage. Our work suggests that DP holds potential as an anthocyanin-based therapy for liver cancer.

#2829 Multifaceted characterization of ferroptosis using live-cell imaging and AI-driven analysis.

J. E. Trigg, G. Lovell, N. Bevan;
Sartorius, Royston, United Kingdom

Ferroptosis is a form of regulated cell death which is distinct from apoptosis and therefore represents a new mechanism by which cancer cells can be targeted and killed. Live-cell imaging was used to capture the dynamic and non-discrete morphology changes associated with ferroptosis in a range of cell types, and to characterize this mechanism of cell death and its contrast with apoptosis. Incucyte® AI Cell Health Analysis uses a trained neural network (NN) to segment cells in phase contrast images. The NNs were trained on a wide range of cell types, including healthy and non-viable, and therefore adapts robustly to unseen cells, yielding highly accurate delineation across a variety of morphologies as well as live/dead classification of ferroptotic cells. Using Incucyte® Advanced Label-free Classification software to perform machine learning-based classification of cells based on morphology, the characteristic ferroptotic transition state was selectively identified using images of cells treated with FIN56. This method was used for label-free quantification of compound efficacy in HeLa cells, comparing apoptosis inducer CMP to ferroptosis inducers Erastin (ERA), FIN56 and RSL3. Pharmacological validation of the mechanism of action showed ferroptosis inhibitor Ferrostatin-1 (FERR) inhibited ERA-induced cell death but not CMP-induced cell death; apoptosis inhibitor Z-VAD-FMK displayed converse selectivity. In addition, we demonstrated that ferroptosis inducer ERA, but not apoptosis inducer staurosporine (STP), was sensitive to the density of cells in the assay. ERA EC_{50} in SK-OV-3 cells decreased from 2.2×10^{-6} to 8.2×10^{-6} as the cell density increased from 500 to 3,000 cells per well while STP EC_{50} remained constant at 1.3×10^{-7} at all cell densities. Fluorescence labeling of live and dead cells was explored to evaluate ferroptosis in 2D monolayer as well as 3D spheroid culture. Fibroblasts were treated with FIN56 in the presence of Incucyte® Cytotox Dye which enters non-viable cells via permeable cell membranes. Rapid ferroptosis was observed with the area of green fluorescence experiencing a rapid increase over 12h post treatment, and cell death was concentration-dependent. Ramos B cell line and adherent A549 cells were labeled with nuclear restricted orange and Near IR fluorophores, respectively. Upon treatment with ferroptosis inducers, both Ramos Nuclight Orange cells and A549 Nuclight NIR spheroids displayed a decrease in fluorescence intensity, consistent with cell death. Ferroptotic cell death in the spheroids was also characterized by an increase in brightfield area as the spheroids lost compactness, in contrast to apoptotic cell death which reduces the total spheroid area. Live-cell analysis provided a valuable platform for characterizing the dynamic process of ferroptotic cell death, yielding insight into the cellular mechanisms, and enabling quantification across multiple cell types.

#2830 Aurora kinase B phosphorylates ZBP1 to drive PANoptosis following treatment with a combination of PARP and ATR inhibitors.

Wenjian Gong[1], Zhiqi Liao[1], Shennan Shi[1], Fan Xiong[1], Mengshi Luo[1], Yuewen Zhang[1], Qiuyang Xu[1], Yijie Wu[1], Linghui Wang[1], Li Zhu[2], Dong Kuang[3], Marilyne Labrie[4], Xuejiao Zhao[1], Gordon B Mills[5], Ding Ma[1], Guangnian Zhao[1], Qinglei Gao[1], Yong Fang[1]

[1]Department of Gynecological Oncology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China,[2]Department of Hematology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China,[3]Department of Pathology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China,[4]Department of Immunology and Cell Biology, Faculty of Medicine and Health Sciences, Universite de Sherbrooke, Sherbrooke, OH, Canada,[5]Division of Oncological Sciences, Oregon Heath and Sciences University, Portland, OR, USA; Knight Cancer Institute, Portland, OR

Background: The combination of DNA damage response inhibitors (DDRis) to induce unrepaired DNA damage entry into mitosis prematurely has emerged as a promising strategy for anticancer therapy. However, the efficacy is often limited by their tolerability due to associated toxicities.
Method & Result: Here we demonstrate that combining poly (ADP-ribose) polymerase (PARP) and ATR inhibitors induces PANoptosis in both cancer and non-cancer cells as a result of abnormal mitotic progression. This is highly dependent on CDK1 activity. Furthermore, ZBP1-dependent PANoptosome (ZBP1-RIPK1-CASP8-CASP6) mediated PARP and ATR inhibitors combination therapy induced PANoptosis. Further exploration revealed that the kinase activity of aurora kinase B (AURKB) was essential for ZBP1-mediated PANoptosis following the treatment. ZBP1 could be phosphorylated by AURKB during mitosis, and phosphorylated ZBP1 subsequently facilitates the assembly and activation of PANoptosome. Finally, our findings were validated in an ovarian cancer patient-derived xenograft (PDX) model in which PARPi and ATRi combination induced PANoptosis in both tumor and normal tissue Importantly, the toxicity to normal tissues was mitigated in ZBP1-knockout mice.
Conclusion: Overall, these results suggest that phosphorylation of ZBP1 by AURKB triggers the activation of ZBP1-dependent PANoptosome after treatment with PARPi and ATRi combination, leading to cell-intrinsic antineoplastic activity and toxicity. Our study elucidates the specific mechanisms underlying cell fate determination during aberrant mitosis progression resulting from PARPi and ATRi combination therapy. These findings provide a theoretical foundation for understanding their anticancer effects and toxicity, crucial for optimizing the use of DDRis combination approaches in the clinic.

MOLECULAR/CELLULAR BIOLOGY AND GENETICS: Origins and Mechanisms of Genomic Instability
Poster Session

#2834 CyclinE1 amplification promotes chromosomal instability and distinct vulnerabilities in gastroesophageal adenocarcinoma.

Zhong Wu[1], Ankur Nagaraja[2], Shangwei Sun[1], Ling Lan[1], **Jin Zhou**[1], Adam Bass[2]

[1]West China Hospital of Sichuan University, Chengdu City, China,[2]Dana-Farber Cancer Institute, Boston, MA

Background: Gastroesophageal adenocarcinomas (GEA) are characterized by chromosomal instability (CIN) predominantly consisting of high amplitude focal amplifications of oncogenes, including Cyclin E1. An initial pan-cancer analysis revealed that *CCNE1* is one of the top genes whose expression correlates with focal CIN.
Objective: We proposed a causal role for excess CCNE1 as a driver of CIN and gastroesophageal tumorigenesis, and investigated the therapeutic vulnerabilities of *CCNE1* amplification/overexpression.
Design: We engineered a novel *CCNE1*-overexpressing mouse gastric organoid model with *Trp53* deletion and studied the functional effects on tumor initiation and progression. Whole genome sequencing of tumors was performed to characterize the effects of *CCNE1* overexpression on genomic instability. To identify dependencies of *CCNE1*-amplified GEA, we executed a CRISPRi functional genomic screen. Top genetic dependencies were translated into potential pharmacologic vulnerabilities and tested in monotherapy and combination.
Results: *CCNE1* overexpression accelerated tumor initiation and progression of mouse gastric organoids with *Trp53* deletion. These tumors demonstrated increased chromosomal complexity, mainly focal amplifications. Our functional genomic screen identified specific genetic dependencies of *CCNE1*-amplified GEA, including *CCNE1*/*CDK2* as the strongest hits, and *SKP2* as a novel dependency likely through its function as a p27 degrader. Pharmacologic inhibition of CDK2 was insufficient and antagonistic with concurrent inhibition of the DNA damage response via targeting the ATR/CHEK1 axis. However, staggered inhibition of these distinct vulnerabilities demonstrated efficacy.
Conclusions: Our study identifies CCNE1 as a driver of CIN in GEA and builds a foundation for further exploration of therapies for *CCNE1*-amplified GEA characterized by genomic instability.

#2835 Lamin AC deficiency promotes genomic instability through increased R-loop accumulation.

Lamin A/C (*LMNA*), a key component of the nuclear envelope, plays an essential role in maintaining nuclear integrity and regulating genome organization. While *LMNA* dysregulation has been linked to genomic instability in both cancer and aging, the specific mechanisms remain poorly understood. We investigated the role of *LMNA* in small cell lung cancer (SCLC), a highly lethal form of lung cancer characterized by neuroendocrine (NE) differentiation, low *LMNA* expression, and extreme genomic instability. We show that *LMNA* depletion leads to increased R-loop formation, transcription-replication conflicts, replication stress, DNA breaks, the formation of micronuclei and increases sensitivity to TOP1 and ATR inhibition. Mechanistically, *LMNA* loss compromises RNA export efficiency by disrupting the nuclear pore complex distribution causing clumping and reducing incorporation of phenylalanine-glycine-nucleoporins (FG-nucleoporins). We found that *LMNA* expression is dynamically regulated during SCLC differentiation from NE to a non-NE state by EZH2, a component of the polycomb repressive complex that epigenetically silences *LMNA*. Inhibition of EZH2 restored LMNA expression in SCLC cells, and functionally led to a reduction in R-loops. Low *LMNA* levels were associated with significantly reduced survival in SCLC patients implicating R-loops as potential detrimental factor in SCLC patients. To confirm this, we utilized multiplexed immunofluorescence and confirmed LMNA protein was inversely correlated with R-loops both within the same SCLC tumor and across SCLC tumors using an SCLC rapid autopsy sample alongside an SCLC tumor microarray. Interestingly, low expression of canonical R-loop suppressing genes (*RNASEH1, BRD4, SETX and DHX9*) also predicted poorer prognosis in SCLC patients, supporting R-loops as a detrimental factor for SCLC prognosis. Critically, we were able to replicate key findings linking low LMNA to decreased FG-nucleoporin incorporation and increased R-loops using patient derived young and old fibroblasts lines demonstrating generalizability of this finding across disease models. Our results reveal a novel mechanism by which *LMNA* safeguards genome integrity by repressing R-loops, with important implications for both cancer and aging.

#2837 Mechanisms promoting chromosomal instability following the loss of p53 and Rb.

Risha Banerjee[1], David G. Kirsch[2]

[1]Department of Medical Biophysics, University of Toronto, Toronto, ON, Canada,[2]Radiation Medicine Program, Princess Margaret Cancer Centre, University Health Network, Toronto, ON, Canada

p53 and Rb co-mutations are common in several human cancers and are associated with the onset of aggressive tumors with complex karyotypes. Canonically, these tumor suppressors respond to DNA damage and cellular stress by inducing cell cycle arrest, activating pro-apoptotic and anti-proliferative signalling, and promoting cellular senescence. While these pathways are sufficient to partially explain the tumor suppressive abilities of p53 and Rb, recent studies in genetically engineered mouse models suggest additional, non-canonical means of tumor suppression, including modulation of cellular differentiation and DNA topology, and interestingly, influencing cellular response to chromosomal instability. Chromosomal instability (CIN) is a hallmark of aggressive, therapy-resistant cancers and is associated with mitotic dysfunction, faulty DNA damage responses, immune evasion, and cellular stress response pathways. While it is known that p53 and Rb maintain the integrity of the genomic landscape, the mechanisms by which they prevent CIN remain understudied. Here, we use mouse embryonic fibroblasts (MEFs) to show that p53 + Rb double knock-out (DKO) causes a dramatic increase in ploidy at very early passages, which stabilizes at tetraploid levels. These cells also harbour high levels of CIN, indicated by the presence of micronuclei, DNA double-stranded breaks, and lagging chromosomes. Additionally, we observed CIN in $p53^{25,26}$ transactivation domain (TAD) mutant MEFs that are unable to activate most canonical p53 targets yet retain the ability to suppress tumorigenesis in vivo, raising the possibility that the maintenance of chromosomal stability is dispensable to the tumor suppressive functions of p53. Using a combination of bulk and scRNA sequencing of aneuploid and diploid DKO MEFs, in future experiments we will identify p53- and Rb-dependent changes in gene expression associated with the onset and progression of CIN. Overall, the results of this study are expected to provide critical insights into the molecular mechanisms by which tumor suppressors p53 and Rb work together to repress CIN.

#2838 Modeling putative oncogenic variants of human topoisomerase II by genome editing of a near haploid cell line.

Karin C. Nitiss, Brigid Conroy, Maureen N. McCoy, **John L. Nitiss**

Retzky College of Pharmacy, University of Illinois Chicago, Rockford, IL

DNA topoisomerases (Topos) carry out changes in DNA structure by introducing transient breaks in DNA. These breaks are needed to change DNA conformation, and the enzyme mechanisms minimize possible genome instability from a failure to resolve the cleaved DNA intermediates. Nonetheless, small molecules can interfere with the Topo reaction, leading to elevated DNA cleavage, genome instability and cell death, and this property is the basis of the action of important anti-cancer drugs. Recent work has led to the identification of mutations in eukaryotic Top2 that also result in high levels of Top2 cleavage; including Lys743Asn in the Top2 alpha isoform which was observed in multiple human cancers. Hyper cleavage Top2 mutants are genome destabilizing in yeast and have been shown to induce 2-5 nucleotide *de novo* duplications, as well as other genetic changes. To generate mammalian cell lines expressing hyper cleavage Top2 mutants, we used Piggybac mediated scarless editing in the haploid mammalian cell line eHap. We accomplished successful editing of both Top2 alpha and Top2 beta in this cell line. Successful editing was assessed by sequencing Top2 cDNAs as well as sequencing of the edited genomic loci. Two independent successfully edited cell lines resulted in changes of Lys600Thr in Top2 beta and Lys579Thr in Top2 alpha; allowing us to compare the effects of mutations at orthologous positions in the two mammalian Top2 isoforms. Both edited cell lines show strong constitutive induction of DNA damage responses with elevated levels of DNA-PKcs and histone H2AX phosphorylation. Interestingly, elevated levels of ubiquitylated H2AX were also seen, suggesting that H2AX ubiquitylation may be indicative of constitutive topoisomerase induced damage. These cell lines are being used to measure genetic changes induced by topoisomerase induced damage and will be a unique tool to identify pathways that repair Topo-induced DNA damage. These cells will also provide insights into topoisomerase mediated mechanisms of oncogenesis.

#2839 The functional role of tumor suppressor WW domain-containing oxidoreductase in maintaining genome integrity.
Li-Jin Hsu

National Cheng Kung Univ. Medical College, Tainan, Taiwan

The induction of DNA damage response (DDR) to ensure accurate duplication of genetic information during DNA replication is crucial for maintaining genome integrity. Cellular senescence is a DDR mechanism that prevents the proliferation of cells with deleterious DNA damage to avoid mitotic anomalies and inheritance of the damage over cell generations. A decreased ability of the cells to undergo senescence has been suggested to be associated with cancer development. Using *Wwox* knockout models, we determined that *Wwox* knockout mouse embryonic fibroblasts (MEFs) failed to undergo replication stress-induced cellular senescence after multiple passages in culture. Importantly, accelerated cell cycle progression and increased apoptosis were detected in *Wwox* knockout MEFs at late passages. Increased γH2AX-positive cells and microsatellite instability were examined in late-passage *Wwox* knockout MEFs, indicating massive accumulation of DNA damages in these cells. We detected significantly reduced expression of p53 and CDK inhibitors $p16^{INK4A}$ and $p21^{cip1/waf1}$ in late-passage *Wwox* knockout MEFs. Inhibition of oxidative stress during *en vitro* passage culture reversed $p16^{INK4A}$ and $p21^{cip1/waf1}$ downregulation and induced senescence in *Wwox* knockout MEFs. Importantly, we demonstrated that WWOX protein expression was upregulated in cells during DNA replication. Significantly enhanced phosphorylation of Chk-1 protein was detected in proliferating WWOX-knockdown HEK-293T cells and *Wwox* knockout MEFs, suggesting that WWOX plays an important role in regulating DDR signaling for maintaining genome stability upon replication stress. Our findings delineate the regulatory role of WWOX in DDR and have great impact on our understanding of molecular pathogenesis of cancer and senescence-related diseases.

#2842 Dual-specificity phosphatase 12 as a key modulator of DNA damage response and nucleolar stress in hepatocellular carcinoma.

Viktor Kalbermatter Boell, **Fabio Luis Forti**

Department of Biochemistry, Institute of Chemistry, University of Sao Paulo, Sao Paulo, Brazil

The dual-specificity phosphatase 12 (DUSP12) has been implicated in liver pathologies, such as hepatocellular carcinoma (HCC), through molecular mechanisms poorly understood. Our group identified protein partners of DUSP12 in tumor cells under genotoxic stress, including the nucleolar proteins NAT10 and TCOF1, well-recognized for their roles in ribosome biogenesis, but which involvement in DNA damage response (DDR) mechanisms has gained attention. Given these proteins are associated with HCC progression and poor prognosis, this study aimed to explore the role of DUSP12 in the hepatic cell lines HepaRG and HuH-7 under treatments with cisplatin (CP) or doxorubicin (DX). Datamining the TCGA database revealed frequent amplification of DUSP12 in HCC patients, resulting in elevated mRNA and protein expression levels, which were strongly correlated with NAT10 and TCOF1 expression. Gene ontology analyses of DUSP12-correlated genes in HCC patients highlighted novel functional relationships between DUSP12 and processes related to DNA repair and DDR. In vitro, DX treatment produced marked cytotoxic and antiproliferative effects in both monolayer cultures of HepaRG and HuH-7 cells. However, noteworthy resistance was observed in 3D spheroid cultures of these cell lines. At the molecular level, DX treatment elicited an early and robust activation of DDR pathways compared to CP treatment, as evidenced by increased levels of p-Chk2 (Thr68), p-p53 (Ser15), and γH2AX (Ser139) in both cell lines. Intriguingly, DX treatment also induced distinct nucleolar stress features, nuclear accumulation of DUSP12, and the redistribution of NAT10 and TCOF1 to the nucleoplasm, although their expression levels remained unchanged. CRISPR-Cas9-mediated knockdown (KD) of DUSP12 in HuH-7 cells sensitized these cells to DX treatment in both monolayer and spheroid cultures in a manner proportional to DUSP12 expression levels. This sensitization to DX occurs independently of reactive oxygen species (ROS) modulation and was accompanied by increased levels of p-p53 (Ser15) and γH2AX, as well as the modulation of double-strand break levels as assessed by comet assay, suggesting that DUSP12 KD affects DDR signaling and DNA repair in these cells. Similarly, transfection with DUSP12 siRNA enhanced γH2AX focus formation in HepaRG cells treated with DX. Notably, DUSP12 KD in HuH-7 cells induced nucleolar stress characteristics, as evidenced by the mislocalization of NAT10 and TCOF1, as well as hyperploidy, increased micronuclei frequency, and a higher mitotic cell population, indicated by elevated p-H3 (Ser10) levels. Altogether, our findings reveal that DUSP12 plays a pivotal role in hepatocellular carcinoma by affecting genomic stability and modulating DNA damage response and nucleolar stress pathways under genotoxic conditions, underscoring its potential as a therapeutic target in HCC.

#2843 Neoantigen evaluation in viably cryopreserved dissociated tissue via large scale proteomic profiling.

Shawn P. Fahl, Casey Smith, Kerri Colwell, Jessica Moore, Jaison Arivalagan, Danielle Gutierrez

Discovery Life Sciences, Huntsville, AL

Genomic instability is a hallmark of cancer where the acquisition of numerous genetic alterations leads to transformation and carcinogenesis. These alterations result in the generation of potentially immunogenic neoantigens, and the clinical success of checkpoint inhibitor therapies has highlighted the importance of neoantigens in cancer immunotherapy. Evaluation of the next generation of neoantigen therapies is complicated by the difficulty in sourcing primary patient material. During tumor resection and pathology review, the tissue is fixed, which prevents the ability to test in vitro model systems for therapy efficacy. While fresh tissue is amendable to in vitro culture, it is not possible to perform large scale genomic and proteomic screens in a timeframe for the culture to occur. By leveraging viably cryopreserved dissociated tissue, the tumor can be analyzed for genetic alterations and then, when novel neoantigens are determined, cultured at a later date. To test this workflow, we profiled dissociated tissues from cancer indications with a high degree of genomic instability for microsatellite instability (MSI). Consistent with previous studies, 17-55% of endometrial, colorectal, and gastric cancer samples were MSI-high. MSI-high and microsatellite stable (MSS) samples were further analyzed for peptide identification using LC-MS/MS (Orbitrap Astral) and over 10,000 protein groups and 80,000 peptides were identified. Samples were also amendable to T cell receptor (TCR) repertoire sequencing to uncover tumor-reactive T cell clones. These deep molecular analyses provided the foundation for the development of short-term spheroid and long-term tumoroid culture systems to understand immune responses using autologous tumor-infiltrating and peripheral lymphocytes. Collectively, this workflow provides a scalable system to identify neoantigens and evaluate the immune response to these antigens in a robust and reproducible pipeline.

#2844 A cytosolic DNA/Ca^{2+}-dependent signaling pathway for genome protection during replication stress.

Z. You;
Washington University School of Medicine, St. Louis, MO

Protecting the replication fork structure, especially under replication stress, is essential for maintaining genome integrity and stability. Defects in fork protection, often linked to mutations in tumor suppressor genes like BRCA1, BRCA2 and FANCD2, can lead to genomic instability and consequently, cancer progression. Such defects may also influence cancer progression by altering the tumor microenvironment through the generation of cytosolic DNA fragments that activate the innate immune response. Intriguingly, our recent findings indicate that cytosolic DNA, produced after replication stress, unexpectedly also supports replication fork protection. This protective effect is mediated through a complex signaling pathway that involves the activation of the cGAS/cGAMP/STING axis, Ca2+ release from the endoplasmic reticulum via the TRPV2 ion channel, activation of CaMKK2 and AMPK protein kinases, and the inhibition of the EXO1 nuclease. Disruption of this pathway results in excessive fork processing, chromosomal instability and heightend sensitivity to replication stress inducers. The newly uncovered links between innate immune factors, intracellular Ca2+ and genome maintenance in this novel signaling pathway may open new avenues for cancer treatment. (Li *et al.*, *Mol Cell* 2019, 74:1123-1137; Li, Kong *et al., Mol Cell* 2023, 85:556-573; Kong, Cheng *et al., Nat Commun* 2024, 15:4609)

#2845 Midasin overexpression drives intrinsic endocrine resistance by stabilizing DNA damage.

Manasa Kotina[1], Afia Ohemeng[1], Mounika Pamukuntla[1], Bipika Banjara[1], Alicia Hudson[1], A. Micheal Davidson[1], Jillian L. Pope[2], Selina Darling-Reed[1], Syreeta L. Tilghman[1]

[1]Basic Pharmaceutical Sciences, Florida A&M University, Tallahassee, FL,[2]Biological Sciences, Florida A&M University, Tallahassee, FL

Midasin (MDN1), a AAA-ATPase protein critical to ribosome biogenesis, has emerged as a key player in the progression of triple-negative breast cancer (TNBC), a subtype characterized by its heterogeneity, absence of therapeutic targets, and poor prognosis. Previous work from our lab and others, demonstrated that estrogen receptor negative (ER-) breast cancer patients with high MDN1 expression are positively correlated with a worse relapse-free survival compared to their ER+ counterparts and breast tumors with MDN1 mutations are associated with high tumor mutation burden and unfavorable prognosis. Additionally, MDN1 alterations are associated with increased expression of a signature of proteins involved in cell cycle dysregulation and genomic instability. Thus, we hypothesize that MDN1 overexpression drives intrinsic endocrine resistance by stabilizing DNA damage which promotes tumor cell survival and progression. To gain mechanistic insight into the role of MDN1 in ER- breast cancer, we employed, Ribozinoindole-2 (i.e., Rbin-2), a potent MDN1 pharmacologic inhibitor to study two TNBC cell lines, which express high (MDA-MB-468) and low (MDA-MB-231) levels of MDN1. Both cell lines were treated with 1-12 μM Rbin-2, and after 72 hour, 12 μM Rbin-2 treatment induced a 50% reduction in cell viability. Western blot analyses were conducted, and MDA-MB-468 cells expressed a 1.5-fold increase in MDN1 expression compared to the MDA-MB-231 cells. Rbin-2 treatment reduced MDN1 expression by 30-50% in both cell lines. To gain an in depth understanding of the impact on MDN1 alterations on the fate of the cell, we conducted a series of *in silico* studies and observed that breast cancer patients with alterations in MDN1 are associated with various forms of DNA damage including higher mutation counts, microsatellite instability, and fractions of the genome that are altered. To confirm this finding, a focused DNA damage antibody array study was performed which revealed that 12 μM Rbin-2 treatment decreased mismatch repair proteins and DNA damage checkpoint markers. We validated this finding by immunoblots and Rbin-2 treatment reduced MSH2, MSH6, and phospho-p53, by 13.8-15.6% in MDA-MB-231 cells and 20-25% in MDA-MB-468 cells further supporting the *in silico* and protein array data. Immunofluorescence and immunoblotting of γH2AX, a marker for DNA double-strand breaks, confirmed that MDN1 inhibition caused a 55-75% increase in DNA damage in both cell lines, suggesting that MDN1 plays a key role in maintaining genomic stability and regulating DNA damage responses in TNBC. Given these findings elevated MDN1 expression may drive DNA repair dysregulation, thereby providing a survival advantage for *de novo* endocrine resistant breast cancer. These preliminary studies suggest that MDN1 may represents a potential therapeutic strategy to exploit TNBC's inherent genomic instability and improve treatment outcomes.

#2846 Association of cyclin E1 expression with genomic instability in ovarian cancer.

Ajay Obla[1], Michelle Kinder[1], Chifei Sun[1], Heather Bullins[1], Cynthia Timmers[1], Ming Poi[2], Sharon Wu[2], Edoardo Missiglia[3], Bettina Bisig[3], Krisztian Homicsko[4]

[1]Incyte Research Institute, Wilmington, DE,[2]Caris Life Sciences, Phoenix, AZ,[3]Institute of Pathology, Department of Laboratory Medicine and Pathology, Lausanne University Hospital (CHUV) and Lausanne University, Lausanne, Switzerland,[4]Department of Oncology, Lausanne University Hospital (CHUV); Ludwig Institute for Cancer Research, Lausanne Branch; Swiss Cancer Center Leman, Lausanne, Switzerland

Background: Cyclin E1 (CCNE1) expression has been associated with replicative stress and defects in double-strand break repair in multiple tumor types; however, this has yet to be demonstrated in ovarian cancer. Herein, we describe *CCNE1* DNA amplification (AMP), messenger RNA (mRNA) expression, and cyclin E1 protein expression in 2 large cohorts of high-grade serous ovarian cancer (HGSOC) (The Cancer Genome Atlas [TCGA] and Caris Life Sciences, Phoenix, AZ, USA).
Methods: 8127 HGSOC samples were analyzed by next-generation sequencing (NextSeq, 592 genes or NovaSeq, whole exome sequencing) and RNA (NovaSeq, whole transcriptome sequencing) (Caris Life Sciences). For genomic loss of heterozygosity (LOH), 22 autosomal chromosomes were split into 552 segments and the LOH of single nucleotide polymorphisms within each segment was calculated (LOH-H ≥16%). Homologous repair deficient (HRD+/−) status was determined by high genomic scar score (GSS) or *BRCA1/2* mutant (MT) [HRD+], or low GSS and *BRCA1/2* wild-type (WT) [HRD−], respectively. GSS was calculated from large-scale state transitions (LSTs) and LOH (GSS-H ≥46). 1177 samples from TCGA were also included in this analysis.
Results: In the Caris data set, HGSOC *CCNE1* AMP was significantly more frequent in *BRCA1/2* WT HGSOC tumors (*CCNE1* AMP: 4.88% *BRCA1/2* MT vs 21% *BRCA1/2* WT; $P<0.0001$), as reported in other studies. Additionally, median expression of *CCNE1* mRNA was higher in *BRCA1/2* WT samples when compared with *BRCA1/2* MT samples (1.11-fc; $P<0.0001$). Median *CCNE1* mRNA was higher in HRD− HGSOC compared with HRD+ HGSOC (Caris: 1.11-fc, $P<0.0001$; TCGA: $P<0.0001$). In both data sets, *CCNE1* AMP was associated with lower global LOH prevalence (CCNE1-AMP %: 22.6% in LOH-L vs 13.9% LOH-H in Caris data, $P<0.0001$; TCGA, $P<0.0001$). However, there was a significant increase in *CCNE1* mRNA expression in LOH-H compared with LOH-L HGSOC Caris samples (1.27-fc, $P<0.0001$). There were no associations between *CCNE1* AMP or RNA/protein expression and LST in either data set, or with telomeric allelic imbalance score in TCGA. *CCNE1* AMP was associated with aneuploidy in TCGA ($P<0.001$). We also examined an independent set of commercial ovarian cancer samples for CCNE1 protein and pH2AX expression by immunohistochemistry to evaluate for an association with double-strand breaks, which will be included in the presentation.
Conclusion: Together, these data demonstrated that *CCNE1* AMP and RNA/protein expression were associated with various types of replicative stress in HGSOC. These data warrant further investigation on the impact of *CCNE1* AMP and CCNE1 expression on clinical outcomes.

#2847 Patterns of APOBEC3-mediated chromosomal rearrangements in solid cancers.

Taek-Chin Cheong[1], Qi Wang[1], Ahram Jang[1], Elif Karaca-Atabay[1], Jake June-Koo Lee[2], Roberto Chiarle[1]

[1]Department of Pathology, Boston Children's Hospital and Harvard Medical School, Boston, MA,[2]Department of Biomedical Informatics, Harvard Medical School, Boston, MA

Chromosomal translocations are complex biological processes that require the formation of DNA double-strand breaks (DSBs) at two different loci, followed by the joining of the broken ends by DNA repair mechanisms. In B-cell lymphoma, chromosomal translocations are directed by the on- or off-target activity of activation-induced cytidine deaminase (AID) that converts cytosine to uracil in single-stranded DNA (ssDNA), facilitating DSBs when two unpaired nicks are close together. However, no such enzymes have been discovered in solid tumors. While AID, a B-cell-specific APOBEC enzyme, is responsible for somatic hypermutations and chromosomal translocations in B-cell malignancies, apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like 3 (APOBEC3; A3) enzymes have been primarily studied for their mutagenic potential in solid cancers. In this study, we present detailed characterizations of A3-induced chromosomal translocations in multiple cell models. While shared features of AID- and A3-driven translocations are expected because they deaminate cytosine at similar consensus sequences which should result in similar patterns of DNA DSB hotspots, their translocation patterns are partially distinct. As expected, AID generated focal DSB clusters (FDCs) near transcription start site (TSS) regions, but AID also induced new types of FDCs in the gene body and in both TSS and gene body, as well as dispersed DSB cluster (DDC)-type translocations. Interestingly, A3s enhanced FDCs and DDCs in fibroblasts with the similar level of AID, but A3s were only able to induce FDCs in the gene body, not in the TSS region. Both AID- and A3-mediated chromosomal translocations were enriched in genomic regions associated with early-replicating constant timing regions (CTRs), A compartments, and topologically associated domain (TAD) boundaries. Moreover, we revealed an enrichment of A3-attributed mutational signatures at the vicinity of A3-induced chromosomal rearrangements and the oncogene amplification boundaries in patient samples. Finally, we found that A3 expression significantly increased the number of oncogenic tyrosine kinase (TK) fusions, such as ALK, RET, ROS1, and NTRK1 fusions that are recurrently found in non-small cell lung cancer (NSCLC). Furthermore, deletion of APOBEC3 genes significantly decreased the number of oncogenic TK fusions. This study highlights that A3 enzymes induce chromosomal translocations and the formation oncogenic TK fusions in human cancers, with their translocation patterns distinct from but partially shared with those induced by AID, suggesting A3s as promising therapeutic targets for reducing genomic instability in cancer patients.

#2849 Comparative analysis of mutational signatures in TumorGraft PDX bank and TCGA dataset to improve patient tumor modeling.

Stefano Cairo, Mara Gilardi, Marianna Zipeto, Michael Ritchie, Gilad Silberberg

Champions Oncology, Inc., Hackensack, NJ

Mutational signatures are unique patterns of DNA alterations that arise from specific mutagenic processes, such as exposure to genotoxic agents or DNA repair deficiencies. Tumors with common mutational signatures can harbor defects in specific DNA repair pathways that may underlie common genetic vulnerabilities. Furthermore, exposure patterns of mutational signatures can vary among clinical types of cancer. Champions' TumorGraft platform, a collection of 1500 patient-derived xenografts generated from more than 50 different types of cancer, is one of the most comprehensive preclinical oncology platforms worldwide and aims to recapitulate the variety of the patient population and tumor biology complexity. We performed the mutational signatures by profiling our models through whole exome sequencing. The results obtained were crossed with the patient's clinical history and showed a good correlation between the mutational signatures identified and tumor etiology and DNA damage repair alterations known to be associated with some indications. To assess the clinical relevance of our findings, we applied the molecular signature profiling method used with our PDXs to the TCGA dataset. This analysis revealed that the mutational profiles enabled the co-clustering of patients' tumors and PDXs from the same indications. As expected, we also observed co-clustering of tumors from indications that share exposure to a specific environmental or therapeutic genotoxic agent (e.g., tobacco smoke, chemotherapy, or radiation), or common pro-oncogenic genetic events associated with DNA damage repair alterations, such as homologous recombination repair, that can be detected in tumor samples across different indications. In addition to this, we found other signatures, associated with known, inferred or unknown etiology, detected across indications and affecting a limited number of tumors per indication. By combining the insights from these mutational signatures with the clinical data and the comprehensive pharmacological and molecular characterization of our models, including whole transcriptome, proteomics, and phospho-proteomics data, we evaluated the association of the tumors that harbor these signatures with tumor biology and clinical outcome. This approach led to the identification of mechanisms of action and biomarkers that might allow the identification of personalized therapies for patients with these tumors that are driven by similar mutational profiles, regardless of tumor indication.

#2851 YAP1-TFE3 fusion protein promotes EndMT in epithelioid hemangioendothelioma.

Ant Murphy, Sam Hartzler, Paula Carranza, Madison Yates, Nimod Janson, Shyaman Jayasundara, Majid Kazemian, **Jason A. Hanna**

Purdue University, West Lafayette, IN

Epithelioid Hemangioendothelioma (EHE) is an ultra-rare vascular cancer driven by chromosomal translocations resulting in the TAZ-CAMTA1 or YAP1-TFE3 fusion transcription factors. Despite some knowledge of the disease defining fusion proteins, the mechanisms driving tumorigenesis remain largely unclear. To study the effects of EHE fusion protein expression on the biology of endothelial cells, we generated EHE cell models using the murine endothelial cell line MS-1 and the human endothelial cell line HUVEC. Expression of TC and YT led to increased Hippo target gene expression, as expected. However, we observed a striking phenotype in YT-expressing endothelial cells associated with morphologic changes, enhanced migratory potential, and anchorage independence growth. These phenotypic changes are consistent with a process known as endothelial-to-mesenchymal transition (EndMT). EndMT is a physiological process where endothelial cells lose their endothelial identity and become more mesenchymal-like. Indeed, we observe transcriptional changes consistent with EndMT such as the reduction in expression of multiple endothelial-specific markers and a significant increase in transcription of mesenchymal marker, *Acta2.* We utilize several gain- and loss-of-function approaches to further investigate the mechanisms and impact of EndMT in tumorigenesis.

#2852 Mapping single cell spatial 3D genome landscape of localized and metastatic breast cancer sub-types.

Shyamtanu Chattoraj, Huy Nguyen, **Jude Dunne**

Bruker Spatial Genomics, San Jose, CA

Metastatic breast cancer is the most aggressive form of breast cancer leading to poor disease-free patient survival and accounting for 90% of all breast cancer-related deaths. The specific mechanisms that promote metastasis are not fully understood owing to the complex interplay between cancer cells and their surrounding microenvironment. This microenvironment involves clonal and sub-clonal heterogeneity in genomic, transcriptomic and protein signaling network across different cancer cell sub-populations. Understanding the molecular mechanism behind cancer metastasis demands state of the art single cell and spatial technologies that can provide deeper insight on disease progression.

Since, cancer is heavily influenced by genetic changes, the study of the 3D- genome organization in single cells helps to improve understanding of disease progression and prognosis. The genome is organized and packaged in a highly structured manner inside the nucleus of mammalian cells and exhibits dynamic reorganization throughout disease progression. Understanding this 3D organization at the single-cell level with high spatial resolution is crucial for disease research.

In this abstract, we present a novel jebFISH^{TM} protocol on the PaintScape^{TM} platform that can be used to understand differences in global 3D genome organization among several localized and metastatic breast cancer cell lines at single cell, sub-population and population level. Using a highly multiplexed genome wide panel of chromosomal targets, we will show disruption in chromosome territory, radius of gyration, chromosomal instability between localized and metastatic breast cancer cells at single cell and sub-population level. We will also show the signature of specific 3D genome structural alterations and interchromosomal interactions related to breast cancer metastasis compared to normal breast cells. In addition, we investigated differences in global 3D genome architecture of different breast cancer sub-types such as HER2 enriched vs triple negative breast cancer cells. We will show how different breast cancer sub-types carry specific chromosomal instability and differential interchromosomal interaction patterns at single cell, sub-chromosomal and sub-population level. We envision this study will improve our understanding on breast cancer disease progression and provide deeper insight into the underlying genomic heterogeneity of single cancer cells and sub-populations which might help to design better treatment options in the future. We propose that this study serves as proof-of-principle and is generalizable to other types of cancers where changes in 3D genome organization may occur at different cancer stages.

#2853 Engineered extrachromosomal oncogene amplifications promote tumorigenesis.

M. A. Yao[1], D. Pradella[1], M. Zhang[1], R. Gao[1], K. M. Gluchowska[1], Y. Cendon Florez[1], T. Mishra[1], G. La Rocca[1], M. Weigl[1], Z. Jiao[1], H. H. M. Nguyen[1], M. Lisi[1], M. M. Ozimek[1], C. Mastroleo[1], K. Chen[1], F. Grimm[1], J. Luebeck[2], S. Zhang[3], A. Zolli[1], E. G. Sun[1], B. Dameracharla[2], Z. Zhao[4], Y. Pritykin[4], C. Siegel[1], H. Y. Chang[3], P. S. Mischel[3], V. Bafna[2], C. R. Antonescu[1], A. Ventura[1];
[1]Memorial Sloan Kettering Cancer Center, New York, NY, [2]UC San Diego, La Jolla, CA, [3]Stanford University, Stanford, CA, [4]Princeton University, Princeton, NJ

Focal gene amplifications are among the most common cancer-associated mutations but have proven challenging to engineer in primary cells and model organisms. Here we describe a general strategy to engineer large (more than 1 Mbp) focal amplifications mediated by extrachromosomal DNAs (ecDNAs) in a spatiotemporally controlled manner in cells and in mice. By coupling ecDNA formation with expression of selectable markers, we track the dynamics of ecDNA-containing cells under physiological conditions and in the presence of specific selective pressures. We also apply this approach to generate mice harbouring Cre-inducible Myc- and Mdm2-containing ecDNAs analogous to those occurring in human cancers. We show that the engineered ecDNAs spontaneously accumulate in primary cells derived from these animals, promoting their proliferation, immortalization and transformation. Finally, we demonstrate the ability of Mdm2-containing ecDNAs to promote tumour formation in an autochthonous mouse model of hepatocellular carcinoma.These findings offer insights into the role of ecDNA-mediated gene amplifications in tumorigenesis. We anticipate that this approach will be valuable for investigating further unresolved aspects of ecDNA biology and for developing new preclinical immunocompetent mouse models of human cancers harbouring specific focal gene amplifications.

#2854 The role of NONO in genome stability: Implications for RNA-DNA hybrid accumulation, genomic instability, and inflammatory signaling.

Vikas Gaur, Sara Knowles, Weihang Chai

Center for Genetic Diseases, and Department of Microbiology and Immunology, Rosalind Franklin Univ. of Med. & Science, North Chicago, IL

Genomic instability, often resulting from replication stress and defects in DNA damage repair pathways, is a hallmark of cancer. The NONO protein, a multifunctional RNA-binding factor, plays a key role in DNA damage repair, transcriptional regulation and genome stability. Emerging evidence has linked NONO to cancer progression, though its mechanistic roles in maintaining genomic stability remain unclear. In our study, we demonstrate that NONO localizes at replication forks, as revealed by iPOND and SIRF assays, and interacts with replication polymerases. Loss of NONO in knockout (KO) cells leads to increased replication speed, significant RNA-DNA hybrid (R-loop) accumulation, and heightened genomic instability. These cells exhibit elevated micronuclei formation, abnormal chromosome segregation during metaphase, and increased 53BP1 foci, a marker of DNA double-strand breaks. NONO KO cells also show higher RPA loading under replication stress, highlighting their vulnerability to DNA damage. Additionally, the loss of NONO activates inflammatory response genes, including phospho-NFκB, p-IKKα, cGAS, and IRF3, suggesting that DNA-RNA hybrid accumulation and DNA damage may drive inflammatory signaling pathways. These findings position NONO as a critical regulator of genome stability, replication dynamics, and inflammation suppression. Our study highlights the essential role of NONO in maintaining genome integrity, interacting with replication machinery, and resolving R-loops. We will present ongoing work to further elucidate the mechanisms by which NONO contributes to genome stability and inflammatory responses in cancer cells.

#2855 CDK12 inhibition remodels DNA replication to drive selective gene amplification.

Shivani Yalala[1], Julia Kutz[2], Helmut Pospiech[2], Harri M. Itkonen[1]

[1]University of Helsinki, Helsinki, Finland,[2]Leibniz Institute on Aging - Fritz Lipmann Institute, Jena, Germany

Background and Objective: Transcription is controlled by phosphorylation of the C-terminal domain (CTD) of RNA Polymerase II (RNA Pol II). Cyclin-dependent transcriptional kinase 12 (CDK12) phosphorylates the CTD to sustain productive transcription elongation of long genes. Unexpectedly, because cancer cells typically exhibit high levels of transcription, CDK12 inactivation defines a subset of aggressive prostate cancers, which have a high number of gene amplifications in the absence of simpler mutations. Defects in transcription of specific genes and collisions between transcription and DNA replication machineries have been proposed as the source of this mutational signature. We hypothesize that DNA replication machinery and program are directly impacted by CDK12 inactivation, and some of the genes selectively amplified in the mutant tumors are required to sustain proliferation of these cells.
Methods: To assess the effects of CDK12 inactivation on DNA synthesis, we have measured nucleotide incorporation and relied on DNA combing assays. ChIP-seq experiments against the DNA replication machinery were used to probe the DNA replication program. Finally, proteomic-profiling of DNA replication machinery in the presence and absence of CDK12 inhibitor was used to evaluate the effects on its composition.
Results: CDK12 inhibition leads to defects in DNA replication as measured by nucleotide incorporation, which are explained, at least in part, due to replication fork stalling as determined using DNA combing assays. Integration of ChIP-seq data against the DNA replication machinery with data from CDK12 mutant prostate cancer patients revealed accumulation of the machinery on a specific sub-set of genes amplified in the patient samples. We termed this gene set as replication-defective and CDK12 mutant amplified (ReDeAmp). Mass spectrometry-based profiling of DNA replication machinery revealed significant remodeling in response to CDK12 inhibition. Currently, we are probing if the genes of the ReDeAmp-signature or the proteins accumulating to DNA replication machinery are essential for the proliferation of the CDK12-mutant cells.
Conclusions: Our data show that decrease in CDK12 activity disrupts DNA replication, which we propose explains the unique mutational signature observed clinically when CDK12 is inactivated. These findings further pose that selective gene amplifications are required in the CDK12-deficient cells. If this was the case, CDK12 inactivation would serve as a biomarker of sensitivity for the acquired synthetic lethality - this is currently under intense investigation in our laboratory.

#2856 Pks+ E. coli trigger intestinal stem cell plasticity and early onset colorectal cancer.

Stefanie Gerstberger[1], Melissa Lumish[2], Saskia Hartner[3], Farheen Shah[1], Seongmin Choi[1], Krystal Lum[4], Christopher Cowley[1], Anisha Luthra[1], Qingwen Jiang[1], Hyung Jun Woo[1], Ahmed Mahmoud[1], Henry Walch[1], Asha Saxena[1], Tavis J. Reed[4], Andrea Cercek[1], Rona Yaeger[1], Ileana Cristea[4], Andrew McPherson[1], Francisco Sanchez-Vega[1], Karuna Ganesh[1]

[1]Memorial Sloan Kettering Cancer Center, New York, NY,[2]University Hospitals Cleveland Medical Center, Cleveland, OH,[3]McGill University, Montreal, QC, Canada,[4]Princeton University, Princeton, NJ

Escherichia coli (E.coli) strains carrying the polyketide synthase (pks) island produce the genotoxin colibactin associated with pathogenesis of colorectal cancer (CRC). The colibactin polyketide induces DNA damage through direct alkylation of DNA, which leads to characteristic mutational A-T rich signatures in the genome (SBS28 and SBS88) that can be identified by whole genome sequencing (WGS). Since WGS is not routinely used clinically, we developed an approach to specifically identify SBS-pks using a clinical targeted exon capture assay, MSK-IMPACT. In an institutional pan-cancer clinical cohort of 78,905 tumors we identified 15,967 samples with >20 mutations detected by MSK-IMPACT. We identified 149/1845 samples with microsatellite stable CRC with >10% mutations attributable to SBS-pks. Examining clinicopathologic and genomic features of SBS-pks+ compared to SBS-pks- CRC tumors, we find that SBS-pks+ signatures are significantly enriched in younger age of onset compared to SBS-pks- CRC patients (median age 52 vs 57, p=0.00059). While global genomic features and oncogenic pathways are similar, we find that the APC:c835-8A>G splice site mutation is overrepresented in SBS-pks+ tumors with 21.7% enrichment compared to 4.99% in SBS-pks- tumors, even further enriched in young onset SBS-pks+ CRC (27% <50 y, 31% <45 y, p<0.0001). To mechanistically investigate colibactin-associated damage we developed a novel long-term human colon organoid-microbe co-culture model system that takes advantage of reversal of polarity in suspension culture. WGS of human CRC organoids co-cultured for three months with pks+ and delta-pks E.coli NC101 confirmed induction of SBS-pks signatures, validating the model. 48h acute exposure to pks+ E.coli upregulates DNA replication and DNA damage repair (DDR) pathways coupled with cell cycle stalling in S phase with activation of ATM/ATR, indicative of replication stress. Strikingly, pks+ E.coli exposure drives a phenotypic shift of tumor and normal epithelial cells into an intestinal stem cell (ISC) state, with pks+ exposed cells demonstrating increased regeneration and proliferation, while thermal proximity coaggregation-MS analysis of protein complexes reveals global chromatin remodeling changes. Thus, our findings suggest that colibactin SBS signature is associated with young onset CRC and that the colibactin genotoxin phenotypically promotes cells to enter a proliferative intestinal stem cell states as precursors to CRC carcinogenesis. Correlating our clinicogenomic findings of an increased pks+ signature presence in young onset patients, we propose a model of colibactin injury in which younger, DNA replication and repair proficient cells are able to overcome colibactin-associated DDR stress, while aged colonic cells exit DDR stress through cell cycle arrest and apoptosis, resulting in the overall observed enriched genomic colibactin signature in young onset CRC.

#2857 Genomic Analysis of UV-induced Mutations in Normal Skin Cells of Dark and Light-skinned Individuals.

Rojina Nekoonam, Aravind K. Bandari, Delahny Deivendran, Bishal Tandukar, Harsh Sharma, Alan H. Shain

Dermatology, University of California San Francisco, San Francisco, CA

Objectives/Goals: Despite the documented link between UV exposure and skin cancer, the role of pigmentation in preventing skin carcinogenesis is not fully understood. This project aims to investigate how pigmentation influences the earliest stages of skin cancer development by examining the genomic landscape in skin cells across individuals of diverse skin tones, which will uncover potential differences in susceptibility and mutation patterns.

Methods/Study Population: We collected skin biopsies from various body sites exposed to different levels of habitual sun exposure. Next, we cultured individual skin cells, including keratinocytes, melanocytes, and dermal fibroblasts, ex vivo to form small colonies of daughter cells. We extracted DNA and RNA from these colonies and amplified the nucleic acids in vitro. Subsequently, we sequenced the expanded clones at exome-level resolution. For our study, we collected samples from seven dark skin donors ranging in age from 35 to 83 years. For comparison, we also analyzed mutations in skin cells from 33 donors with light skin tones, who served as the control group.

Results: Our preliminary analysis of the existing data suggests expected trends. The average mutation burden in individuals with light skin tones was 4.967 Mut/Mb, whereas in those with dark skin tones, it was only 1.609 Mut/Mb. These findings align with the prevailing hypothesis that melanin acts as a protective factor against skin cancer, as it appears to reduce the mutagenic effects of UV radiation. There is evidence to suggest that individuals with darker skin may have fewer cumulative mutations, possibly decreasing their risk of skin cancer. One limitation of our study is that we are underpowered to draw definitive conclusions, as we had to group specific anatomical sites and lacked data from all skin cell lineages across all sites. Despite this, our results revealed variations in mutational burdens between different anatomical locations, with higher burdens observed in areas subjected to greater UV exposure. These findings suggest a potential link between UV exposure and mutational load. To build on our current findings, we plan to increase the sample size and refine our control over site and cell lineage factors to enhance the strength of our results.

Conclusion/Implications: Understanding how skin tone affects the risk of skin cancer is imperative for gaining a deeper insight into the mechanisms driving cancer development across diverse populations. While individuals with darker skin tones are less commonly diagnosed with skin cancer, they often experience more advanced stages at diagnosis due to delayed recognition of symptoms. By understanding the differences in mutational patterns and the role of UV exposure in darker skin, we can improve early detection and treatment strategies for this underserved group and refine screening and prevention methods for lighter-skinned individuals who are at higher risk.

#2858 Pleiotropy of experimental signatures across species and model systems.

Maria Zhivagui[1], Shams Al-azzam[2], Mark Barnes[2], Ludmil B. Alexandrov[2]

[1]School of Medicine, University of Nevada Las Vegas, Las Vegas, NV,[2]Moores Cancer Center, University of California San Diego, San Diego, CA

Mutational signatures in cancer genomes provide crucial insights into the etiology and progression of malignancies. While numerous signatures have been identified, many lack known causes, hindering our understanding of cancer development. This study presents a comprehensive analysis of mutational patterns induced by diverse environmental agents across multiple model systems. We compiled data from over 4,000 genome-wide sequencing experiments, exposing various biological models—including human cell lines, rodent tumors, avian cells, and C. elegans—to more than 120 different agents under controlled conditions. By comparing mutational profiles across 30+ model systems, we identified significant inter-model disparities, underscoring the importance of diverse experimental approaches in confidently characterizing mutational signatures observed in human cancers. Our findings enhance the interpretation of clinical and epidemiological data related to specific carcinogen exposures and provide a robust framework for elucidating the role of environmental factors in cancer etiology. This research contributes to a more nuanced understanding of the complex interplay between environmental exposures, genetic susceptibility, and cancer development, potentially informing novel prevention strategies and therapeutic interventions.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Antibody-Based Cancer Therapeutics 2
Poster Session

#2862 Anti MSLN ADC RC88 engages unique binding to target positive tumor cells with less interference from the soluble MSLN protein.

Lili Wang[1], Yidan Xu[1], Mingyang Li[1], Kailin Wang[1], Xiao Wang[1], Xiaoping Zhang[1], Zhanjiao Yu[1], Yinghao Xin[1], Chenglin He[1], Xiangyi He[1], Xiaoshan Min[2], Hang Chen[2], Min Li[1], Zhulun Wang[2], **Dong Li**[3], Yuanhao Li[1]

[1]RemeGen Co., Ltd., Yantai, China,[2]RemeGen Biosciences,Inc., South San Francisco, CA,[3]RemeGen (Shanghai) Co.,Ltd, Shanghai, China

Background: Mesothelin (MSLN) is a cell surface protein in various cancers, including ovarian, pancreatic and malignant mesothelioma. Soluble mesothelin (sMSLN) can be detected in the circulation of patients and may reduce the efficacy of antibody drugs targeting surface MSLN. Acting as a decoy receptor, sMSLN competes for binding or neutralizes the drug, affecting antibody properties. This study examined the anti MSLN antibody-drug conjugate (ADC) RC88, focusing on its ability to target cancer cells and the interference caused by sMSLN, thereby highlighting its competitive advantage over other drugs in clinical studies.
Methods: RC88, a novel anti MSLN ADC developed by RemeGen, is in phase I/II trials for advanced solid tumors, either as monotherapy (NCT04175847, NCT06173037) or in combination therapy (NCT05804526). We compared RC88 with other anti MSLN antibodies from relevant trials by antigen and cell binding assays. To show the unique binding of RC88, we treated cellular MSLNs in various conditions to mimic *in vivo* pathological environments. Additionally, we expressed a truncated MSLN fragment in 293 cells to focus on the C-terminal region near the cell membrane for binding comparisons.
Results: Our analysis revealed the distinctive properties of RC88 that may provide clinical advantages. RC88 had a strong primary binding site in the N-terminal domain and a weaker secondary site in the C-terminal region. The primary binding site at amino acids 317-352 was characterized by cross-linking mass spectrometry and mutagenesis. This epitope also facilitates CA125 binding, and RC88 effectively blocks CA125 from binding to MSLN. The secondary binding site located in the C-terminal stem region (amino acids 577-606) was less prominent and appeared to enhance tumor cell binding of RC88. Although further studies are required to refine the location of this secondary site, RC88 demonstrated its ability to bind and induce ADC-mediated cell death in cells expressing the C-terminal fragment of MSLN, a response not seen with other anti MSLN antibodies. When comparing cell binding in the presence of sMSLN, RC88 showed stronger cancer cell binding than others.
Conclusions: Our findings show RC88 has unique binding kinetics to different MSLN regions, with a dominant N-terminal binding site by rigorous methods. RC88 displayed superior binding to MSLN-positive cancer cells than other anti MSLN antibodies and maintained effectiveness despite sMSLN interference. Its stronger binding to the C-terminal MSLN fragment compared with other antibodies further underscores its targeting potential in tumor cells. Given its distinctive binding properties, RC88 may bring enhanced clinical benefits for treating MSLN-positive cancers, even with sMSLN and various truncated forms of MSLN in tumor cells. Therefore, RC88 is likely to have greater clinical benefits than other MSLN ADCs in clinical studies.

#2863 TAVO307, a novel ADC targeting CDH17, for the therapy of gastrointestinal cancers.

Guangmao Mu[1], Fulai Zhou[1], Zhengxia Zha[1], Sheng Huang[1], Ying jin[1], Yuanting Chen[2], Mark Chiu[2], **Di Zhang**[2]

[1]Tavotek Biotherapeutics, Suzhou, China,[2]Tavotek Biotherapeutics, Lower Gwynedd, PA

Background: Gastrointestinal (GI) cancers account for about 28% of all cancers globally, however, the treatment options remain limited partly due to the lack of appropriate cancer targets. Cadherin-17 (CDH17) is a cell adhesion membrane protein predominantly expressed at the tight junctions of intestinal epithelial cells of healthy individuals. However, the aberrant expression of CDH17 in 50-90% of GI tract tumors (including stomach, pancreas, liver/bile duct and colon cancers) is associated with poor prognosis and shorter survival of GI cancer patients. In these tumors, CDH17 interacts with α2β1 integrin to drive the proliferation, adhesion, and metastasis of tumor cells. Such overexpression of CDH17 makes it an attractive target for the developing novel treatments of GI tract cancers.
Methods and Results: We discovered an anti-CDH17 antibody with high binding affinity to CDH17 with an EC50 at sub nM range. We prepared an ADC molecule loaded with the anti-mitotic toxin MMAE/MMAF via a lysosomal cleavable dipeptide linker. CDH17-ADC showed potent cytotoxicity (IC50 at sub nM level) to multiple GI and pancreatic cancer cell lines in *in vitro* cell cytotoxicity assays. In addition, CDH17-MMAE (DAR=4) treatment led to potent tumor growth inhibition (70% to 95% TGI) in multiple CDX and PDX pancreatic, colon, and gastric cancer xenograft models. The mice in the CDH17-MMAE treatment group maintained normal body weight throughout the treatment course without observed toxicity.
Conclusions: Targeting CDH17 in GI tract cancers, our lead CDH17-MMAE molecule (TAVO307) showed potent tumor cell cytotoxicity in multiple tumor cell lines in cytotoxicity assays as well as in CDX and PDX tumor models. Further preclinical safety assessment, pharmacokinetics and IND-enabling studies are on-going with the goal to develop TAVO307 as the “best-in-class” ADC molecule for the treatment of colon, gastric, pancreatic and oesophagus cancers with significant unmet medical needs. This antibody can also be applied to alternative targeting modalities.

#2864 DXA023-G017, a bispecific PD-1/VEGF conjugate elicits potent anti-tumor efficacy in preclinical studies.

Xiaobo Cai, Wei Zheng, Junxiang Jia, Shishan Hu, Hui Xia, Qingliang Yang, Zhixiang Guo, Wei Liu, Lu Bai, Jun Zheng, Wenjun Li, Yuanyuan Huang, Zhongliang Fan, Binbin Chen, Meng Dai, Robert ZHAO

Hangzhou DAC Biotechnology Co., Ltd., Hangzhou, China

Background: Programmed cell death protein 1 (PD-1) and vascular endothelial growth factor (VEGF) are often co-expressed in the tumor microenvironment. VEGF not only promotes tumor vessel normalization but also effectively alleviates immunosuppression, thereby enhancing the infiltration and activation of immune effector cells. The synergistic effect of combining immunotherapy with anti-angiogenic agents (anti-PD-1 in combined with anti-VEGF) has been validated in the clinical treatment of advanced non-small cell lung cancer (NSCLC). Although Ivonescimab, a PD-1/VEGF bispecific antibody, has exhibited a notable prolongation of progression-free survival (PFS) versus Keytruda in individuals with PD-L1-positive NSCLC, the impact on overall survival (OS) necessitates further validation. Furthermore, the combination of Ivonescimab with chemotherapy has demonstrated more extensive antitumor efficacy compared to Ivonescimab monotherapy. Consequently, a chemotherapeutic drug conjugates to the anti-PD-1/VEGF bispecific antibody with functional linker may represent a novel and promising strategy for enhancing clinical outcomes. DXA023, the bispecific antibody, possesses a tetravalent structure similar to Ivonescimab, demonstrated both efficacy and safety against both PD-L1 and VEGF targets. DXA023 was conjugated to a small molecule/functional linker complex, G017 to form a PD-1/VEGF conjugate (DXA023-G017), which holds promise for further enhancing antitumor activity.
Methods: The antigen binding activities of DXA023 to PD-1 and VEGF were evaluated using ELISA and ForteBio assays. The protein binding affinities of both DXA023 and DXA023-G017 to PD-1 and VEGF were assessed by ELISA. The blockade of the PD-1/PD-L1 signaling pathway was determined using a luciferase reporter cell assay. Cell proliferation inhibitory assay was used to test in-vitro pharmacology of DXA023 and DXA023-G017. In vivo anti-tumor activities of DXA023 and DXA023-G017 were studied in an HCC827 tumor mouse model reconstituted with human peripheral blood mononuclear cells (PBMCs).
Results: DXA023 exhibits specific and high-affinity binding to human PD-1 and VEGF. The AAS mutations introduced significantly reduces FcγR binding, thereby effectively diminishing the antibody's ADCC effect, while still maintaining FcRn affinity. Both DXA023 and DXA023-G017 effectively block the PD-1/PD-L1 signaling pathway and demonstrate notable in-vitro antitumor activity. Furthermore, DXA023-G017 exhibits superior antitumor efficacy compared to DXA023 in the HCC827-PBMC mouse model.
Conclusions: DXA023-G017, a dual-blocking anti-PD-1/VEGF bispecific conjugate, demonstrates impressive antitumor efficacy in a mouse tumor model, providing robust support for its clinical development as a treatment for various advanced solid tumors.

#2866 An innovative T cell engager platform with optimized CD3 affinity and formats for targeting hematologic and solid tumors.

Cuicui Guo, Yu Pang, Zhen Han, Fenglin Yun, Ao Li, Hai Wu, Xun Gui

Mabwell (Shanghai) Bioscience Co., Ltd., Shanghai, China

Background: T-cell engagers (TCEs) are a promising class of immunotherapies that bridge T cells to tumor cells, triggering T-cell activation and subsequent tumor cell cytotoxicity. While TCEs demonstrated substantial efficacy in hematologic malignancies, their clinical benefit in solid tumors remains less established. The development of effective TCEs is hindered by challenges related to the complex interplay between CD3 affinity, TCE format, tumor-associated antigen (TAA) density, and specificity. To address these challenges, we have developed an innovative TCE platform designed to optimize CD3 affinity and TCE format to better match TAA expression profile and improve therapeutic efficacy.
Methods: Humanized CD3 and TAA-targeting antibodies were generated by Mabwell's integrated novel antibody discovery system. CD3 activity was assessed through T-cell binding and activation assays, while TAA binding potency was measured using tumor cell binding assays. Various bispecific and trispecific TCE formats were evaluated and optimized for developability, stability, and functional activity. Tumor-directed cytotoxicity (TDCC) assays were used to assess the efficacy of TCEs *in vitro*, while cytokine release syndrome (CRS) potential was also evaluated.
Results: CD3 parental antibodies with varying T-cell binding and activation potencies, including cross-reactivity with monkey CD3, were generated. TAAs were identified and prioritized using a bioinformatics analysis system, leading to the selection of tumor-specific targets such as LILRB4, CLL-1, CLDN6, MUC16, MSLN, CDH17, GUCY2C, SEZ6, DLL3, and ENPP3. Several optimized 1+1, 1+2, and 2+2 TCE formats were developed, demonstrating excellent developability and potent *in vitro* tumor cell killing. Importantly, these TCEs exhibited minimal cytokine release syndrome (CRS) potential. Our platform also integrates comprehensive indication analysis, target validation, and TCE format optimization, facilitating the identification of multiple TAAs across a broad range of cancer types.
Conclusion: Our innovative TCE platform offers a flexible and powerful approach for designing TCEs with enhanced efficacy and minimal CRS. This platform holds significant promise for developing novel T-cell engagers with robust therapeutic activity and favorable safety profiles for both hematologic and solid tumor indications.

#2868 Preclinical evaluation of LM-350: An innovative anti-CDH17 antibody drug conjugate for gastrointestinal cancer therapy.

Wentao Huang, Jin Li, Xia Qin, Da Fei, **Runsheng Li**

LaNova Medicines Limited, Shanghai, China

Background: Cadherin 17 (CDH17) is a membrane cell adhesion protein selectively expressed in gastrointestinal cancers, including colorectal (CRC), gastric (GC), and pancreatic cancers (PC). Its expression in normal intestinal epithelial cells is limited. LM-350, a CDH17-targeted antibody-drug conjugate (ADC), is composed of a humanized monoclonal antibody (LM-150) conjugated to the next-generation topoisomerase I inhibitor LDX2 via a cleavable linker, with a drug-antibody ratio of 8.

Methods: Target binding activity, specificity, and cross-species reactivity of LM-350 was evaluated by flow cytometry. Internalization was evaluated using an acidic pH-sensitive dye, with fluorescence signal detection via flow cytometry. Cytotoxicity and bystander effects were evaluated using the CellTiter-Glo luminescent cell viability assay. *In vivo* anti-tumor activity of LM-350 was evaluated in CDH17-positive CRC and GC cell line-derived xenografts (CDX) and patient-derived xenografts (PDX). Immunohistochemistry was used to assess CDH17 expression in tumor tissues.

Results: LM-350 demonstrated concentration-dependent binding to CDH17-expressing human CRC and GC cells, with EC_{50} values ranging from 0.13 to 0.94 nM, which was comparable to the un-conjugated monoclonal antibody LM-150. LM-150 exhibited high specificity and binding affinity to monkey CDH17 but not to rodent CDH17. In addition, LM-350 induced concentration and time dependent cellular internalization and potent cytotoxic effects in CDH17-positive cells. *In vivo*, LM-350 treatment at doses of 3 or 6 mg/kg significantly inhibited or regressed tumor growth in multiple CRC and GC xenograft models, with tumor growth inhibition rates ranging from 70% to 129%.

Conclusion: The novel ADC LM-350 targeting CDH17 exhibited potent anti-tumor activity *in vitro* and in CRC and GC xenograft models. LM-350 demonstrated high therapeutic potential in CDH17-positive gastrointestinal cancers, particularly in CRC and GC.

#2869 DXC014, a novel bispecific ADC targeting B7-H3 and PSMA, demonstrates favorable antitumor efficacy and safety profiles in preclinical evaluations.

Huihui Guo, Zhicang Ye, Yuanyuan Huang, Weibin Li, Qingliang Yang, Hangbo Ye, Junxiang Jia, Jun Zheng, Yongxiang Chen, Xiafen Wu, Yunxia Zheng, Binbin Chen, Meng Dai, Naiyan Yang, Gaituo Chen, Li Chen Chen, Xiaolei Liu, Junpeng Wang, Yi Luo, Xiaoqiang Xie, Xia Zhou, Lu Bai, Miaomiao Chen, Wenjun Li, Xiang Cai, Wei Liu, Robert Y. Zhao

Hangzhou DAC Biotechnology Co., Ltd, Hangzhou, China

B7-H3 (also known as CD276), a member of the B7 ligand family, is overexpressed on differentiated malignant cells and cancer-initiating cells, with limited heterogeneity, and high frequency (60% of 25,000 tumor samples), such as the cells of prostate cancer, non-small cell lung cancer (NSCLC), melanoma, bladder cancer, breast cancer, clear cell renal carcinoma, and head and neck squamous cancer cell (HNSCC), but scarcely detected in normal tissues. PSMA is highly expressed in prostate cancer cells and the endothelial neovasculature of several solid human malignancies. High PSMA expression is an independent biomarker of poor prognosis throughout the course of prostate cancer and across anatomical sites. Normal human tissues, including prostate epithelium, small intestine, renal tubules, and salivary glands, demonstrate considerably lower levels of PSMA expression than prostate cancer. DXC014 is an innovative bispecific antibody-drug conjugate (ADC) targeting both B7H3 and PSMA, utilizing a topoisomerase I inhibitor as its payload. This dual-target design aims to enhance therapeutic efficacy across a wide range of solid tumors, in particular, for prostate cancers. In vitro studies demonstrated that DXC014 binds to B7H3 and PSMA with high specificity and affinity, enabling precise targeted cytotoxicity. DXC014 induces DNA damage in cancer cells while exhibiting a significant bystander effect, and thus kills both target-positive cells and surrounding target-negative cells. Furthermore, DXC014 exhibited broad cytotoxic activity across various cancer cell lines, including prostate cancer and small-cell lung cancer cells with different levels of target expression. Overlapping pharmacokinetic profiles of both ADC and total antibody indicated excellent linker stability. DXC014 was well-tolerated at doses up to 300 mg/kg in mice and 40 mg/kg in repeat-dose studies in cynomolgus monkeys. In xenograft models, including C4-2B, 22RV1, and SHP77 models, DXC014 showed superior or comparable antitumor efficacy to Dxd conjugate at equivalent doses. These findings underscore the therapeutic potential of DXC014 as a dual-targeting ADC for the treatment of various solid tumors. Its innovative design and excellent preclinical performance position DXC014 as a promising candidate for further clinical development.

#2870 Enhancing Topo1i ADC efficacy: development of homogeneous dual-payload ADCs combining Topo1i with microtubule inhibitors or PARP inhibitors.

Gang Yin, Daniel Calarese, Alice Yam, Werner Rubas, Krishna Bajjuri, Xiaofan Li, Helena Kiefei, Miao Wen, Guifen Xu, Abigail Yu, Hans-Peter Gerber

Sutro Biopharma, Inc., South San Francisco, CA

There is a critical need to safely enhance the potency of antibody-drug conjugates (ADCs) for targeting low-expression and heterogeneous tumors, as well as to overcome drug resistance and relapse. Cancer cells often develop resistance to single-agent therapies, making it essential to explore combination approaches. One promising strategy presented in this work is combining two payloads with different mechanisms of action (MOA) into a single ADC, creating dual-payload ADCs. Clinical data have shown that if resistance develops to a topoisomerase I inhibitor (Topo1i) ADC, it will also result in resistance to a Topo1i ADC administered sequentially, regardless of the target antigen. This implies that anti-tumor activity of Topo1 ADCs is limited by formation of resistance towards the payload (cross-payload resistance). In contrast, switching to a payload with different MOAs, such as transitioning from Topo1i to microtubule inhibitor or vice versa, can help to restore the effectiveness of ADCs. The combination study of sacituzumab govitecan and enfortumab vedotin has clinically validated the concept of concomitant administration of a Topo1i payload with a microtubule inhibitor (MTi) payload to increase response rates without significantly increasing toxicity. Dual-payload ADCs that combine Topo1i and MTi agents are specifically designed to maximize their anti-tumor activity by overcoming resistance and broadening the therapeutic potential. Another promising dual-payload strategy involves combining PARP inhibitors (PARPi) with Topo1i, as PARP plays a critical role in repairing DNA damage induced by Topo1i. Such a Topo1i/PARPi dual-payload ADC has the potential to improve anti-tumor activity while avoiding toxicities commonly associated with conventional PARPi chemotherapy, due to the lack of targeted delivery. By leveraging Sutro's cell-free expression platform and its precise dual conjugation technology, we fine-tuned the drug-to-antibody ratio (DAR) and dual payload ratios to achieve optimal synergy between the two MOAs. The homogeneous, dual-payload ADCs demonstrate desirable physicochemical properties, enabled by the careful selection of conjugation sites and a best-in-class hydrophilic β-glucuronide linker. These design features also resulted in favorable pharmacokinetics and stability of dual-payload ADCs. Using this approach, we identified superior anti-tumor activities against low-antigen and Topo1 ADC-resistant tumor models treated with dual-payload ADCs compared to mono-payload ADCs. Furthermore, the dual payload approach streamlines preclinical, clinical development and the manufacturing process compared to the parallel development of two mono-payload ADCs.

#2871 Comparative anti-tumoral efficacy of endoglin-targeting ADCs harbouring different payloads for the treatment of gastric cancer.

Isabel Egana[1], **Patricia Gonzalez-Callejo**[1], Alvaro Gonzalez[1], Cristina Ferrer[1], Roland Kontermann[2], Oliver Seifer[2], Klaus Pfizenmaier[2], Myriam Fabre[1]

[1]Oncomatryx Biopharma, S.L., Derio, Spain,[2]Institute of Cell Biology and Immunology, Stuttgart University, Stuttgart, Germany

Endoglin (CD105), a TGFb-RII co-factor, overexpressed in tumor microvasculature and endothelial-derived CAFs, has been extensively validated as a therapeutic target for cancer treatment. Endoglin-targeting ADCs have been developed in this work, using a human IgG1 antibody, OMTX003, conjugated to different microtubule inhibitors such as eribulin (OMTX603-3) or MMAE (OMTX103), with DAR values between 4 and 8. Target binding was maintained within subnanomolar values for each ADC, similar to the unconjugated antibody. Internalization was efficient, with 75% intracellular localization within 60 minutes, regardless of the conjugated payload. *In vitro* activity in Endoglin-expressing HT1080 cells was target- and concentration-dependent, with IC50 values of 6 and 95.5pM, respectively. ADCs were tested for their *in vivo* anti-tumor efficacy in a gastric cancer PDX murine model. Complete tumor regression was observed. No re-growth occurred up to 40 days after treatment end, showing the lack of resistance to treatment. ADCs were well tolerated with no weight loss. These encouraging results are postulating these anti-ENG ADCs for further development.

#2872 DXC018: A novel HER2 dual-payload bispecific ADC with promising potential for gastrointestinal cancers and other solid tumors.

Huihui Guo, Yong Du, Yuanyuan Huang, Juan Wang, Qingliang Yang, Junxiang Jia, Jun Zheng, Hangbo Ye, Fang Du, Meng Dai, Hui Xia, Xiaoxiao Chen, Xingyan Jiang, Ziyu Zhao, Wei Liu, **Robert Yongxin Zhao**

HANGZHOU DAC BIOTECHNOLOGY CO., LTD, Hangzhou, China

HER2 (human epidermal growth factor receptor 2) is a transmembrane tyrosine kinase receptor critical for cell growth and differentiation. As a pivotal therapeutic target, HER2 has been extensively investigated in ADC drug development, resulting in numerous innovative designs along with approval in recent years. Among these, dual-payload ADCs, particularly those utilizing small molecules with distinct mechanisms of action, represent a promising yet still evolving area of research. DXC018 is a novel HER2-targeting bispecific antibody-drug conjugate (ADC) featuring dual epitope binding and dual payload delivery. The bispecific feature of DXC018 to bind HER2 domains II and IV with high affinity, enables its target specificity and therapeutic efficacy. Its payload, comprising an antimetabolite inhibitor and a topoisomerase I inhibitor, effectively induces DNA damage and cytotoxic effects. Pharmacokinetic studies in mice revealed favorable properties, with overlapping pharmacokinetic profiles for the ADC and total antibody, indicating excellent linker stability. Toxicological evaluations confirmed its tolerability at doses up to 300 mg/kg. In xenograft models of human cancer cells, including NCI-N87, JIMT-1, and CFPAC-1 cells, DXC018 exhibited superior or comparable antitumor activity to Dxd conjugate at equivalent doses. These findings suggest that DXC018, by leveraging dual HER2 binding and the complementary mechanisms of the antimetabolite and the topoisomerase I inhibition, offers significant therapeutic potential for the treatment of gastrointestinal malignancies and the other solid tumors. This innovative dual-action design establishes DXC018 as a promising next-generation ADC to address unmet needs in gastrointestinal cancers.

#2873 Preclinical development of SMP-656: An eribulin-SuperHydra^{TM} linker based ADC.

Jinkun Huang, Chenglong Wu, Chaoyang Feng, Xiaojie Heng, Tingting Yang, Rang Gao, Tianyi Ke

Xiling Lab Co., Ltd., Chengdu Sichuan, China

Background: To date, 15 ADCs have been globally approved, 9 of which employ Michael addition reactions between maleimide and the free thiol groups of antibodies. This reaction is characterized by high selectivity, mild conditions, and rapid kinetics. However, the retro-Michael addition reaction in vivo can reverse this process, leading to payload detachment, which compromises the drug's efficacy and safety. The SuperHydra^{TM} linker promotes maleimide ring-opening via ortho effects, preventing retro-Michael deconjugation and enhancing ADC stability. Consequently, ADCs with the SuperHydra^{TM} linker demonstrate remarkable efficacy, safety, and better stability as represented by our clinical stage candidate, SMP-656, a HER2-eribulin ADC.

Methods: SuperHydra™ linkers were designed with varying ortho groups, distances, and pro-hydrolysis group optimizations. A medium hydrolysis-rate linker was chosen for SMP-656 to balance stability during CMC stages with controlled hydrolysis in circulation, ensuring ADC homogeneity. Comparative studies of SMP-656 vs. DS-8201a were performed in vitro and in vivo. Additionally, we evaluated SMP-656's cytotoxicity against DS-8201a-induced resistant cells and cells overexpressing the DXd efflux pump. Bystander effects, critical for DS-8201a efficacy, were assessed for SMP-656. Repeat-dose PK and toxicology studies in non-human primates provided PK data and HNSTD.

Results: SMP-656 demonstrated significantly higher efficacy than DS-8201a in various cancer cell lines, including DS-8201a-resistant gastric cancer and HER2-low breast cancer cells. It retained potency in resistant models where DS-8201a was ineffective, highlighting its potential for treating resistant and HER2-low patients.In vivo studies showed that SMP-656 achieved higher tumor growth inhibition rates than DS-8201a, with only half the DAR and one-third the dosing amount. This translates to superior tumor inhibition with one-sixth the toxin dosage, highlighting its enhanced safety profile. In NCI-N87 xenografts model, SMP-656 extended tumor inhibition to 62 days at an equivalent payload dose 0.08 mpk (single dose), compared to DS-8201a's 23 days. SMP-656 also demonstrated significant bystander effects, addressing tumor heterogeneity.Repeat-dose PK studies showed high concordance between ADC and total antibody concentration curves, confirming SuperHydra^{TM} linker stability. Additionally, SMP-656 achieved an HNSTD of 10 mpk, representing the highest safety profile among eribulin-based ADCs known to date.

Conclusions: The SuperHydra^{TM} linker enabled SMP-656 to combine superior stability, efficacy, and safety with the ability to overcome DS-8201a resistance. SMP-656 represents the safest and most effective eribulin-based ADC and is currently in Phase I clinical trials, showing promising tolerability and efficacy.

#2874 ZW327, a novel Ly6E-targeting antibody-drug conjugate bearing a topoisomerase 1 inhibitor payload.

Dunja Urosev, Saki Konomura, Michael Lee, Germanna Righetto, Elizabeth Porter, Katina Mak, Ambroise Wu, Amos Chua, Linglan Fu, Diego Alonzo, Spencer Boisjoli, Edward Lau, Janice Tsui, Vidhi Khanna, Alex Wu, Devika Sim, Mark E. Petersen, Jamie R. Rich, Stuart D. Barnscher

Zymeworks Inc., Vancouver, BC, Canada

Ly6E (lymphocyte antigen 6 family member E) is a GPI anchored cell surface protein frequently expressed in a number of cancers such as TNBC, NSCLC, HNSCC, ESCC, OVCA, and PDAC, with minimal presence in normal tissues. ZW327 is an antibody-drug conjugate (ADC) targeting human Ly6E, composed of a humanized IgG1 antibody bearing Fc-silencing mutations, conjugated to a novel camptothecin-based topoisomerase 1 inhibitor, ZD06519, via a maleimide anchor and a glycyl glycyl phenylalanyl glycine (GGFG)-aminomethyl (AM) cleavable linker with DAR8. The antibody was discovered from animals immunized with Ly6E HEK293 transfected cells, utilizing proprietary B-cell culture-based technology followed by humanization. Antibody binding to human and cynomolgus monkey Ly6E was evaluated by KinExA^{TM} and flow cytometry. To understand therapeutic potential of ZW327, antibody internalization was assessed by flow cytometry in several Ly6E-expressing tumor cell lines and *in vitro* cytotoxicity of ADC was assessed in tumor spheroids using a panel of breast, lung and other tumor cell lines. Tumor spheroid penetration of ZW327 was also investigated, as well as tumor cell co-culture assays performed to assess bystander-mediated cell killing by ZW327. Developability was assessed utilizing methods such as, NS-ELISA, AC-SINS, cIEF, LC/MS and UPLC-SEC, under normal and stressed conditions. Anti-tumor activity of ZW327 and PK were investigated in a number of xenograft mouse models representing a range of Ly6E-expression. ZW327 antibody was successfully humanized and demonstrated low nanomolar binding affinity to both human and cynomolgus monkey Ly6E, as well as strong binding to target-expressing tumor cell lines. Robust internalization of ZW327 antibody was observed in Ly6E-expressing tumor cell lines, as well as spheroid penetration and ADC exhibited potent and target-specific cytotoxicity in a panel of breast, lung and other tumor cell spheroids. The antibody binding, internalization and spheroid penetration were all superior to the hu9B12.v12 clinical benchmark antibody and ZW327 exhibited pronounced cytotoxicity when compared to DLYE5953A clinical benchmark ADC. ZW327 showed good bystander-mediated killing of Ly6E-negative cells when co-cultured with target positive tumor cells. A single administration of ZW327 resulted in tumor regression across xenograft models and demonstrated a favorable PK profile. Overall, these results support the potential of ZW327 as a novel therapeutic agent against Ly6E-bearing cancers.

#2875 IL1RAP-targeting antibody-drug conjugate: a novel therapeutic targeting both tumor cells and the tumor microenvironment.

Elin Jaensson Gyllenback[1], Camilla Rydberg Millrud[1], Olga Ab[2], David Liberg[1]

[1]Cantargia AB, Lund, Sweden,[2]AbbVie, Waltham, MA

Background: Overexpression of Interleukin-1 receptor accessory protein (IL1RAP) has been linked to various malignancies, including acute myeloid leukemia, renal, urothelial and ovarian cancer as well as pancreatic ductal adenocarcinoma and non-small cell lung cancer, making it a promising therapeutic target. Expression on tumor cells, as well as throughout the tumor microenvironment, including expression on cancer associated fibroblasts, cancer endothelium and suppressive infiltrating immune cells sets it apart from most existing antibody-drug conjugate (ADC) targets. Here, an IL1RAP-targeting ADC was developed, consisting of a monoclonal antibody conjugated via a linker to a potent cytotoxic payload, designed to selectively deliver the cytotoxic agent to IL1RAP-expressing cells. The ADC was tested *in vitro* and *in vivo* to evaluate its therapeutic potential.

Methods: A library of IL1RAP-binding clones was screened for affinity, cell binding, cynomolgus cross-reactivity and internalization. The selected antibody was conjugated to a maytansinoid using a cleavable linker. *In vitro* cell killing was assessed using SK-MEL5 WT and SK-MEL5 IL1RAP KO cells. The anti-IL1RAP ADC was tested *in vivo* using the human subcutaneous SK-MEL5 melanoma or the human BxPC3-CAF model (BxPC3 pancreatic cancer cells co-inoculated with pancreatic cancer-associated fibroblasts). Mice were treated with single (5mg/kg, SK-MEL5 and BxPC3-CAF) or multiple (3mg/kg or 10mg/kg in SK-MEL5; 5mg/kg or 10mg/kg in BxPC3-CAF) doses of the IL1RAP-targeting ADC to evaluate anti-tumor activity. A surrogate anti-mouse IL1RAP ADC was developed and used to assess toxicity in mice (C57Bl/6 1, 3, 5 or 10mg/kg antibody, Q1W x 2 doses; Balb/c 20mg/kg antibody, Q1W x 2 doses).

Results and Conclusions: The selected clone showed low nanomolar affinity to human (KD 4.9nM) and cynomolgus (KD 5.4nM) IL1RAP, strong binding to IL1RAP-expressing cells (IC50 6.9nM) and robust internalization in IL1RAP-expressing cells. Conjugation to the payload did not compromise binding of the antibody to IL1RAP-expressing cells. *In vitro*, the IL1RAP-targeting ADC showed IL1RAP-dependent cell killing. Furthermore, the IL1RAP-targeting ADC demonstrated significant dose-dependent anti-tumor activity, with tumor regression observed in both *in vivo* models used. Both the anti-human IL1RAP ADC and the anti-mouse IL1RAP ADC were well tolerated in mice as indicated by kidney and liver histology, hematology assessment and body weight. These results suggest that ADCs targeting IL1RAP may have promising therapeutic potential and support clinical development for IL1RAP-targeting ADCs across a broad spectrum of cancers.

#2876 BR116: An antibody drug conjugate targeting CDH17 for gastrointestinal cancer therapy.

Xiaobei Zhao[1], Jie Zhu[1], Zhenhua Wu[2], Yiqun Li[1], Cindy Wu[1], Lei Nie[2], Haibin Wang[2], Gang Chen[1]

[1]BioRay Pharmaceutical Co., San Diego, CA,[2]BioRay Pharmaceutical Ltd., Hangzhou, Zhejiang, China

Cadherins are Ca^{2+}-dependent cell adhesion molecules that mediates cell-to-cell adhesion and plays a key role in tissue development. Classical cadherins, such as E-cadherin (CDH1), N-cadherin (CDH2), P-cadherin (CDH3), and VE-cadherin (CDH5) are implicated in cancer progression, invasion, and metastasis when their expression or function changes.

CDH17 (Cadeherin-17, LI-cadherin) is a structurally unique member of the cadherin superfamily, with seven extracellular EC repeats, a transmembrane domain, and a shorter cytoplasmic domain. Originally discovered in rat liver and intestine, CDH17 is also called liver and intestine cadherin. In humans, the expression of CDH17 is mainly limited to the digestive tract, including the duodenum, jejunum, ileum, colon, pancreas, and is rarely detected in other tissues. In the intestinal epithelium, CDH17 is mainly localized to lateral and basolateral cell membranes.

CDH17 overexpression is observed in various gastrointestinal malignancies, such as gastric cancer, colorectal cancer, bile duct cancer, pancreatic cancer and hepatocellular carcinoma, with almost no expression in normal tissues and organs. High expression of CDH17 is also associated with poor prognosis. The tumorigenic role of CDH17 involves interaction with α2β1 integrin to regulate cell adhesion, proliferation and migration, particularly in colon cancer liver metastasis, making CDH17 a promising therapeutic target in cancer research.

BR116 is a novel anti-CDH17 ADC that consists of a humanized, highly specific monoclonal antibody, stably conjugated to an innovative topoisomerase I inhibitor with hydrophilic linker. Notably, our unique conjugation platform CysX™ offers site-specific, stable and irreversible conjugation. CysX™ not only prevents payload detachment during circulation and reducing the off-target toxicity, improved therapeutic window, but also enables a uniformed drug-to-antibody ratio (DAR) of 4. The toxin was carefully selected based on the target characterization and cancer cell sensitivity.

BR116 has demonstrated remarkable antitumor activity in both *in vitro* and *in vivo* studies. Preclinical evaluations have shown strong safety profile in cynomolgus monkeys, indicating its potential as a therapeutic treatment for gastrointestinal cancers. With its enhanced safety profile and promising efficacy, BR116 holds significant potential for further clinical development. BR116 is aiming to file for an IND in 2025.

#2877 MRG007, a cadherin 17-targeted, glycan-linked, exatecan-based antibody-drug conjugate, demonstrated potent anti-tumor activity and a good safety profile in preclinical studies.

Peng Zeng[1], Qi Wu[1], Yongjun An[1], Yili Feng[1], Yanchun Wang[2], Shoujia Liu[2], Deliang Li[3], **Feifei Cui**[1], Lei Fang[1]

[1]Concept to Medicine Biotech Co., Ltd., Shanghai, China,[2]Shanghai Miracogen Inc., Shanghai, China,[3]Lepu Biopharma Co., Ltd., Shanghai, China

Background: Colorectal cancer (CRC) is the one of the most challenging cancers with unmet medical needs. Cadherin 17 (CDH17) is a membranous cell adhesion molecule. It is frequently overexpressed in CRC and several other gastrointestinal (GI) cancers, with limited expression in normal intestinal tissue and pancreatic duct. The differential expression profile in tumor versus normal tissue makes it an attractive target for antibody-drug conjugate (ADC) in GI cancers, particularly CRC. MRG007 is a CDH17-targeting ADC consisting of a novel humanized IgG1 antibody site-specifically conjugated with the cytotoxin Exatecan using Synaffix's GlycoConnect^{TM} technology with a well-balanced DAR value. This differentiated drug design will potentially improve anti-tumor efficacy and broaden the therapeutic window.

Materials and Methods: The biological activity and safety profile of MRG007 were investigated in a series of preclinical studies, including (1) binding ability to CDH17 expressed on GI cancer cells as well as rhesus CDH17 evaluated by flow cytometry; (2) internalization rate in GI cancer cells evaluated by pHAb Reactive Dye labeling; (3) in vitro cytotoxicity against a panel of GI cancer cell lines; (4) anti-tumor activity evaluated in several GI cancer cell line-derived xenograft (CDX) and CRC patient-derived xenograft (PDX) mouse models with different levels of CDH17 expression; (5) plasma stability evaluated in human, rhesus, rat and mouse plasma; (6) an exploratory pharmacokinetic (PK) and toxicology study in rhesus monkey.

Results: MRG007, the CDH17-targeting ADC, and its antibody moiety showed strong binding activity to CDH17 expressed on a panel of GI cancer cell lines. Similar binding potency to both human and rhesus monkey CDH17 makes rhesus monkey suitable for toxicological evaluation. Rapid internalization of MRG007 was observed in a panel of CDH17-expressing GI cancer cells, and MRG007 maintained comparable internalization efficiency to the naked antibody. MRG007 demonstrated efficient and CDH17-dependent cytotoxic activity in a panel of GI cancer cells expressing varying levels of CDH17. MRG007 exhibited a robust and dose-dependent tumor growth inhibition in multiple GI cancer CDX and CRC PDX mouse models with varying levels of CDH17 expression, which was significantly better than GGFG-DXd DAR8 ADC conjugated with the same naked antibody. Remarkable stability of MRG007 was shown in the plasma of various species tested with minimal payload release and stable DAR value. MRG007 demonstrated a favorable PK and safety profile with good tolerability in the exploratory toxicology study.

Conclusion: Overall, the preclinical study results suggest that MRG007 is a differentiated and potent ADC drug candidate for the treatment of CDH17-expressing cancers in clinical trials.

#2878 Preclinical characterization of GLR1061, a B7H3-targeted ADC with a novel DNA topoisomerase I inhibitor, demonstrated superior bystander effect to overcome tumor heterogeneity.

Jiao Jiao, Yingjie Sun, Jiaxing Wang, Menghan Cui, Siyao Li, Wenjie Shao, Hairui Yuan, Haitong Sheng

Gan & Lee Pharmaceuticals, Beijing, China

B7H3 (CD276) belongs to the B7 superfamily of immune checkpoint molecules. It is present at low levels in most normal tissues but is overexpressed in a variety of cancers, such as lung cancer, prostate cancer, breast cancer, head and neck squamous cell carcinoma, and esophageal squamous cell carcinoma. Notably, B7H3 overexpression has been found to be associated with a poor prognosis in a broad spectrum of malignant tumors, and it has become an attractive target for cancer therapy in recent years. B7H3-targeted antibody-drug conjugates (ADCs), such as DS7300, have shown positive clinical efficacy in small cell lung cancer, squamous non-small cell lung cancer, metastatic castration-resistant prostate cancer. GLR1061 is a B7H3 targeting ADC comprised of a humanized IgG1 monoclonal antibody, a cleavable linker and a novel DNA topoisomerase I inhibitor. Our independently developed topoisomerase I inhibitor had super strong cancer cell inhibition activity, which was 5 to 10 times stronger than DXd, and enhanced key advantages such as ADC bystander effect. Conjugated with B7-H3 antibody, which had superior binding and internalization, GLR1061 demonstrated more significant anti-tumor efficacy across various cancer types than DS7300 both in vitro and in vivo. In addition, in the CDX model of co-culture of antigen-positive and antigen-negative cells, GLR1061 exhibited much stronger bystander activity than DS7300, which was expected to overcome tumor heterogeneity and effectively eliminate cancer cells with different antigens expressions. In plasma stability studies, GLR1061 showed significantly lower free-payload release than DS7300 in different species (PBS, rat, monkey, and human). In a preclinical repeated-dose toxicology study in mice, GLR1061 showed good tolerability and reversible toxicity. Overall, GLR1061 demonstrated excellent specificity, efficacy, and safety as a next-generation therapy for the treatment of B7H3-positive tumors.

#2879 A novel therapeutic approach to treat patients with Type I interferon autoantibodies.

E. Garcia-Reino[1], N. Gao[1], T. Udumulla[1], E. Sosa[1], N. Ayoluwa[1], P. Mashati[2], A. Patera[2], J.-L. Casanova[3], **P. Premsrirut**[1];
[1]Mirimus, Inc., Brooklyn, NY, [2]SUNY Downstate Medical Center, New York, NY, [3]Rockefeller University, New York, NY

Type I interferons (IFNs) are a group of nonredundant pleiotropic cytokines that play an important role in eliciting antiviral responses and have also been shown to have antineoplastic effects. Deficits in this signaling pathway have been shown to increase susceptibility to viral infection and decrease immune surveillance to block tumorigenesis. Prior studies demonstrate that inhibition of the type I IFN pathway markedly compromises the anti-neoplastic effects of chemotherapies, such as anthracycline-based drugs like doxorubicin, and dramatically decreases the number of tumor-free mice in experimental settings. Recent large-scale clinical studies revealed that circulating anti-type I interferon autoantibodies capable of neutralizing type I IFN signaling contributed to disease severity in patients infected by SARS-CoV-2 and may be responsible for nearly 20% of COVID-19 deaths. These IFN autoantibodies were directly capable of hindering innate antiviral responses, thus allowing viral replication to occur more robustly and spread to distal tissues. Additional studies revealed that these type I IFN autoantibodies are quite prevalent in the aging population, found at high levels in nearly 1 in 15 over the age of 65 and confer a 100-fold risk of severe life-threatening viral illness. Despite their high prevalence and ability to block IFN signaling, no study to date has examined the role of type I IFN autoantibodies in cancer progression and tumor response. Here, we investigate whether neutralizing type I IFN autoantibodies can block critical innate immune signaling pathways that result in a higher conversion of pre-malignant cells to malignant tumors. We hypothesize that carriers of type I IFN autoantibodies may respond poorly to primary anticancer therapies, including standard chemotherapy regimens and immunotherapies. Furthermore, using a first-in-class therapeutic decoy, we test whether blockade of type I IFN autoantibodies can provide a synergistic benefit when combined with standard anticancer agents.

#2880 TM4SF1 as a novel target for different modalities (mAb, bispecific ADC, targeted siRNA) for the treatment of different solid tumor cancers.

Mingquan Xie[1], Peter Li[1], Han Lu[1], ShuTing Dong[1], Nicole Wilski[2], Poonam Pandey[2], Nishida Motohiko[2], Peter Haytko[2], **Mark Chiu**[2], Maria P. MacWilliams[2]

[1]Tavotek Lab Inc., Suzhou, China,[2]Tavotek Lab Inc., Lower Gwynedd, PA

Background: Transmembrane-4-L-six-family member-1 (TM4SF1) is a tetraspanin superfamily member that is overexpressed in cancers such as breast, colon, lung, liver, and prostate. A contributor to tumor development and progression, TM4SF1 participates in microdomains that regulate cancer cell migration and invasion via induction of the epithelial-mesenchymal transition, and angiogenesis. The overexpression of TM4SF1 makes it an attractive target for the developing novel treatments of GI tract cancers.
Methods and Results: We have engineered an anti-TM4SF1 antibody that binds with nM affinity to TM4SF1-expressing cells. The mAb has anti-tumor growth inhibition in gastric, ovarian cancer cell lines. This mAb can serve as an efficacious targeting carrier for toxins in an ADC and for siRNA in an ARC. To broaden the scope of cancer cell engagement, we prepared constructed a TM4SF1-cMET bispecific ADC which showed potent cytotoxicity in multiple GI, lung, ovarian, breast, TNBC, and pancreatic cancer cell lines in in vitro cell cytotoxicity assays. The bispecific TM4SF1-cMET MMAE (DAR=4) treatment led to potent tumor growth inhibition (70% to 95% TGI) in CDX pancreatic and gastric cancer xenograft models. The mice in the TM4SF1-cMET MMAE treatment group maintained normal body weight throughout the treatment course without observed toxicity. The TM4SF1 - MYC siRNA conjugates were stable. Treatment of MYC-dependent cancer lines led to MYC protein knockdown and cell growth inhibition.
Conclusions: A bispecific TM4SF1 ADC had activity in multiple cancer cell lines. Notably, the TM4SF1-MMAE molecule showed potent in vivo tumor growth inhibition in ovarian, pancreatic, and gastric cell lines. The TM4SF1 - siRNA ARC had tumor cell proliferation inhibition in lung, pancreatic, and gastric cancer cell lines. Preclinical safety assessment, pharmacokinetics and IND-enabling studies are on-going with the goal of developing TM4SF1 as the “best-in-class” ADC molecule for the treatment of lung, gastric, breast, and pancreatic cancers with significant unmet medical needs. This antibody can be applied to alternative targeting modalities.

#2881 QLS5133-a novel CDH6-targeting antibody-drug-conjugate for solid tumors.

Ying Huang[1], Fanrui Meng[1], Liuqing Yang[1], Shuyong Zhao[2], Xinmei Wang[2], **Ling Zhang**[1], Yang Yang[1], Hua Ying[1], Weikang Tao[1]

[1]Shanghai Qilu Pharmaceutical Research and Development Center LTD., Shanghai, China,[2]Qilu Pharmaceutical Co., Ltd., Jinan, China

Background: Cell-cell adhesion molecule cadherin-6 (CDH6), a member of the CDH family, is expressed in the basolateral membrane of epithelial cells and mediates calcium-dependent cell-cell adhesion. Although the function of CDH6 has not been fully elucidated, it is believed to be associated with epithelial-mesenchymal transition (EMT) and metastasis during tumor development. CDH6 is upregulated in various cancers, including ovarian cancer, renal cell carcinoma, and thyroid carcinoma, while its expression in normal tissues is limited. The therapeutic potential of CDH6 as an ADC target was recently unraveled by DS-6000a, a Dxd-based ADC from Daiichi/MSD. In this study, we present the development of a novel CDH6 ADC that is in the IND enabling stage. The new ADC demonstrates a superior safety profile compared to DS-6000a and shows robust anti-tumor activities in preclinical studies.
Method: QLS5133 is built on the QILU's proprietary novel topoisomerase-1(TOPO 1) inhibitor QLS6917 platform, with site-specific conjugation to yield a uniform DAR 8 product. The payload QLS6916 displayed nanomolar activity across various cancer cell lines and much faster systematic clearance than Dxd in vitro.
Result: QLS5133 exhibited a higher affinity and internalization compared to DS-6000a. Treatment with QLS5133 induced significant tumor regressions in multiple CDH6-expressing human cancer cell line xenograft studies encompassing ovarian cancer and renal cell carcinoma. Notably, in one CDX model with ultralow and highly heterogeneous CDH6 expression, QLS5133 still demonstrated strong efficacy. Additionally, QLS5133 was able to achieve a durable response even after resistance to Mirvetuximab soravtansine (FRα ADC/ImmunoGen) in preclinical models. This suggests that QLS5133 could potentially serve as a late-line treatment following treatment failure with Mirvetuximab soravtansine. More importantly, QLS5133 showed much less severe hematotoxicity than DS-6000a particularly regarding changes in platelets, white blood cells, neutrophils, as well as having a lesser impact on body weight reduction when dosed up to 80 mg/kg (single dose administration) in cyno monkeys. Meanwhile, QLS5133 demonstrated a better PK profile than DS-6000a in cyno monkeys, with longer $T_{1/2}$ and slower systematic clearance as intact ADC, and sustained DAR retention for a period of 21 days.
Conclusion: The promising efficacy, superior tolerability, and favorable PK profile support the potential of QLS5133 as a novel therapeutic agent to address the high unmet needs in patients with variable CDH6-expressing cancers. QLS5133 will enter clinical trials.

#2882 Development and preclinical characterization of HER2×Trop-2 bispecific antibody-drug conjugates (bsADCs) with auristatin microtubule inhibitors.

Daniel He, Greg Liang, Haixia Chen, Mingqi Shao, Songyan Huang, Qiong Wang, Yinfei Yin, **Qikuan Chen**

Shanghai ChemPartner Co., Ltd., Shanghai, China

Background: The emerging field of biparatopic (bpADC) and bispecific antibody-drug conjugates (bsADC) provides an innovative therapeutic category combining the merits of ADCs and bispecific/biparatopic antibodies. Promise in the field stems from the ability of bsADCs to overcome the existing clinical challenges associated with ADCs, such as poor internalization, drug resistance, and off-target toxicity. To date, more than 10 bsADCs are undergoing clinical trials, including HER2×Trop2 BsADCs. HER2 is a well-established target for ADCs such as trastuzumab emtansine and trastuzumab deruxtecan, demonstrating significant clinical benefits in HER2-positive breast cancers. The human cell-surface trophoblast protein 2 (Trop-2) is overexpressed in a wide range of solid tumors, including HER2-low expressing tumors, with minimal expression in normal tissues. Trop-2-directed ADCs such as sacituzumab govitecan and datopotamab deruxtecan have demonstrated potent antitumor efficacy in a broad range of solid tumors including patients with advanced triple-negative breast cancer, lung cancers and urothelial cancers. The dual-targeting approach offered by bsADCs has the potential to increase tumor cell binding affinity and internalization, leading to enhanced payload delivery and better tumor efficacy.
Methods and Results: We developed two different HER2×Trop-2 bispecific antibodies (Saci/Tras-hIgG1 and Dato/Tras-hIgG1) leveraging a monovalent bispecific IgG1 format, which is monovalent for each antigen based on the Fab fragments of trastuzumab, sacituzumab or datopotamab. The fully human anti-HER2/Trop-2 bispecific antibodies were conjugated with monomethyl auristatin E (MMAE) via a lysosomally cleavable linker to generate uniform HER2×Trop-2 bsADCs (Saci/Tras-vc-MMAE and Dato/Tras-vc-MMAE) with an average DAR of 4.2. The binding affinity and specificity of anti-HER2/Trop-2 bsADC was evaluated by ELISA and FACS, respectively. The bsAb-vc-MMAE conjugates exhibited greater tumor killing efficiency and specificity with an IC50 in sub nM level in cell lines with high Trop-2 expression and medium/low HER2 expression. Furthermore, in vivo studies demonstrated antitumor activity with improved efficacy compared to monotherapy ADCs targeting either HER2 or Trop-2 alone, with favorable safety and pharmacokinetic profiles.
Conclusion: HER2×Trop2 bsADCs represent a novel and exciting class of therapeutic agents with the potential to transform the treatment of multiple cancer types. Preclinical studies of HER2×Trop2 bsADCs have demonstrated that bsADCs can effectively inhibit tumor growth and prolong survival in xenograft animal models, with a favorable safety profile and low incidence of severe adverse events.

#2883 Cetuximab increases LGR5 expression and enhances efficacy of LGR5 antibody-drug conjugates in patient-derived models of colorectal cancer.

Peyton High, Zhengdong Liang, Cara Guernsey-Biddle, Adela Aldana, Yukimatsu Toh, Qingyun Liu, Kendra S. Carmon

UT Health Houston, Houston, TX

Colorectal cancer (CRC) is the second-leading cause of cancer-associated deaths in the United States with a need for improved therapies. Antibody-drug conjugates (ADCs) are a rapidly expanding class of anticancer drugs that utilize monoclonal antibody (mAb) specificity to hone cytotoxic payloads to cancer cells. We generated ADCs targeting leucine-rich repeat-containing G protein-coupled receptor 5 (LGR5), a cancer stem cell biomarker that is highly overexpressed in CRC. LGR5 ADCs demonstrated high specificity and efficacy in CRC cells and xenograft models without notable toxicity, although tumors eventually relapsed following treatment cessation. Interestingly, FDA-approved therapies targeting epidermal growth factor receptor (EGFR) have been shown to increase LGR5 expression in patient-derived models of CRC. This study therefore aims to determine the mechanisms of EGFR-mediated regulation of LGR5 expression and evaluate the therapeutic efficacy of EGFR-targeted therapies in combination with LGR5 ADCs for the improved treatment of CRC. We have demonstrated that cetuximab (CTX), an EGFR-targeting mAb approved for *KRAS*^{WT} metastatic CRC (mCRC), increases LGR5 protein levels independent of *KRAS*/*PIK3CA* mutational status in CRC cell lines, tumor organoids, and cell line-derived xenografts. Additionally, we identified a novel EGFR-LGR5 interaction that is enhanced by CTX treatment. Furthermore, we have generated a camptothecin-based LGR5 ADC (8E11-CPT2) utilizing site-specific conjugation technology that demonstrates target- and dose-dependent cytotoxicity in CRC cells and was well-tolerated. Importantly, combination treatment of 8E11-CPT2 with CTX in *RAS*^{mut} CRC patient-derived xenograft models significantly reduced tumor burden with notable regression in some mice and extended survival compared to LGR5 ADC and CTX monotherapies. These results demonstrate that combination treatments of LGR5 ADCs with CTX may prove more effective than ADC monotherapies in treating CRC and implicate expanded clinical utility for CTX to treat mCRCs with *KRAS* and/or *PIK3CA* mutations.

#2884 Development of antibody drug conjugates targeting MUC16 in ovarian cancer subtypes.

Mengyao Xu[1], Bo Rueda[2], David Spriggs[1], Yeku Oladapo[1]

[1]Massachusetts General Hospital Cancer Center, Boston, MA,[2]Massachusetts General Hospital Vincent Center for Reproductive Biology, Boston, MA

Background: Ovarian cancer (OC) remains a formidable challenge due to limited treatment options and inevitable development of multidrug resistance. Antibody-drug conjugates (ADCs) have emerged as a promising therapeutic modality, particularly for cancers with high unmet needs such as ovarian cancer (OC). MUC16, also known as CA125, is a high-molecular-weight glycoprotein overexpressed in ovarian cancer, serving as a biomarker for diagnosis and monitoring while contributing to tumor progression and immune evasion. Our laboratory previously identified 4H11, an antibody that preferentially binds to the retained (ectodomain) portion of MUC16. To exploit this target, we have systematically evaluated a panel of ADC payloads and linkers, including Auristatins (MMAE, MMAF), Camptothecin (SN-38), Maytansinoids, Calicheamicin, Nemorubicin, and Belotecan, conjugated to our proprietary antibody 4H11. Given the heterogeneity of OC, we investigated the efficacy of these ADCs across various subtypes, including high-grade serous ovarian carcinoma (HGSOC) and patient derived organoids.

Methods: ADCs were synthesized by conjugating 4H11 to different payloads via established linker chemistries. The resulting ADCs were characterized for drug-to-antibody ratio (DAR) and stability. In vitro cytotoxicity was assessed using a panel of OC cell lines and patient-derived organoids representing multiple subtypes. Dose-response curves were generated to evaluate IC50 values, and selectivity for antigen-positive cells was confirmed. Additionally, we analyzed differential sensitivity among subtypes to identify the most effective payload and ADC formulation.

Results: All ADCs demonstrated high stability and target specificity in vitro. Notably, ADCs with maytansinoids exhibited superior potency across HGSOC and other subtypes, achieving sub-nanomolar IC50 values in MUC16-positive cell lines. However, nemorubicin-conjugated ADCs showed enhanced efficacy in certain non-HGSOC subtypes, suggesting subtype-specific vulnerability. In organoid models, ADC efficacy closely mirrored cell line data, highlighting the translational potential of these findings. Importantly, payload and linker selection significantly impacted ADC performance, with maytansinoids yielding the best overall therapeutic index across of broad spectrum of OC histologic subtypes.

Conclusion: The retained portion of MUC16 is a viable target for ADC development. The maytansinoid conjugates emerged as leading candidates for further preclinical evaluation and potential clinical development based on their broad spectrum of activity against multiple histological subtypes. Our findings further underscore preferential susceptibility of different OC histologic subtypes to different ADC payloads.

#2885 IKS04, an antibody drug conjugate with a highly potent DNA crosslinker payload for the treatment of gastrointestinal cancers.

Jutta Deckert, Justyna Mysliwy, Adam Lodge, James Stephenson, Sarah Robinson, Robert J. Lutz

Iksuda Therapeutics Ltd, Newcastle-upon-Tyne, United Kingdom

IKS04 is an antibody drug conjugate (ADC) targeting human CA242, also known as CanAg, a tumor-associated carbohydrate antigen. This glycotope is highly expressed in most colorectal, pancreatic, gallbladder, and gastric cancers, with limited expression in normal tissues. While prior experience demonstrated that CA242 can be safely targeted with an ADC, the limited clinical efficacy observed with microtubule inhibitor payloads in gastrointestinal indications suggests that alternate payloads such as DNA crosslinkers could provide an improved therapeutic to target CA242+ tumors more effectively.

The ADC was generated by site-specific bioconjugation of a pyrrolobenzodiazepine (PBD) prodrug payload to the antibody light chain at a drug-to-antibody ratio of 2. The linker-prodrug incorporates two glucuronide-trigger moieties that require lysosomal cleavage by beta-glucuronidase to both release and activate the PBD dimer payload. In vitro antiproliferative and bystander activity was evaluated by CellTiterGlo assay. In vivo efficacy studies for ADC alone and antibody co-administration were performed with subcutaneous human xenografts in CB17-SCID mice. CA242 expression was determined in formalin fixed tumor samples by immunohistochemistry and on cell lines by quantitative flow cytometry.

In vitro, IKS04 results in potent and specific cell killing of panel of CA242+ target cells and potency correlated with antigen expression determined by flow cytometry. The PBD payload confers strong bystander activity in co-culture studies in vitro, an attribute that may allow treating tumors with heterogeneous antigen expression. The ADC was active against gastric and colorectal cancer xenograft models at single doses of 0.5 to 1 mg/kg, while the maytansinoid-based ADC benchmark cantuzumab ravtansine was inactive even at 2 mg/kg. Contrary to in vitro results, we observed a trend towards greater in vivo activity in models with lower antigen expression. This is suggestive of an antigen barrier effect where high target expression results in ADC accumulation at the tumor surface, precluding deeper penetration into tumor tissue. As the maximum tolerated ADC dose can be limited by target-independent payload toxicities, we increased the overall in vivo dose by addition of antibody to improve delivery. Consistent with this concept, co-administration of the unconjugated antibody with the ADC at a 5 to 50-fold excess improved the minimally effective dose in the CA242-high SNU16 gastric and HT29 colon cancer models compared to ADC alone while the antibody itself had no anti-tumor activity.

IKS04 is an ADC with a DNA crosslinker payload that shows potent in vitro and in vivo efficacy against gastric and colorectal cancer tumor models. Co-administration of the unconjugated antibody can improve ADC delivery which drives increased efficacy in preclinical models without increasing toxicity.

#2886 A *de novo* designed miniprotein enables modular and specific CAR-T targeting.

M. E. Llases[1], C. McKay[2], S. Syed[2], V. Andrusyshyn[1], E. Carcamo Noriega[1], J. W. Bowman III[1], T. Howard[1], N. Rodriguez[1], F. Teets[1], I. Truebridge[1], **X. Michelet**[1], Z. Caruolo[2], L. Webb[2], J. Newcomb[2], F. Mermelstein[2], C. Novina[2], C. Bahl[1];
[1]AI Proteins, Boston, MA, [2]Dynamic Cell Therapies, Watertown, MA

A definitive cure for acute myeloid leukemia (AML) remains elusive. Inter and Intra-patient heterogeneity in antigen expression profiles is a major challenge for AML treatment. Adapter CAR-T cell therapies utilize a chimeric antigen receptor (CAR) which binds to a non-natural small molecule, which in turn can be attached to a soluble affinity domain that binds the tumor antigen. Decoupling cancer cell binding and CAR engagement provides flexibility and control in directing the CAR-T therapy through dosing of the adapter, which can improve safety and decrease T cell exhaustion. A critical challenge for the success of adapter CAR-T is finding an ideal adapter molecule.

De novo designed miniproteins are a novel therapeutic modality. They are approximately 45 amino acids in length and adopt a highly stable tertiary structure, are easily produced recombinantly or synthetically, and present many additional advantages over traditional biologics. The structure of the miniprotein is created from scratch using generative artificial intelligence and is therefore controllable, permitting specific design of the conjugation site, as well as precise tuning the affinity. The small size, high solubility, and compact structure confers better biodistribution and lower internalization in the tumor cell surface. Here, we show that miniproteins outperform antibodies as the targeting moiety of an adapter CAR-T therapy, and we demonstrate this using CD123 directed treatment of AML.

We engineered AIP26GQ, a 5.6 kDa miniprotein that binds selectively to CD123 with KD = 0.5 pM. AIP26GQ is thermostable, and can be conjugated to a fluorescein molecule (FITC) via an engineered lysine residue. We demonstrated that AIP26GQ can direct anti-FITC CAR-T cells to kill AML model cell lines (MV-4-11) in vitro. We evaluated multiple positions for selective attachment of FITC, and identified the optimal geometric orientation for maximizing CAR-T activation. In vivo efficacy studies using MV-4-11 in NCG mice showed that AIP26GQ-directed CAR-T treatment reduces tumor burden to background levels and the remission is stable at least 15 days after the last dose. In the same study, a talacotuzumab antibody based adapter molecule and a direct anti-CD123 CAR-T were used for comparison. The miniprotein-directed CAR exhibited multiple advantages over both the antibody and the direct CAR-T, including increased efficacy with lower dose required of both the adapter and the CAR-T cells, improved tumor occupation, and less CAR-T exhaustion.

Our system combining a FITC-conjugated miniprotein with anti-FITC CAR-T cells yields complete remission in an MV-4-11 xenograft mice model, outperforming both an antibody adapter and direct CAR-T approaches. We demonstrated that the use of controllable CAR-T cells combined with miniprotein adapters exhibits an unprecedented potential for the design of dosable, redirectable and multiplexable cancer treatments.

#2887 Next generation antibody drug conjugates targeting HER2 and TROP2: Multi-Payload Conjugates™ targeting orthogonal mechanisms of cell killing.

Richard L. Kendall[1], Devin Trinter[1], Maxwell Nguyen[1], Daniel Gutierrez[1], Samantha Brady[1], Chanez Symister[1], Andrew Lau[1], Derek Garcia-Almedina[1], Saurabh Johri[1], Matthew Francis[2], Marco Lobba[1]

[1]CatenaBio Inc., Berkeley, CA,[2]Chemistry, University of California at Berkeley, Berkeley, CA

Introduction: Antibody-Drug Conjugates (ADCs) have had tremendous impact on patient outcomes in breast and other cancers. T-DXd, for example, is second-line therapy for stage IV, HER2 positive metastatic breast cancer as well as HER2 low expressing tumors. Sacituzumab govitecan, a TROP2 targeted ADC, has been approved as a 3rd line therapy in locally advanced or metastatic HER2 negative breast cancer. However, many patients fail to respond or relapse after treatment with ADC therapies due to tumor heterogeneity and eventual resistance to the ADC payload. We are developing next generation Multi-Payload Conjugates™ (MPCs™) that deliver targeted combination chemotherapies within a single molecule to address shortcomings in current ADCs.
Method: CatenaBio has developed novel, highly stable, single-molecule targeted combination therapies, MPCs™, with tunable payload ratios. Our selective conjugation platform allows the attachment of distinct payloads targeting different mechanisms of action at three unique sites on antibody scaffolds.
Results: Catena's MPCs show superior inhibition and excellent tolerability in mouse models of tumor growth in HER2 high and HER2 low/TROP2 expressing xenograft models including models of TNBC (triple negative breast cancer). In head-to-head comparisons MPCs out-perform current standards of care T-DXd and sacituzumab govitecan, demonstrating tumor elimination at low mg/kg doses. To produce the MPCs, combinations of different payloads targeting orthogonal mechanisms of cell division attached to trastuzumab as well as sacituzumab were screened at different DARs and payload ratios to optimize tumor cell killing. These targeted combination ADCs demonstrated robust killing in multiple cell lines containing high and low expression of HER2 and TROP2, as well as a T-DXd resistant cell line.
Conclusion: While advances have been made in the design of ADCs to expand to previously unaddressed populations, high patient relapse and the failure of recent mono-payload ADCs in late-stage trials indicate a need for novel conjugate modalities. Multi-payload Conjugates™ offer the next step in ADC design and allow for the targeted combination of multiple mechanisms of action with a single MPC™ that are highly efficacious at eliminating tumors across multiple cell line derived xenograft models with a range of target expression. Successfully constructed with a variety of targeting antibodies, these molecules offer the potential to circumvent tumor resistance pathways to deliver deeper and more durable patient responses.

#2888 DB-1418, a bispecific antibody-drug conjugate (ADC) targeting EGFR and HER3, demonstrates superior and broad antitumor efficacy and favorable safety in preclinical models.

Yunhua Zhou, Jun Yao, Rong Shi, Yang Qiu, **Haiqing Hua**

Duality Biologics, Shanghai, China

Background: EGFR and HER3 are co-overexpressed in a spectrum of tumors, including lung, breast, gastrointestinal, renal cell, ovarian, bladder, and prostate cancers. Importantly, HER3 expression is further enhanced upon inhibition of EGFR, suggesting that simultaneous targeting of both EGFR and HER3 could enhance tumor selectivity and improve therapeutic efficacy in EGFR tyrosine kinase inhibitors resistant tumors. This hypothesis has been supported by the clinical data of BL-B01D1, a bispecific ADC currently in clinical development. Here, we developed a differentiated bispecific ADC with stronger antitumor activity in preclinical studies.
Methods: We generated DB-1418, an asymmetric IgG-like bispecific ADC, featuring a Fab arm targeting EGFR with medium affinity and a scFv arm targeting HER3 with high affinity. The antibody is conjugated to a linker-payload L101P1021 at a drug-to-antibody ratio (DAR) of 6.
Results: The bispecific antibody showed low affinity on EGFR-only or HER3-only cell lines but demonstrated high affinity on tumor cells co-expressing both EGFR and HER3 compared to the parent monospecific antibodies. It also showed higher internalization capacity than the parent monospecific antibodies. DB-1418 exhibited broad anti-tumor activity across different expression levels of EGFR and HER3. Superior tumor inhibition was observed compared to a BL-B01D1 analog, based on both equal molar and mass concentrations. In the EGFR-dominant CAL-27 model, DB-1418 demonstrated a significant tumor growth inhibition (TGI) of 83% at a dose of 1.9 mg/kg Q3W, whereas the BL-B01D1 analog achieved only a 73% TGI at a dose of 3 mg/kg Q3W. In the HER3-dominant SW-620 model, DB-1418 treatment at a dose of 10 mg/kg Q3W resulted in complete tumor regression in 4 out of 5 mice and persisted up to 63 days after administration, whereas the BL-B01D1 analog at the same dose level and frequency failed to inhibit tumor growth. Notably, in an osimertinib-resistant NSCLC xenograft model with the C797S mutation, DB-1418 induced tumor regression with a TGI of 98% at a dose of 6 mg/kg Q3W, significantly higher than the BL-B01D1 analog at 6 mg/kg Q3W (TGI of 68%, $p<0.01$). DB-1418 demonstrated in vitro plasma stability in human, monkey, and rat models. In cynomolgus monkeys, the dose-range finding study showed favorable safety, with the highest non-severely toxic dose (HNSTD) reaching up to 45 mg/kg.
Conclusion: DB-1418 has shown promising pharmacological and pharmacokinetic properties, differentiated from the current clinical trial bispecific ADC targeting EGFR and HER3, with a broader therapeutic window. DB-1418 offers additional treatment options for patients who have developed resistance to EGFR tyrosine kinase inhibitors (TKIs) and addresses other unmet medical needs.

#2889 Multabodies: A next-generation approach for cancer immunotherapy and 4-1BB agonist therapy.

Joanne Hulme, Peter Bayliss, Abilasha Rao, Shrayasee Saha, Xinwen He, Debbie Jin, Yvonne Tsao, Amy Berkley

Radiant Biotherapeutics Inc., Toronto, ON, Canada

4-1BB agonism represents a promising strategy in cancer immunotherapy, targeting the 4-1BB receptor (CD137, TNFRSF9) expressed on activated T cells and NK cells. This co-stimulatory receptor, when activated by receptor multimerization, enhances immune cell proliferation, survival and effector functions. Agonistic antibodies against 4-1BB, optimized for FcγR cross-linking, have demonstrated potent anti-tumor activity in preclinical models. However clinical development has been hindered by severe liver toxicity (i.e., urelumab), or insufficient single agent activity, as seen with utomilumab. Here we describe a novel MULTi-specific, multi-Affinity antiBODY (Multabody™, MB) platform that exploits multi-valency to deliver an innovative 4-1BB Multabody™ with broad therapeutic potential. To understand the impact of epitope on 4-1BB agonism, we generated a panel of 4-1BB Multabodies to unlock comprehensive comparisons of potency and maximal activity of these molecules in a suite of assays including a 4-1BB Jurkat reporter assay vs urelumab and utomilumab. We identified 4-1BB MBs that demonstrated a range of Fc-independent agonistic profiles, including those mimicking the natural ligand, 4-1BBL. Identified lead 4-1BB MB candidate, RBT101, was further evaluated in vivo using the syngeneic MC38 murine tumor model. RBT101 demonstrated robust in vivo efficacy resulting in durable complete tumor regressions. Unlike urelumab which demonstrated splenomegaly and liver inflammation, RBT101 showed no signs of spleen or liver toxicity. Furthermore, RBT101 also provided long-term protection in a tumor rechallenge study, suggesting generation of a durable immunological memory response driven by RBT101. These data suggest the Multabody™ platform provides a novel approach to delivering a 4-1BB therapeutic with a differentiated profile to address an unmet clinical need in cancer immunotherapy for patients with solid malignancies.

#2890 Anti-tumor effect and mechanism of action of a nuclear transportable antibody drug conjugate Y-TR-1: Anti CD26 antibody conjugated with RNA polymerase II inhibitor triptolide.

M. Hayashi[1], H. Madokoro[1], K. Yamada[2], R. Hatano[3], C. Morimoto[3], T. Yamada[1];

[1]Saitama Medical University, Saitama, Japan, [2]The Jikei University, Tokyo, Japan, [3]Graduate School of Medicine, Juntendo University, Tokyo, Japan

Introduction: CD26 is a multifunctional transmembrane glycoprotein that is overexpressed in many cancers. We established the humanized anti-CD26 monoclonal antibody YS110, which has a direct anti-tumor effect through nuclear translocation of CD26 and transcriptional suppression of the POLR2A gene, a subunit of RNA polymerase II (Pol II). Subsequently, we developed an antibody-drug conjugate Y-TR-1 with YS110 and the Pol II inhibitor triptolide and evaluated its in vitro and in vivo antitumor efficacy and toxicity. We then elucidated the mechanism of action of Y-TR-1.

Experimental procedures: 5 triptolide molecules on average were crosslinked to YS110 by the heterobifunctional linker SMCC (designated Y-TR-1). The in vitro cytotoxicity of Y-TR-1 was analyzed in CD26-positive or -negative cancer cells and normal cells. The in vivo antitumor effect of Y-TR-1 was assessed using a xenograft assay. Pharmacokinetics/pharmacodynamics studies and toxicity tests were conducted using cynomolgus monkeys. Western blotting and immunofluorescence imaging were performed to confirm the nuclear translocation of Y-TR-1. The inhibitory effect of Y-TR-1 against Pol II was analyzed using quantitative polymerase chain reaction and a live cell imaging assay. The molecular mechanism of Y-TR-1 nuclear translocation was elucidated by immunofluorescence imaging.

Results: A conjugation method of Y-TR-1 was established, and the average drug-to-antibody ratio (DAR) was 4.76 by LC/MS. Y-TR-1 showed in vitro cytotoxicity on CD26-positive cancer cells, whereas non-cancer cells were less susceptible to Y-TR-1. The in vivo antitumor effect of Y-TR-1 was confirmed in a xenograft study using three CD26-positive cancer cell lines. Toxicity studies of cynomolgus monkeys with cross-reactivity to Y-TR-1 revealed no severe toxicity. The animals that received 30 mg/kg body weight of Y-TR-1 showed some decline in the reticulocyte count and slight increase in the thrombocyte count, whereas no histological damage was observed in the liver, kidney, heart, or lungs. Nuclear translocated Y-TR-1 was confirmed in the nuclear fraction of CD26-positive cancer cells by western blotting or immunofluorescence imaging. Quantitative polymerase chain reaction and live cell imaging assays revealed Pol II inhibition by Y-TR-1. Y-TR-1 was internalized via caveolae-dependent endocytosis and subsequently colocalized with endosomes before translocation to the nucleus.

Conclusions: Y-TR-1 is an ADC with a novel mechanism of action, i.e., nuclear translocation and subsequent Pol II inhibition. Transcriptional repression of POLR2A expression by nuclear-localized CD26 and Pol II inhibition by internalized triptolide are expected to have additive effects. Y-TR1 exhibited potent antitumor activity against CD26-positive cancer cells in vitro and in vivo.

#2891 In vitro comparison of Kadcyla and Enhertu in breast cancer with varying HER2 expression: proliferation, internalization, bystander effects and toxicity.

Veronica Bergo, Philipp Metzger, Valerie Oberhardt, Jan Eric Ehlert, **Holger Weber**

Reaction Biology Europe GmbH, Freiburg, Germany

HER2-positive breast cancer is characterized by overexpression of the HER2 receptor, driving aggressive tumor growth. Antibody-drug conjugates (ADCs), like trastuzumab emtansine (Kadcyla, T-DM1) and trastuzumab deruxtecan (Enhertu, T-DXd), are effective in targeting HER2-positive tumors, though their efficacy across varying HER2 levels remains under study. This study compares Kadcyla and Enhertu regarding cell proliferation, ADC internalization, and bystander cytotoxicity in cancer cell lines with high (SK-BR-3/SKOV-3), moderate (JIMT-1), and low (MDA-MB-231/MDA-MB-435) HER2 expression. It also examines off-site ADC toxicity in primary non-tumor cells caused by off-target payload delivery.
The xCELLigence system, which works via label-free impedance measurements on living cells, was employed to monitor real-time cell proliferation and viability. Both, Kadcyla and Enhertu, eliminate tumor cells, effectively at nanomolar concentrations, correlating with HER2 expression levels. Interestingly, Kadcyla's effect appears at least 24 hours earlier than Enhertu, whereas the unconjugated antibody Trastuzumab itself has little to no effect on tumor cell growth. Low HER2-expressing cells were killed at 1 µM, the highest dose tested. ADC internalization was analyzed using pH-sensitive, fluorescently labeled Trastuzumab in flow cytometry and microscopy, assessing uptake by mean fluorescence intensity (MFI) in viable cells. This analysis allowed the comparison of the rate and extent of Trastuzumab uptake across the tested cell lines. A co-culture system evaluated bystander effects, with high HER2-expressing SKOV-3/SK-BR-3 cells co-cultured with luciferase-labeled HER2-negative LN-229 cells. After treatment with Kadcyla or Enhertu, luciferase assays were conducted to assess whether the cytotoxic payload released by the ADCs in HER2-positive cells could affect the viability of neighboring HER2-negative cells. Enhertu demonstrated a bystander effect, whereas Kadcyla, on the other hand, showed a more limited activity, reflecting the non-cleavable linker and the membrane-impermeable nature of its payload DM1.
Toxicity analyses of Kadcyla and Enhertu on non-tumor cells, and especially on bone marrow, complement on-target investigations by revealing critical results about their safety profiles. While these ADCs are designed to selectively target tumor cells, off-site toxicity can affect healthy tissues and impair immune system function. Studies on hematopoietic stem cells are essential to assess potential adverse effects on hematopoietic regeneration and differentiation, aiming to reduce unintended immunosuppression. These findings support the optimization of ADC design, to enhance both selectivity and therapeutic windows.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: DNA Damage Response and Modulation of DNA Repair 1
Poster Session

#2894 NTX-452: a non-covalent, potent, selective and highly efficacious WRN inhibitor with best-in-class potential for the treatment of MSI-H tumors.

Rob Svensson, Scott Boiko, Beth Browning, Sam Carreiro, Derun Li, Angela Toms, Justin Caravella, Silvana Leit, Suzanne Jacques-O'Hagan, Hyesun Oh, Emily Florine, Zhenhong Li, Avinash Phadke, Yuet Mei Khong, Anita Scheuber, Peter Tummino

Nimbus Therapeutics, LLC, Boston, MA

Microsatellite instability (MSI-H) is a phenotypic consequence of defective mismatch repair (dMMR) in cancer and is observed in over 20 solid tumor types, with the highest prevalence in colorectal, gastric and endometrial cancers. While the treatment landscape of MSI-H is improving with the use of immune checkpoint inhibitors, substantial unmet medical need remains for patients with MSI-H cancers that fail to respond or relapse on standard-of-care therapies. Werner Syndrome Helicase (WRN) has been validated as a promising synthetic lethal drug target for MSI-H tumors, thus inhibitors of WRN may offer a novel therapeutic option for patients with MSI-H tumors. Our efforts to develop inhibitors of WRN led to the generation of two series of novel small molecules that had either a covalent or non-covalent mechanism of action. Treatment of MSI-H cell lines with exemplars from each series led to dose-dependent and rapid degradation of WRN protein, followed by an accelerated WRN protein re-synthesis rate that was independent of inhibitor mechanism. Washout studies using covalent inhibitors revealed that substantial target engagement was lost in MSI-H cells within 24- hours, suggesting rapid WRN resynthesis may limit sustained target inhibition. Prioritization of our non-covalent inhibitor series led to the generation of NTX-452, our lead candidate with best-in-class potential for the treatment of MSI-H cancers. The preclinical profile of non-covalent NTX-452 was characterized and compared to clinical-stage WRN inhibitors, including those from Novartis (HRO761, non-covalent) and Roche/Vividion (RO7589831, covalent). NTX-452 displayed excellent metabolic stability- with low in vivo clearance, good oral bioavailability, and high oral exposures in rodents and non-rodents. In vivo, low dose NTX-452 treatment induced robust pharmacodynamic and tumor regression across multiple MSI-H Cell line Derived (CDX) and Patient Derived (PDX) xenograft models. Notably, NTX-452 outperformed existing clinical stage WRN inhibitors at lower doses across multiple MSI-H tumor models. NTX-452 has broad efficacy across MSI-H CDX and PDX models from colorectal, gastric and endometrial lineages and is highly efficacious in models with diverse genomic and clinical characteristics. Moreover, NTX-452 promoted durable tumor regression and complete responses in MSI-H PDX models that were refractory to immunotherapy (anti-PD1) or chemotherapy. Lastly, resistance to clinical stage WRN inhibitors was explored and the potential for NTX-452 efficacy in WRN inhibitor resistant cell lines and tumors was evaluated.Taken together, our results highlight the broad, best-in-class potential of NTX-452 in MSI-H tumors and support its advancement to clinical evaluation.

#2895 Efficacy of DNA-PK inhibitor as maintenance strategy after cisplatin induction in SCLC.

Luisa Amato[1], Caterina De Rosa[1], Concetta Tuccillo[1], Francesca Iommelli[2], Viviana De Rosa[2], Virginia Tirino[3], Federica Papaccio[4], Kavya Ramkumar[5], Qi Wang[6], Jing Wang[6], Alberto Servetto[7], Floriana Morgillo[1], Lauren Averett Byers[5], Fortunato Ciardiello[1], Carminia Maria Della Corte[1]

[1]Department of Precision Medicine, University of Campania "Luigi Vanvitelli", Napoli, Italy,[2]Institute of Biostructures and Bioimaging, National Research Council, Napoli, Italy,[3]Department of Experimental Medicine, University of Campania "Luigi Vanvitelli", Napoli, Italy,[4]Department of Medicine, Surgery and Dentistry, "Scuola Medica Salernitana", University of Salerno, Napoli, Italy,[5]Departments of Thoracic/Head & Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX,[6]Bioinformatics & Computational Biology, The University of Texas MD Anderson Cancer Center, Houston, TX,[7]Department of clinical medicine and surgery, University of Naples Federico II, Napoli, Italy

Given the aggressive nature of small cell lung cancer (SCLC) and the frequent relapse after initial chemotherapy, this work aims to identify novel approaches to enhance the immune response. DNA-dependent protein kinase (DNA-PK) is a targetable enzyme involved in non-homologous end joining (NHEJ) and antiviral responses. DNA-PK plays a role during cGAS/STING dependent and independent viral DNA sensing pathway. Thus, we investigated the role of DNA-PK inhibition (DNA-PKi) as a maintenance strategy following cisplatin treatment in SCLC patients, focusing on its ability to enhance antitumor immune responses. We included different models of SCLC, in particular SCLC patient-derived peripheral blood mononuclear cells (PBMCs), SCLC cell lines and cocultures of PBMCs with SCLC cells and SCLC tumor spheroids. SCLC cells were treated in vitro with low-dose cisplatin (0.5 μM), and blood was collected from SCLC patients on day 3 of cisplatin treatment. SCLC cells and PBMCs were subjected to transcriptomic sequencing and gene expression profiling to assess the effect of DNA-PKi on PBMC subsets (CD8+ T cells, NK cells and monocytes). Gene set enrichment analysis (GSEA) of RNA-seq data revealed that cisplatin treatment enriched several DDR pathways and upregulated immune-related pathways in both SCLC cell lines and patient-derived PBMCs. Sequential treatment with DNA-PKi after cisplatin significantly activated CD8+ T-cell and NK-cell pathways, as well as enhancing interferon-related pathways and gene signatures associated with viral infections. In vitro treatment with DNA-PKi resulted in increased expression of pro-inflammatory markers in PBMCs, promoting M1 polarization of macrophages (TNF-α, IL-6 and CXCL10) while inhibiting M2 polarization (IL-10, IL4 and CCL22). This shift towards an anti-tumor phenotype was confirmed by enhanced NK cell-mediated cytotoxicity against SCLC cell lines. In addition, combination therapy with DNA-PKi and anti-PD-L1 resulted in increased immune cell infiltration into tumor spheroids, demonstrating a synergistic effect on anti-tumor immunity. In conclusion, our data suggests that DNA-PKi may improve immune responsiveness and potentially prolong antitumor effects in SCLC patients. Future investigations are warranted to further elucidate these mechanisms and to evaluate the clinical applicability of DNA-PKi in combination with existing therapies for SCLC.

#2896 Transforming treatment paradigms: A cutting-edge polθ Inhibitor (DWP223) targeting PARP resistance in BRCA-mutant cancers.

Juno Kim[1], Jie Luo[2], Bin Cao[2], Ling Zhao[2], Xiaojing Zhang[2], Xiaohua Lin[2], Xiaojing Lin[2]

[1]Daewoong Pharmaceutical, Seoul, Korea, Republic of,[2]XtalPi, Shanghai, China

A significant portion of tumors with BRCA1 or BRCA2 mutations exhibit only weak responses to PARP inhibitor (PARPi) treatment, and often develop resistance to PARPi over time. Both Polθ and PARP1 play critical roles in MMEJ for DNA double-strand break repair, and Polθ inhibition holds the potential to overcome PARPi resistance driven by BRCA reversion mutations. To address these challenges, we have developed DWP223, a novel selective and potent Polθ inhibitor. This compound can be used as a single agent or in combination with PARPi to treat tumors harboring BRCA mutations.DWP223 has shown potent and selective inhibition of BRCA-deficient cell proliferation in vitro, achieving an IC50 value below 20 nM, while demonstrating minimal impact on parental cell lines. In vivo, DWP223 monotherapy is effective at doses as low as 30 mg/kg, and when used in combination with PARP inhibitors, it induces over 50% tumor regression at a lower dose. Notably, even at high doses, DWP223 is well-tolerated, with no observable weight loss or hematological toxicity in animal models.Furthermore, DWP223 extends therapeutic potential by exhibiting synthetic lethality in tumors deficient in non-homologous recombination (HR), broadening its application to patients without homologous recombination repair (HRR) mutations. The compound’s favorable pharmacokinetic profile and robust safety data across multiple species underscore its suitability for clinical development, highlighting the opportunity to reduce hematological toxicity and target PARP inhibitor-resistant cancers.Collectively, DWP223 represents a promising therapeutic candidate, either as a standalone treatment or in combination with PARPi, for targeting HR-deficient cancers and potentially overcoming PARPi resistance. DWP223 is advancing toward IND filing in 2025.

#2898 SS induces BRCA1 reduction and sensitizes breast cancer cells to PARP inhibitor therapy.

J. Chen, B. Yi, Y. Xi;
University of Georgia, Athens, GA

Background: PARP inhibitors (PARPi) have demonstrated substantial clinical efficacy in treating BRCA-mutant breast cancers through synthetic lethality, where the inhibition of DNA single-strand break repair in BRCA-mutant cells leads to the accumulation of DNA damage and cell death. However, in the majority of breast cancer patients with BRCA wild-type (BRCAwt) tumors, PARPi therapy has limited effectiveness. Several approaches, such as CRISPR/Cas9-mediated BRCA1 gene editing, have been explored to induce BRCA deficiency in BRCAwt cancers, but these strategies face challenges for clinical application. Our recent work has focused on novel methods to sensitize BRCAwt breast cancer cells to PARPi. Sulindac sulfide (SS), the active metabolite of the FDA-approved NSAID sulindac, has emerged as a potential agent to enhance cancer cell death when combined with DNA-damaging agents, potentially by impairing DNA repair mechanisms.
Methods: This study investigates the mechanisms by which SS inhibits DNA repair, potentially through modulating BRCA1 expression. We assessed the effects of SS on BRCA1 protein levels using western blot analysis and examined BRCA1 mRNA levels using RT-PCR. DNA damage and repair were evaluated by γH2AX foci formation, RAD51 recruitment assays, and slot blot assays. To assess the therapeutic potential of combining sulindac sulfide with PARPi, we conducted both *in vitro* and *in vivo* studies.
Results: Sulindac sulfide treatment resulted in a dose-dependent reduction of BRCA1 protein levels via ubiquitin-proteasomal degradation. This reduction led to impaired homologous recombination repair capacity and increased DNA damage accumulation. *In vitro*, the combination of sulindac sulfide and olaparib exhibited synergistic cytotoxic effects in BRCA1wt triple-negative breast cancer (TNBC) cells. *In vivo*, the combination therapy significantly inhibited tumor growth compared to either agent alone. These findings suggest that sulindac sulfide can sensitize BRCA1wt TNBC cells to PARPi therapy by inducing homologous recombination deficiency.
Conclusion: This study provides a mechanistic basis for the combination of sulindac sulfide and PARPi as a potential therapeutic strategy for BRCA1wt TNBC. By downregulating BRCA1 and impairing DNA repair, sulindac sulfide induces a synthetic lethality effect, expanding the therapeutic reach of PARPi to BRCAwt cancers.
Keywords: Sulindac Sulfide, Olaparib, TNBC, BRCA1, and homologous recombination repair

#2899 PARG inhibition provokes a DNA damage-dependent innate immune reaction that enhances ICI-driven anti-tumor immunity.

Reeja Maskey, Megan Conway, Pei Xin Lim, Amber C. Donahue, Emily Fitz, Vidhya Nagarajan, Arjun A. Rao, Zabrisky Roland, Natalie Bresnahan, David Trinh, Ivan Shabalin, Kelly Trego, Jonathon Ryan, Rebeca M. Choy, Peter Teriete, Christian Frey, Yuchen Bai, Paul A. Barsanti, Claire Neilan, Mike White, **Diana M. Munoz**

IDEAYA Biosciences, South San Francisco, CA, CA

Poly (ADP-Ribose) glycohydrolase (PARG) is an emerging oncology drug target with a unique role in the resolution of DNA damage repair and DNA replication fork restart through hydrolysis of Poly (ADP-ribose) (PAR) chains. IDE161 is a potent, orally bioavailable, small molecule that directly binds the active site of PARG to impede PAR chain hydrolysis and exhibits robust anti-tumor activity in preclinical models associated with replication stress. Molecular profiling of baseline cell states across 257 tumor cell lines indicated innate immune signaling was strongly associated with responsiveness to IDE161. Moreover, induction of interferon regulatory factor (IRF) activity was the dominant gene regulation program detected in tumors in response to IDE161 exposure in vivo. Given the body of evidence indicating replication stress can lead to a type 1 interferon response via nucleic acid sensing, we speculated that IDE161-induced innate immune signaling is a consequence of cytosolic exposure to DNA repair intermediates including RNA: DNA heteroduplexes produced by failed resolution of stalled DNA replication forks. Consistent with this, IDE161-dependent cancer cell death was preceded by transcription-replication conflicts, replication catastrophe, innate immune pathway activation, and IFN-β production and secretion. To evaluate the potential for innate immune priming of an adaptive immune reaction, IDE161/immune checkpoint inhibitor (ICI) combination activity was assessed in a syngeneic mouse tumor model reported to be partially responsive to PARG inhibition. The combination of IDE161 with RPM1-14, an antibody directed against the mouse-programmed cell death protein 1 (PD-1) receptor, showed greater anti-tumor activity than either agent alone and altered the frequency of tumor-infiltrating lymphocytes towards an immune-activated phenotype. Moreover, T-cell receptor sequencing of clinical PBMC specimens from IDE161 monotherapy patients revealed clonal expansion in the T-cell receptor repertoires on treatment as compared to baseline. These cumulative observations suggest that IDE161 can induce an innate-immune-pathway-mediated priming of an antitumor adaptive immune response, and thus may deliver both tumor autonomous and nonautonomous therapeutic benefits. This relationship is currently under evaluation with IDE161/pembrolizumab combination therapy In patients with advanced endometrial cancer who have previously progressed on anti-PD-1 therapy (NCT05787587)

#2900 Musashi-1 regulated oncogenic switch enhances therapy resistance to DNA damage in glioblastoma.

X. Liu, T. Kong, M. Wong, L. Lin;
Hong Kong Polytechnic University, Hong Kong, Hong Kong

Glioblastoma (GBM) is notoriously resistant to treatment, largely due to its inherent enhancement of DNA repair mechanisms. Standard therapies, which include ionizing radiation and alkylating agents, primarily exert their effects by damaging DNA. Therefore, targeting the DNA damage response (DDR) has emerged as a promising strategy to sensitize tumor cells to these treatments. The RNA-binding protein Musashi-1 (MSI1) is known to contribute to the aggressive nature of GBM, yet its specific role in DNA damage-mediated therapy resistance remains largely unexplored. This study employed three GBM cell lines, an orthotopic GBM model in immunodeficient mice, and tissue samples from 35 GBM patients. We developed a specialized antibody to detect phosphorylation at the MSI1-S347 site in both cells and tissues. Site-directed mutagenesis and transcriptome sequencing were used to investigate the effects of MSI1 phosphorylation on GBM. The comet and colony formation assays were conducted to assess therapy resistance in GBM cells following treatment with carmustine (BCNU) or X-ray irradiation. Flow cytometry, immunofluorescence, and immunohistochemistry were utilized to identify cancer stem cell markers in GBM. A luminescence reporter system was created to pinpoint the binding site of non-phosphorylated MSI1 and to establish a visual drug screening platform targeting MSI1-S347. We identified a new phosphorylation site at serine-347 (S347) on the C-terminal of MSI1, which transcriptome analysis linked to the processing of DNA double-strand breaks in GBM. Patient tissue samples showed significantly higher levels of phosphorylated MSI1-S347 compared to normal brain tissues, regardless of tumor location or GBM subtype. Phosphorylation at MSI1-S347 enhanced BCNU resistance by promoting DNA repair mechanisms, and it also increased resistance to X-ray irradiation by preserving colony-forming ability. Additionally, higher levels of S347 phosphorylation were associated with reduced survival rates in GBM animal models. Mechanistically, we observed a positive correlation between phosphorylated S347 and the cancer stem cell marker CD133 expression. Further analysis revealed changes in binding interactions between MSI1 and p21 mRNA depending on the S347 phosphorylation state. To address this, we developed a luminescence reporter system to visually screen drugs that can modulate MSI1-S347 phosphorylation. This platform measures S347 phosphorylation levels in vivo and serves as a drug screening tool targeting GBM therapy resistance. This study uncovers a novel mechanism by which MSI1 enhances DNA damage repair, contributing to therapy resistance in GBM. Understanding the DNA damage response can guide clinical strategies to inhibit the MSI1 binding switch and enhance treatment efficacy. Targeting the MSI1 binding switch could offer a more effective approach to overcoming GBM therapy resistance.

#2901 Targeting *miR-19b*/PPP2R5E regulatory axis to enhance alkylating agent efficacy: a new avenue to counteract temozolomide resistance in recurrent glioblastomas.

Erik Vassella, Elham Kashani

University of Bern, Bern, Switzerland

Glioblastoma (GBM), the most aggressive primary brain tumor, notorious for its inevitable recurrence despite standard of care, presents a pressing need for novel treatment paradigms. Temozolomide (TMZ), a frontline DNA alkylating agent, induces extensive DNA damage. However, TMZ response is counteracted by intricate or acquired survival mechanisms. Through functional TMZ-resistance screens using microRNAs, we uncovered a novel mechanism involving the *miR-19b* target, *PPP2R5E*, a subunit of PP2A serine-threonine phosphatase, in TMZ response. Specifically, the induced expression of *PPP2R5E*, resulting from *miR-19b* attenuation, triggers genotoxic stress, priming GBM cell lines and primary GBM cells for heightened TMZ cytotoxicity. Elevated DNA damage in *PPP2R5E*-overexpressing cells is attributed to increased nuclear and mitochondrial ROS production, which is accompanied by enhanced ROS-mediated senescence and ferroptosis. Of note, all these phenotypes are reversed in GBM cells with concomitant *miR-19b* and *PPP2R5E* attenuation, indicating that *miR-19b* exerts its role in TMZ resistance by targeting *PPP2R5E*. In line with this finding, our orthotopic human-derived GBM stem cell xenograft model confirmed that *PPP2R5E* attenuation not only decreases TMZ cytotoxicity in the brain, but also at the spinal metastatic location. Consistently, treating cells with the PP2A-activating drug FTY720 or knocking down endogenous PP2A-inhibiting proteins mirrors the effects of *miR-19b* attenuation in enhancing TMZ cytotoxicity. This intricate interplay between *miR-19b* and *PPP2R5E* underscores a novel strategy to modulate the TMZ response, highlighting promising results in our pre-clinical models. Intriguingly, PP2A inhibiting proteins CIP2A and ANP32A (PHAP1) are upregulated in TMZ-resistant GBM cells and recurrent GBM tumors following TMZ treatment, suggesting a role of the PPP2R5E axis in TMZ resistance. In conclusion, our findings advocate for the therapeutic targeting of the *miR-19b*/PPP2R5E axis as a promising strategy to overcome TMZ resistance in GBM, indicating a potential novel strategy in the pursuit of effective therapeutic interventions for the formidable recurrent GBM tumors.

#2902 Systematic mapping of chemo-genomic interactions between DNA damaging agents and DNA damage repair genes with targeted CRISPR knockout screening.

Collin D. Heer[1], Spenser S. Johnson[1], James L. Elia[1], Sam Friedman[1], Xin Pei[2], Sofia R. Arbelaez[1], Ranjini Sundaram[1], Vijay Menon[1], Joseph Edmonds[1], Karlie Lucas[1], Nadeem Riaz[2], Susan E. Gueble[1], Ranjit S. Bindra[1]

[1]Therapeutic Radiology, Yale University, New Haven, CT,[2]Radiation Oncology, Memorial Sloan Kettering, New York, NY

Genetic instability is a hallmark of cancer, often arising from mutations in DNA damage repair and response (DDR) proteins. It is our goal to map the repair dependencies associated with different DNA-damaging agents (DDA) and DDR inhibitors (DDRi). To this end, we developed a DDR-targeted, CRISPR knockout screening approach to assess relationships among 355 DNA repair genes and 30 DDA and DDRi in LN229 glioma cells.

Systems-level analysis of over 11,000 interactions revealed that DDA cluster into distinct classes. In contrast, DDRi including ATR, Pol-θ, DNA-PK, WRN, Wee1, USP1, ATM and PKMYT1 inhibitors exhibited a variety of unique dependency profiles. Pathway analysis revealed clear associations between the knockout of Fanconi anemia pathway genes and sensitivity to bifunctional alkylating agents (e.g. chlorambucil), nucleotide excision repair and monofunctional alkylating agents (e.g. illudin S), homologous recombination and PARP inhibitors (e.g. talazoparib), and non-homologous end-joining and radiomimetics (e.g. bleomycin).

Furthermore, this platform identified differences in repair dependencies of compounds with subtle variations in chemical structure, highlighted by the imidazotetrazines temozolomide (TMZ) and KL50. In contrast to the methyl adducts deposited by TMZ, DNA modifications deposited by KL50 slowly evolve into DNA interstrand crosslinks (ICLs), circumventing mismatch repair (MMR)-driven resistance observed with TMZ. Indeed, screening revealed that resistance to TMZ, but not KL50, is driven by loss of MMR genes. Furthermore, we observed that BRIP1, a helicase known to play a key role in repair of ICLs, emerged as a unique sensitizing hit for KL50, but not TMZ, providing biological support for the formation of ICLs by KL50.

Finally, we sought to identify the most clinically actionable chemo-genomic interactions from our screens. Bi-allelic inactivating mutations (BI) of DNA repair genes are often necessary for manifestation of a DDR deficiency phenotype. Thus, we subjected our gene list to a custom bioinformatic pipeline to quantify rates of BI in samples from The Cancer Genome Atlas (TCGA). Excluding genes listed as Level 1 biomarkers on OncoKB, we found that 4.73% of TCGA samples harbored putative BI of at least one of the 138 genes that emerged as a hit (FDR < 0.01) in our screens.

Overall, our screens validated established chemo-genomic interactions while also identifying genetic dependencies associated with DDA of previously unknown mechanisms of action. Furthermore, we elucidated subtle differences in repair dependencies between structurally similar compounds. Finally, we identified novel genetic biomarkers with frequent BI in human tumor samples that sensitized to specific therapeutic agents upon loss, nominating chemo-genomic interactions with potential clinical relevance.

#2903 Evaluation of SMP-3124, a novel liposome-encapsulated CHK1 inhibitor, in patient-derived preclinical models of treatment-resistant ovarian cancer.

Yuka Kumagai[1], Junzo Hamanishi[2], Ryusuke Murakami[2], Kana Shimizu[3], Yosuke Ota[3], Yusuke Sawayama[4], Naoaki Shimada[3], Kento Hayashi[3], Yoshiko Fukuoka[3], Steven L. Warner[1], Jason M. Foulks[1], Masaki Mandai[2], Makoto Matsuoka[3], Seiji Kamioka[3], Hitoshi Ban[3], Hiroki Umehara[3]

[1]Translational Research and Medicine, Sumitomo Pharma America, Inc., Marlborough, MA,[2]Department of Gynecology and Obstetrics, Kyoto University Graduate School of Medicine, Kyoto, Japan,[3]Cancer Drug Discovery Research Unit, Sumitomo Pharma Co Ltd, Osaka, Japan,[4]Sumitomo Pharma Co Ltd, Osaka, Japan

Purpose: Checkpoint kinase 1 (CHK1) plays a critical role in DNA damage repair by responding to and managing DNA replication stress. CHK1 activation results in cell cycle arrest and the induction of DNA damage repair pathways. Targeting CHK1 is a promising therapeutic strategy due to high levels of replication stress in cancer cells. CHK1 inhibition causes replication catastrophe and inhibits cell growth in a wide range of cancers (Toledo L, 2017). In the past decade, multiple drugs targeting this pathway have been tested in clinical trials (de Costa AABA, 2023). Although some of the CHK1 inhibitors showed promising clinical responses as monotherapies or in combination therapies in patients with gynecological cancers, efficacies were limited due to toxicities. To maximize the potential for efficacy and limited toxicities, we utilized a CHK1 inhibitor formulated as a liposomal nanomedicine since liposomal drugs are reported to alter drug distribution to achieve longer drug retention in plasma and higher accumulation in tumors in preclinical and clinical settings (J Vaage, 1997, Barenholz Y, 2012, Northfelt DW, 1996).
Methods: SMP-3124 is an investigational selective CHK1 inhibitor encapsulated within a liposome. SMP-3124 showed a durable pharmacodynamic response due to the liposomal accumulation in the tumor in an ES-2 ovarian cancer xenograft model.
Results: We confirmed potent anti-tumor activities of SMP-3124 in multiple preclinical subcutaneous xenograft models without weight loss. To further evaluate the potential of SMP-3124, especially in recurrent ovarian cancer, we established a novel preclinical model from the ascites of a patient with multiple treatment-resistant ovarian cancers. The preclinical study using this model revealed resistance to the standard treatment drugs in ovarian cancer, while showing sensitivity to SMP-3124. Furthermore, we investigated the therapeutic potential of SMP-3124 in patient-derived xenograft models of ovarian cancer, including platinum-resistant models generated at Kyoto University. SMP-3124 showed more than 40% tumor regression relative to baseline in seven out of fourteen of the preclinical patient-derived xenograft models and achieved complete remission in three cases. These results support the investigation of SMP-3124 in ovarian cancer patients and the ongoing phase 1/2 study of SMP-3124 in adults with advanced solid tumors overall.

#2904 Synthetic lethal relationship between pharmacologic PARP inhibition and loss of LIG1 in chordoma.

Kwang Seok Lee[1], Tatjana Walther[1], Stefanie Reinhart[2], Lena Wickenhauser[2], Christina Schniederjohann[2], Maria Frolova[1], Dominic Helm[3], Schneider Martin[3], Mikolaj Slabicki[4], Claudia Scholl[2], Stefan Frohling[1]

[1]Translational Medical Oncology, German Cancer Research Center, Heidelberg, Germany,[2]Applied Functional Genomics, German Cancer Research Center, Heidelberg, Germany,[3]Proteomics Core Facility, German Cancer Research Center, Heidelberg, Germany,[4]Krantz Family Center for Cancer Research, Massachusetts General Hospital Cancer Center, Charlestown, MA

Impaired homologous recombination (HR) repair of DNA double-strand breaks (DSB) renders cancer cells sensitive to poly(ADP-ribose) polymerase inhibitors (PARPi). This synthetic lethal relationship is used to treat several epithelial cancers. However, the efficacy of PARPi is often limited by primary or acquired resistance, which might be overcome by rational combination therapies. We previously observed that most patients with advanced chordoma, a spinal neoplasm with no standard treatments, show genomic imprints of HR deficiency without mutations in HR-related genes such as *BRCA1/2 or PALB2*. Notably, a patient with HR-deficient, refractory chordoma responded to the PARPi olaparib for 10 months before developing resistance through a secondary PARP1 mutation (PMID: 30967556). To identify genes whose depletion increases the sensitivity of chordoma cells to olaparib, we conducted a genome-wide CRISPR/Cas9 screen in a patient-derived chordoma cell line (UM-Chor1). We identified several strong synthetic lethal interactors whose depletion conferred higher sensitivity to olaparib than knockout of *BRCA1*. These included *LIG1*, encoding an ATP-dependent DNA ligase involved in Okazaki fragment maturation and base excision repair, and *PRDX1*, encoding an enzyme that mitigates oxidative stress by neutralizing reactive oxygen species (ROS). Functional validation showed that *LIG1* knockout alone had only a minor effect on chordoma cell lines. In contrast, its combination with olaparib induced significant toxicity, associated with increased DSB, as determined by γH2AX staining, G2/M cell cycle arrest, and apoptosis. Furthermore, the screening results could be recapitulated with the second-generation PARPi talazoparib. Proteome analysis of *LIG1*-depleted, olaparib-treated chordoma cells revealed significant downregulation of proteins involved in DNA repair and oxidative phosphorylation. Concomitant phosphoproteome profiling identified increased kinase activity in pathways responsive to ROS, DNA damage, and apoptosis. Proteomic analysis of nuclear fractions revealed that olaparib treatment of *LIG1*-depleted cells upregulated the E3 ligase TRIM4, which collaborates with PRDX1 to mediate cell death caused by oxidative stress. Consistent with this, we observed significant ROS induction in *LIG1*-depleted, olaparib-treated cells. In summary, our integrated genomic and proteomic analysis revealed that *LIG1* loss enhances the effect of PARPi in chordoma cells, suggesting a potential strategy for combination therapies. Further investigation is required to determine if LIG1 is a viable therapeutic target and to unravel the mechanisms underlying olaparib-induced cell death in *LIG1*-deficient chordoma cells. This process may be influenced by the collaborative roles of TRIM4 and PRDX1, offering avenues for future research.

#2905 Combination of the ATR inhibitor, ART0380, with irinotecan for treating ATM-negative tumors.

Helen M. R. Robinson, Desiree Piscitello, Elias Elinati, Lucy Armstrong, Emily Graham, Silvia Peripolli, Giorgia Lillo, Joana F. B. P. Neves, Jayesh Majithiya, Eeson Rajendra, Marina Roy-Luzarraga, Lerin Geo, Vera Grinkevich, Ian C. Smith, Alessandro Galbiati, Arya Ashok Nair, Graeme C. M. Smith

Artios Pharma, Cambridge, United Kingdom

Ataxia telangiectasia mutated (ATM) and Ataxia telangiectasia and Rad3-related (ATR) proteins function in concert to regulate the cellular response to both intrinsic and extrinsic factors that induce replication stress such as oncogene activation and DNA damaging agents. Loss or inhibition of ATR has been well documented to be synthetic lethal with ATM deficiency in cancers and this concept is being explored in clinical trials, however, the efficacy of monotherapy with ATR inhibitors has been limited with objective response rates of ~10%. Here, using a novel ATR kinase inhibitor, ART0380, we provide mechanistic preclinical evidence that exacerbating replication stress with a low dose of the TOPO1 inhibitor, irinotecan, further sensitizes ATM negative tumors to ATR inhibition. This enhanced cancer cell killing by the combination of ART0380 and irinotecan in ATM negative cells is linked to loss of cell cycle control and entry of ATM negative cancer cells into mitosis with DNA damage, leading to mitotic catastrophe. In a range of CDX and PDX mouse models we show that the combination of ART0380 with irinotecan leads to robust tumor growth inhibition and, in some instances, regressions across diverse ATM negative tumor types and is well tolerated. These findings highlight ART0380 in combination with low-dose irinotecan as a promising therapeutic strategy for ATM negative cancers, which supports the ongoing clinical investigation NCT04657068.

#2906 Functional and therapeutic significance of DNA ligase I (LIG1) depletion in triple-negative breast cancer (TNBC).

Anh M. Tran Huynh[1], Sumimasa Arimura[2], Lacey E. Dobrolecki[1], Mariah J. Berner[1], Xuxu Gou[3], Junkai Wang[1], Michael T. Lewis[1], Jason Mills[2], Jun Xu[4], Gloria V. Echeverria[1], Susan M. Rosenberg[5], Christopher J. Lord[6], Simon Powell[7], Jonathan T. Lei[1], Matthew J. Ellis[1], Meenakshi Anurag[1]

[1]Breast Center, Baylor College of Medicine, Houston, TX,[2]Medicine-Gastroenterology, Baylor College of Medicine, Houston, TX,[3]University of California, San Francisco, Houston, CA,[4]Biochemistry, Baylor College of Medicine, Houston, TX,[5]Molecular and Human Genetics, Baylor College of Medicine, Houston, TX,[6]Cancer Genomics, The Institute of Cancer Research, London, United Kingdom,[7]Breast Center, Memorial Sloan Kettering Cancer Center, New York, NY

Background: We recently reported a proteogenomic study of TNBCs that demonstrated a correlation between chemoresistance and heterozygous LIG1 loss, a critical ligase serving DNA replication and repair (PMID: 36001024). Thus, this translational study aims to functionally characterize and investigate therapeutic opportunities driven by LIG1 depletion.

Methods: Heterozygous LIG1 knockouts ($LIG1^{het\text{-}KO}$) were engineered into the non-tumorigenic breast epithelial cell line, MCF-12A. Since TP53 was also mutated in almost all TNBC cases with LIG1 het deletion, $LIG1^{het\text{-}KO}$ was attempted in both $TP53^{wt}$ and $TP53^{null}$ MCF-12A. In contrast to $LIG1^{het\text{-}KO}$ in $TP53^{null}$ model, $LIG1^{het\text{-}KO}$ in $TP53^{wt}$ cells were not viable. Roles of LIG1 in cellular transformation, cell cycle dynamics, and the effect of carboplatin and PARP inhibition (PARPi) on these cells were investigated. RNA-seq was also employed to determine the impact of $LIG1^{het\text{-}KO}$ loss at a molecular level.

Results: $LIG1^{het\text{-}KO}$ in MCF-12A $TP53^{null}$ cell lines enhanced cell migration, decreased epithelial and increased mesenchymal gene expression, suggesting LIG1 depletion induced epithelial-to-mesenchymal transition (EMT). Recapitulating patient data, $LIG1^{het\text{-}KO}$ cells were less responsive to carboplatin than LIG1 intact cells. RNA-seq and western blotting demonstrated upregulated homologous recombination (HR) genes in MCF-12A $TP53^{null,}$ $LIG1^{het\text{-}KO}$ versus MCF-12A $TP53^{null}$ $LIG1^{wt}$ cells. Consistent with enhanced DNA repair, lower DNA repair foci (yH2AX) were observed in $TP53^{null}$ $LIG1^{het\text{-}KO}$ and the proportion of S-phase cells remained unchanged. This suggests that progression through cell cycle was not delayed despite $LIG1^{het\text{-}KO}$, due to compensatory upregulation of HR. To further assess therapeutic vulnerabilities in $LIG1^{het\text{-}KO}$ cells, a published CRISPR KO screen of PARPi was reanalyzed to identify LIG1 loss as a robust determinant of PARPi sensitivity (PMID: 29973717). This was confirmed in genome-wide CRISPR screenings with different PARPi(s) in the MCF-10A $TP53^{null}$ cells. Experimentally, MCF-12A $TP53^{null}$ $LIG1^{het\text{-}KO}$ cells displayed a significant increase in PARPi sensitivity, which was reversed upon over-expressing LIG1. Knocking down LIG1 in the LIG1 intact, HR-proficient TNBC line (MDA-MB-468) induced PARPi sensitivity, while overexpressing LIG1 in the LIG1-low, HR-deficient TNBC cell line (MDA-MB-436) reduced PARPi sensitivity. PARPi and carboplatin in combination was more effective than either drug alone in MCF-12A $TP53^{null}$ $LIG1^{het\text{-}KO}$ cells.

Conclusion: LIG1 depletion drives chemotherapy resistance through EMT and HR pathways activation. LIG1 depleted TNBC tumors could benefit from combination of PARPi and carboplatin, potentially driving future studies to investigate biomarker-guided TNBC treatment strategies.

#2908 WEE1 as a therapeutic target in *TP53* and *ARID1A* concurrent mutant colorectal cancers.

C. Zhang, K. Peng, Q. Liu, Y. Zhu, L. Ai, J. Wang, Q. Huang, T. Liu;
Zhongshan Hospital Fudan University, Shanghai, China

The development of next-generation sequencing (NGS) technology has provided us a comprehensive mutation profile of colorectal cancer (CRC). However, large number of genetic alterations, especially tumor suppressers, remain undruggable. *ARID1A*, as a member of tumor suppresser complex SWI/SNF, is frequently mutated (~9%) in CRC and its mutations contribute to the tumorigenesis of CRC. Recent evidence indicates targeting DNA damage response pathways exhibits promising efficacy in *ARID1A*-mutant cancers. WEE1 is a key regulator of G2/M cell cycle checkpoint, and WEE1 inhibition results in the accumulation of DNA damages and ultimately leads to cell death. Our present study demonstrates that WEE1 inhibitor (WEE1i) exhibits the highest sensitivity [ln (IC50) median difference = -1.85, $P < 0.0001$] among a panel of 199 compounds in *ARID1A*-mutant CRC cells based on GDSC2 dataset screening. As *ARID1A* mutation is considered as loss of function (LoF), *ARID1A* knockout was performed to simulate LoF in multiple CRC cell lines. Notably, *ARID1A* knockout sensitizes *TP53*-mutant, but not *TP53*-wildtype CRC cell lines, to WEE1 inhibitor MK-1775 or ZN-c3. In vivo study also indicated preferable efficacy to MK-1775 in COLO205 *ARID1A* knockout xenografts, compared with their wildtype counterparts. Mechanistically, *TP53*-wildtype cells exhibited robust rebound of P53 and P21 pathway under WEE1i treatment which significantly limited the efficacy. Besides, ARID1A deficiency enhanced replication stress (EdU incorporating assay) and DNA damage (γH2AX) through accumulation of pathological R-loops, which were detected by S9.6 nuclear intensity. Immunofluorescence colocalizing analysis also indicated that after WEE1i treatment, γH2AX signal tended to culminate in S9.6 positive loci, suggesting an R-loop associated DNA damage. These studies paralleled a phase 1b/2 clinical trial with SC0191 (a novel WEE1 inhibitor) based combination therapy in a cohort of late-line metastatic CRC patients (NCT06363552). In this cohort, one patient who had previously undergone 6 treatment regimens and harbored concurrent mutations in *TP53* and *ARID1A*, achieved stable disease for at least five months, accompanied by tumor regression in the liver lesion. In conclusion, our research showed that targeting WEE1 is effective in *TP53* and *ARID1A* mutant colorectal cancers. This therapeutic strategy is being tested in a phase 2 study for mCRC patients.

#2909 Targeting Polθ suppresses CCNE1-amplified cancers via transcription-replication conflicts mediated DNA damage and RAD51 toxicity.

Chuancong Zhu[1], Yu Xu[1], Xuejiao Zhao[2], Gordon B. Mills[2], Ding Ma[1], Qinglei Gao[1], Yong Fang[1]

[1]Department of Gynecological Oncology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China,[2]Department of Cell, Development and Cancer Biology, Oregon Health and Sciences University;Knight Cancer Institute, Portland, OR

Background: CCNE1 amplification is prevalent in various cancers, including ovarian, endometrial, and breast cancers, and is associated with elevated cyclin E levels, chemotherapy resistance, and poor prognosis. Despite its clinical relevance, no approved therapeutic strategies currently target CCNE1-amplified tumors. DNA polymerase θ (Polθ) has emerged as a promising therapeutic target in DNA repair-deficient cancers, such as HRD tumors. However, its function in oncogene-amplified cancers characterized by high replication stress and endogenous DNA damage remains underexplored.

Methods & Results: Public dataset analyses revealed a positive correlation between Polθ and CCNE1 expression across various tumor types in both clinical samples and cancer cell lines. Elevated Polθ expression was linked to worse survival outcomes exclusively in CCNE1-high tumors. Using a doxycycline (Dox)-inducible CCNE1 overexpression HeLa cell model and a panel of CCNE1-amplified, CCNE1-gain, and CCNE1-low cell lines, we demonstrated that CCNE1 overexpression upregulated Polθ expression, enhanced MMEJ repair activity, and increased sensitivity to Polθ inhibitors. Polθ inhibition, achieved through chemical inhibitors or shRNA knockdown, significantly impaired cell viability and exacerbated DNA damage, replication stress, and genomic instability in CCNE1-overexpressing cells. RNA-seq analysis revealed that CCNE1 overexpression promoted replication and transcription initiation events, while immunofluorescence and proximity ligation assays confirmed transcription-replication conflicts (TRCs) as a key outcome of CCNE1 overexpression. Polθ inhibition exacerbated TRC-associated DNA damage, both at the end of early S phase and after a round of cell cycle. In CCNE1-high cells, Polθ inhibition resulted in the accumulation of large RAD51 foci. Unlike normal CCNE1-high cells, where RAD51 foci resolved during cell cycle progression, Polθ inhibition caused persistent foci, indicating failed homologous recombination (HR) repair. Colocalization studies implicated genome G4 sites in this process, suggesting that Polθ compensates for stalled RAD51-mediated repair at G4-prone regions.

Conclusions: Polθ inhibition suppresses CCNE1-amplified tumors by amplifying replication stress, DNA damage, and genomic instability. We propose that Polθ supports tumor cell survival in CCNE1-amplified contexts by resolving TRC-associated DNA damage and toxic HR intermediates. Additionally, CCNE1-induced TRCs primarily occur at G4-prone regions, where Polθ mitigates RAD51 repair failure, underscoring its critical role in maintaining genomic stability under oncogene-induced replication stress.

#2910 Pamiparib-induced replication stress augments the efficacy of temozolomide in GBM PDX models.

Shiv K. Gupta, Ann C. Mladek, Sonia Jain, Katrina K. Bakken, Zeng HU, Brett L. Carlson, Danielle M. Burgenske, Jann N. Sarkaria

Department of Radiation Oncology, Mayo Clinic, Rochester, MN

Temozolomide (TMZ) is the main chemotherapy for GBM, but resistance develops in most patients, highlighting the need for sensitizing strategies. PARP inhibitors (PARPi), which disrupt DNA repair, are being investigated as TMZ-sensitizing agents. Here we evaluated the efficacy and explored molecular mechanisms of pamiparib-mediated TMZ sensitization. In vitro, low concentrations of pamiparib (0.1-1.0 μM) synergized with TMZ and enhanced DNA damage, particularly during the S- and G2/M phases. In vivo, pamiparib monotherapy (0.75 or 3 mg/kg, twice daily) was ineffective, however, TMZ afforded survival benefit in orthotopic patient-derived xenograft (PDX) models (GBM12, GBM22, and GBM84) of *MGMT*-methylated primary GBM. Pamiparib combined with TMZ (25 or 50 mg/kg daily) prolonged survival in GBM12 [median survival 272 vs. 114 days with TMZ (P=0.02), 30 days with placebo (P<0.001)] and GBM22 (median survival 88 vs. 60 days with TMZ (P=0.05), 26 days with placebo, (P<0.001)] but not in GBM84 [median survival 355 vs. 404 days with TMZ (P=0.44), 37 days with placebo (P<0.001)]. These findings align with prior studies indicating that PARPi can potentiate TMZ efficacy in a subset of primary GBM models sensitive to TMZ. TMZ induces cytotoxic DNA adducts, N_7MeG, N_3MeA, and O_6MeG. While N_7MeG and N_3MeA are repaired by base-excision repair (BER), MGMT removes O_6MeG. Suppressed *MGMT* expression, due to promoter methylation, drives TMZ sensitivity in ~40% of primary GBM cases. In *MGMT*-methylated tumors, O_6MeG-thymine mispairs trigger futile mismatch repair, causing replication stress. Although BER is PARP-dependent, BER inhibition did not replicate the TMZ-sensitizing effects of pamiparib. Beyond DNA repair, PARP regulates replication stress by recruiting translocases like SMARCAL1 and controlling endonucleases such as MRE11 and EXO1, protecting stressed forks and nascent DNA. We targeted these components using siRNA and small-molecule inhibitors to elucidate their roles in TMZ sensitization. Unexpectedly, silencing SMARCAL1 or MRE11, or inhibiting MRE11 with mirin, did not affect pamiparib-mediated sensitization in U251 cells. While EXO1 silencing attenuated DNA damage signaling, it had minimal impact on TMZ sensitivity or pamiparib-mediated sensitization. These results suggest that fork protection mechanisms may be epistatic to PARP but redundant for TMZ sensitivity. Alternatively, replication stress may be mitigated by lesion bypass via translesion synthesis (TLS), where replicative polymerases are replaced with low-fidelity polymerases. Consistent with this, silencing RAD18, involved in TLS, enhanced sensitivity to both TMZ and pamiparib, with the combination being more effective than either drug alone. In conclusion, pamiparib enhances TMZ efficacy in a subset of primary GBM. While further *in vivo* validation is needed, TLS deficiency may be a key determinant of pamiparib-mediated sensitization.

#2911 Unravelling the role of AP-1 transcription factor in DNA damage signaling and response (DDR), platinum and PARP inhibitor resistance in ovarian cancers.

Shatha Alqahtani, Rinad Mahmoud, Mashael Algethami, Asmaa Ibrahim, Ahmed Shoqafi, Jennie N. Jeyapalan, Sophie Kellaway, Nigel P. Mongan, Emad A. Rakha, Alan McIntyre, Srinivasan Madhusudan

University of Nottingham, Nottingham, United Kingdom

Background: Hypoxia is a feature of high grade serous ovarian cancer (HGSOC) microenvironment and contributes to platinum and PARP inhibitor resistance. Hypoxia induces activator protein-1 (AP-1) transcription factor (TF) activity leading to sustained proliferation, invasion, metastasis and angiogenesis. The role of AP-1 in DNA damage signaling and repair (DDR) and platinum/PARP resistance is unclear in HGSOC.
Methods: PARP sensitive and resistant HGSOC cells (PEO1, PEO1R) were monitored for the activity of 48 different TFs using a luciferase-based reporter assay. AP-1 subunits including c-JUN, JUND, JUNB, cFOS and FOSL2 were profiled for protein expression under normoxia and hypoxia (1% O_2). PEO1 and PEO1R tumor xenografts were immunohistochemically evaluated for JUNB, FOSL2, MRE11, CA-9 and CD-31 expression. CRISPR knock outs (KO) of JUNB and FOSL2 were generated and investigated for DNA repair gene expression (by DNA repair profiler PCR arrays), whole genome RNA sequencing, proliferation, invasion, cisplatin sensitivity (clonogenic and 3D-spheroids). Functional assays included DNA double strand break (DSB) accumulation, cell cycle progression, apoptosis, immunofluorescence, protein stability assay, co-immunoprecipitation and chromatin immunoprecipitation. The clinicopathological significance of FOSL2, JUNB and MRE11 expression was investigated in 331 clinical epithelial ovarian cancers.
Results: In platinum/PARP resistant PEO1R cells, upregulation of AP-1 transcription activity was evident compared to PEO1. Overexpression of JUNB and FOSL2 proteins was observed in normoxia and hypoxia (1% O_2). PEO1 and PEO1R tumor xenografts showed high levels of JUNB and FOSL2 in tumor hypoxic areas. Compared to controls, JUNB and FOLS2_KO cells were less proliferative and have increased sensitivity to cisplatin/PARPi (olaparib), which was associated with increased DSBs, G2/M cell cycle arrest and increased apoptosis. DNA repair profiling revealed down regulation of several DNA repair genes in KO cells including MRE11, a key DDR factor. JUNB/FOSL2 proteins physically interacted with MRE11 and promoted its stability. RNA sequencing revealed enrichment of pathways such as platinum response, oxidative phosphorylation, translation and others in KO cells compared to control. In clinical cohorts, high FOSL2, high JUNB and high MRE11 expression was significantly associated with shorter progression-free survival (PFS) and worse overall survival (OS).
Conclusion: Our data provides evidence that JUNB and FOSL2 may operate at the hypoxia-DDR interface in HGSOC. JUNB and FOSL2 not only have predictive and prognostic significance but could also be attractive anti-cancer targets including in platinum/PARP resistant HGSOC.

#2913 Preclinical characterization of GSK4418959 (IDE275): A potent, selective, and highly efficacious WRN inhibitor for MSI-H tumors across multiple cancer types.

Yang Lee[1], Phil Landis[2], Nanhua Deng[1], Diana Munoz[3], Jay Prakash Jain[3], Brian T. Jones[3], Edward J. Brnardic[2], Joshua Cottom[2], Jianxia Shi[3], Youyou Zhang[1], Robert Silvers[1], Xin Linghu[3], Ian Young[3], Yang Peng[2], Dawin Khiev[1], Gabriele Picco[4], Mathew Garnett[4], Joshua Taygerly[3], Mike P. DeMartino[2], Claire Neilan[3], Paul Barsanti[3], Michael White[3], Gul Y. Serbest[2], Yanhua Rao[2], Benjamin Schwartz[1], Geeta Sharma[1]

[1]GlaxoSmithKline, Cambridge, MA,[2]GlaxoSmithKline, Upper Providence, MA,[3]IDEAYA Biosciences, San Francisco, CA,[4]Wellcome Sanger Institute, Cambridge, United Kingdom

Large-scale genome-wide CRISPR screens have identified WRN helicase, RecQ family, as a promising synthetic lethal target for microsatellite instability-high (MSI-H) cancers across tumor types. GSK4418959 (IDE275) was discovered as a novel WRN helicase inhibitor to treat MSI-H cancer. Here, we present the cellular and in vivo evidence to demonstrate the selectivity and efficacy of GSK4418959 (IDE275) in multiple MSI-H models across various solid tumor types, including colorectal (CRC), endometrial, and gastric cancers. GSK4418959 (IDE275) demonstrates potent anti-proliferative effects in MSI-H cancer cell lines and patient-derived organoids across multiple tumor types, with no measurable impact on microsatellite-stable (MSS) models. In vivo, GSK4418959 (IDE275) induces tumor regression and activates DNA damage response (DDR) markers in several MSI-H CDX and PDX models across diverse tumor types, including CRC, endometrial, and gastric cancers with varying oncogenic drivers and tumor suppressor mutations, while sparing MSS models. One notable model is an MSI-H CRC PDX derived from a patient who had failed three prior lines of therapy, including the immune checkpoint inhibitor Nivolumab. With its unique binding mode, GSK4418959 (IDE275) showed tumor regression in an MSI-H CRC CDX model resistant to other existing WRN inhibitors. Additionally, GSK4418959 (IDE275) showed efficacy in chemotherapy-refractory MSI-H, HER2-negative gastric cancer patient-derived models. Furthermore, GSK4418959 (IDE275) also demonstrated combinatorial effects with existing standard-of-care therapies to benefit MSI-H cancer patients. These findings underscore GSK4418959 (IDE275)'s potency and highly selective activity against MSI-H cancer models in preclinic, highlighting its potential as a promising treatment option for MSI-H cancer patients in clinical setting, both as in monotherapy for those unresponsive to current cancer treatments and in combination with existing therapies for enhanced clinical benefit.

All studies were conducted according to GSK's Policy on the Care, Welfare and Treatment of Animals and reviewed by the Institutional Animal Care and Use Committee at GSK or by the ethical review process at the institution where the work was performed.

#2914 The WEE1 inhibitor Debio 0123 is synergistic with the PKMYT1 inhibitor lunresertib in preclinical models of ovarian and breast cancer.

Luke Piggott[1], Diana Bianca Rocha Gomes[1], Paula Martinez Sanz[2], Violeta Serra[2]

[1]Debiopharm International S.A., Lausanne, Switzerland,[2]Vall D'Hebron Institute of Oncology, Barcelona, Spain

Background: Debio 0123 is a highly selective and brain penetrant WEE1 inhibitor that has previously shown significant preclinical efficacy in combination with DNA damaging agents and is currently being investigated in several phase 1 clinical studies either as a monotherapy or in combination. WEE1 plays an important role in regulating the cell cycle during the S-phase and at the G2/M transition. Lunresertib (RP6306) is a selective and potent PKMYT1 inhibitor currently in phase 1 clinical studies as a monotherapy or in combination. Like WEE1, PKMYT1 regulates the G2/M transition, arresting cells with DNA damage to permit repair before progressing into mitosis. Herein, we present pre-clinical data that demonstrates the synergistic activity of the lunresertib and Debio 0123 combination in breast and ovarian tumor models.

Methods: Knockdown studies were performed utilizing siRNA against PKMYT1 and WEE1 to explore potential synergistic relationship of these targets in different cancer cell types. *In vitro,* combination efficacy of the selective WEE1i (Debio 0123) and PKMYT1i (lunresertib) was assessed by cytotoxicity in cell lines across different cancer types. Additionally, combination efficacy of lunresertib and Debio 0123 was further assessed *in vivo* in subcutaneous breast and ovarian cancer cell line-derived and patient-derived xenograft models.

Results: Knockdown of either PKMYT1 or WEE1 alone resulted in minor decrease in cell viability, however, concomitant knockdown of both targets resulted in no surviving cell populations. *In vitro*, combination of lunresertib and Debio 0123 resulted in significant synergy (Bliss) at low nM doses of both compounds. *In vivo*, in models of ovarian or breast cancer, monotherapy treatments with either Debio 0123 or lunresertib only resulted in minor tumor growth inhibition. Strikingly, the combination of Debio 0123 and lunresertib at all dose levels and schedules tested across all 5 models resulted in complete and sustained regression of all tumors.

Conclusions: These results demonstrate, in preclinical models of ovarian and breast cancer, the WEE1 inhibitor, Debio 0123, is synergistic with the PKMYT1 inhibitor, lunresertib, and consistently leads to deep and sustained regressions *in vivo*.

#2915 WRN depletion sensitizes the ARID1A-mutated cancers by inducing a distinct DNA damage response.

Jiwon Kim, Sung-Yup Cho

Department of Biomedical Sciences, Seoul National University College of Medicine, Seoul, Korea, Republic of

SWI/SNF complex, which remodels chromatin structure to regulated transcription, is frequently mutated in various cancer types. ARID1A, a critical subunit of the SWI/SNF complex, is mutated in approximately 20% of colorectal cancers. Several synthetic lethal targets have been identified to address ARID1A-mutated cancers in various studies; ARID1B, EZH2, ATR, and AURKA-CDC25C. Notably, around 15% of ARID1A mutations are associated with microsatellite instability (MSI). In this study, we propose that WRN, already established as a synthetic lethal target of MSI cancers, is a promising therapeutic target in ARID1A-mutated cancers. In ARID1A-mutated cancer cells, WRN depletion reduced proliferation and increased apoptosis, underscoring its potential as a selective vulnerability. Interestingly, we observed distinct DNA damage response pathways triggered by WRN depletion depending on the presence of ARID1A mutations. In ARID1A wild type cells, WRN knockdown predominantly activated Chk1, whereas in ARID1A-mutated cells, Chk2 activation was more prominent. Further investigation revealed that ATR and Chk1 expression were downregulated in ARID1A-mutated cells. These findings suggest that Chk1 defects drive Chk2 activation in ARID1A-mutated cancers, presenting a distinct therapeutic opportunity to exploit this differential DNA damage response mechanism in ARID1A-mutated cancers.

#2916 DNA polymerase theta inhibitor, ART6043, potentiates the efficacy of 177Lu- and 225Ac-based radioligand therapies in vitro and in vivo.

Marco Ranzani, Alessandro Cicconi, Joseph Barlow, Paula Costales, Elias Elias, Alessandro Galbiati, Jayesh B. Majithiya, Silvia Peripolli, Eeson Rajendra, Marina Roy-Luzarraga, Nan Shao, Martin L. Stockley, Asmita Thapa, Robert A. Heald, Graeme C. M. Smith, Helen M. R. Robinson

Artios Pharma, Cambridge, United Kingdom

DNA polymerase theta (Polθ) is a DNA repair enzyme critical for microhomology mediated end joining (MMEJ). Loss or inhibition of Polθ has been shown to potentiate external beam radiation in a tumour-specific manner[1,2]. However, the ability of Polθ inhibitors to potentiate open source radiation has not been explored. This potential is pertinent to cancer therapy, as radioligand therapy (RLT), where a radionuclide is targeted to tumour cells by linking to peptides binding tumour-specific receptors, has had recent clinical success, in particular with ^{177}Lu-PSMA-617 for prostate cancer. Hence, we investigated the ability of the clinical Polθ inhibitor, ART6043[3], to potentiate different forms of RLT. Here, we show that ART6043 treatment significantly potentiate the cell killing activity of ^{177}Lu-RLT and ^{225}Ac-RLT in different prostate cancer cell models. Mechanistic studies show that the combination of ART6043 with ^{177}Lu-RLT caused a significant activation of DNA damage response pathways, accumulation of DNA damage and an increase in apoptosis compared to RLT or ART6043 alone. Key findings were confirmed for the combination of ART6043 with ^{225}Ac-RLT.Furthermore, *in vivo* studies in mouse prostate cancer xenografts showed that the combination of ART6043 with ^{177}Lu-RLT induced significant tumour growth inhibition and a significant improvement in median survival with regimens that were well tolerated. This work supports the clinical development of the combination of ART6043 with RLT to improve the clinical efficacy of RLT.

#2917 Utilizing artificial intelligence for the discovery of a novel CNS-penetrating ATR inhibitor.

Sarah Truong[1], Beibei Zhai[1], Louise Ramos[1], Mona Marzban[1], Fariba Ghaidi[1], Peter Guzzo[2], Mehran Khodabandeh[2], Ahmad Issa[2], Seyed A. Saberali[2], Jason Rolfe[2], Sarah Omar[2], Marshall Drew-Brook[2], John Langlands[3], Dennis Brown[3], Jeffrey Bacha[3], Mads Daugaard[4]

[1]Vancouver Prostate Centre, Vancouver, BC, Canada,[2]Variational AI, Vancouver, BC, Canada,[3]Rakovina Therapeutics, Vancouver, BC, Canada,[4]University of British Columbia, Vancouver, BC, Canada

Introduction: Ataxia telangiectasia and Rad3-related protein serine/threonine kinase (ATR) plays a crucial role in regulating DNA damage repair. ATR inhibitors have shown promise against solid tumors, not only as monotherapies, but also in combination with chemotherapy, radiotherapy, and immunotherapy with several clinical trials ongoing. The ATR inhibitors currently in clinical development have low CNS-penetration and are therefore sub-optimal for the treatment of brain tumors and brain metastases. It has been proposed that ATR inhibitors could be used as a monotherapy or could be used to potentiate the cytotoxicity of radiotherapy, one of the mainstay treatments for brain tumors. Development of novel, potent, CNS-penetrating ATR inhibitors could provide a new treatment alternative for patients with few options. Traditional drug discovery methods are time-consuming and costly, necessitating innovative approaches. Here, we describe the application of the Enki™ platform, an artificial intelligence approach, in the discovery of a novel ATR inhibitor for use against brain tumors.

Methods: The Enki™ platform utilizes generative AI and deep machine learning to search a broad chemical space to identify hits. It uses variational autoencoders to optimize many properties simultaneously within the search space, including maximal potency against the primary target, selectivity, ADMET, and physicochemical properties. This platform was used to generate de novo molecules with optimized properties to penetrate the blood-brain barrier and specifically target ATR.

Results: We will present preliminary results from the de novo molecule generation by the Enki™ platform. Validation of in vitro data, including ATR inhibition and selectivity, BBB permeability and metabolic stability, will be described.

Conclusion: The Enki™ platform is being leveraged for the development of a CNS-penetrant ATR inhibitor, significantly accelerating the drug discovery and development process. Use of this system enables a broader exploration of the vast chemical space and refinement of drug properties, both shortening the drug development process and increasing specificity and efficacy of potential therapeutics.

#2918 Wild-type IDH1 inhibition induces BRCAness to sensitize pancreatic cancer to PARP inhibitors.

Mehrdad Zarei[1], Omid Hajihassani[1], Hallie J. Graor[1], Soubhi Tahhan[1], Alexander W. Loftus[2], Faith Nakazzi[1], Semmer A. Ali[1], Vinayak Uppin[1], Luke D. Rothermel[2], Jonothan R. Brody[3], Jordan M. Winter[2]

[1]Case Western Reserve University School of Medicine, Cleveland, OH,[2]University Hospitals, Cleveland, OH,[3]Oregon Health & Science University, Portland, OR

Introduction: Pancreatic ductal adenocarcinoma (PDAC) remains one of the most fatal cancers in the United States. Homologous recombination (HR) deficiency has facilitated the development of targeted therapies like Poly (ADP-ribose) polymerase (PARP) inhibitors. However, only 10-20% of PDAC cases exhibit HR deficiency, leaving a majority of patients without targeted therapeutic options. This study identifies wild-type isocitrate dehydrogenase 1 (wtIDH1), a cytosolic metabolic enzyme, as a critical factor for HR repair in HR-proficient tumors. Inhibiting wtIDH1 disrupts genomic stability, sensitizing HR-proficient PDAC to PARP inhibitors.
Methods: We evaluated wtIDH1 inhibition on HR and non-homologous end joining (NHEJ) activity using DNA repair protein quantification and reporter assays. We also examined its effect on histone methylation. Synergistic anti-tumor effects of IDH1 and PARP inhibitors were assessed through drug combination assays, DNA damage response analysis, and apoptosis quantification. In vivo efficacy was studied in xenograft and orthotopic murine PDAC models.
Results: WtIDH1 inhibition impaired HR repair pathways, induced a BRCAness phenotype by reducing α-ketoglutarate levels, and promoted histone hypermethylation. Combination therapy with IDH1 and PARP inhibitors significantly reduced cell viability in vitro and amplified DNA damage and apoptosis markers. In murine models, co-administration of ivosidenib and olaparib synergistically reduced tumor growth and improved survival compared to monotherapies.
Conclusion: This study uncovers a novel strategy to target HR-proficient PDAC using combined IDH1 and PARP inhibition, demonstrating significant preclinical efficacy. Future studies will focus on optimizing and translating this approach into clinical practice.

#2919 Homologous recombination deficiency in non-small cell lung cancer: genetic and epigenetic causes beyond HRR.

Katerina Tsilingiri[1], Anna Chalari[1], Georgia Christopoulou[2], Alexandra Voutsina[3], Pantelis Constantoulakis[4], Konstantinos Potaris[5], Ioannis Vamvakaris[6], Dora Hatzidaki[7], Georgina Zachou[7], Giannis Vatsellas[8], Vassilis Georgoulias[7], Athanasios Kotsakis[9], **Apostolos Klinakis**[10]

[1]Department of Basic Research, BRFAA, Athens, Greece,[2]Genotypos SA, Athens, Greece,[3]National Hellenic Research Foundation, Athens, Greece,[4]Genotypos S.A., Athens, Greece,[5]Department of Thoracic Surgery, General Hospital of Thoracic Diseases Sotiria, Athens, Greece,[6]Department of Pathology, General Hospital of Thoracic Diseases Sotiria, Athens, Greece,[7]Hellenic Oncology Research Group, Athens, Greece,[8]Greek Genome Center, BRFAA, Athens, Greece,[9]Department of medical oncology, University General Hospital, Larissa, Greece,[10]Department of Rasic Research, BRFAA, Athens, Greece

Introduction: The mechanisms of homologous recombination deficiency (HRD) in non-small cell lung cancer (NSCLC) remain understudied, mainly due to the low prevalence of germline or somatic mutations in relevant genes such as BRAC1/2 in this cancer type. However, recent reports suggest that an important subset of patients present high genomic scarring score (GSS), indicating HRD, although the causes are not always clear. In this work, we examined a cohort of 147 patients and sought to correlate GSS, mutational profile and relevant gene expression with response to PARP inhibition in preclinical functional experiments.
Experimental Procedures: We used next generation sequencing to evaluate the GSS of each primary tumor with a commercially available sequencing kit which also provides information on the genetic status of relevant HRR and other genes. We performed rt-PCR analyses to assess the expression of certain genes, and we established patient-derived xenografts to examine the response of high and low GSS (h-GSS and l-GSS respectively) tumors to PARP inhibition.
Results: 42 out of 147 tumors (28.6%) presented a GSS>50 (h-GSS). The prevalence of germline or somatic mutations in HRR genes was not significantly different between h-GSS and l-GSS tumors (18/42 vs 37/105, p=0.388). On the contrary, TP53 mutation frequency ($p<0.001$) as well as variant allele frequency ($p<0.0001$) correlated significantly with GSS. Expression of HRR genes was marginally higher in h-GSS tumors, whereas expression of the epigenetic factor KMT2C was significantly lower in that subset and presented an inverse correlation with both GSS (p=0.0059) and TP53 variant allele frequency (p=0.02). The growth of h-GSS PDXs was significantly hampered upon PARP inhibition.
Conclusions: Our data show that for early-stage NSCLC, the GSS might be a valuable biomarker to stratify patients who might benefit from PARP inhibition. As this is not dependent on HRR genetic status in this cohort, further experimentation is needed to elucidate the complex relationship between TP53 status, KMT2C expression and HRD.

#2920 ZBP1 antagonizes MRE11-mediated DNA end resection and confers synthetic lethality to PARP inhibition in Ovarian cancer.

Shi Shennan[1], Qiuyang Xu[1], Xuejiao Zhao[1], Gordon B. Mills[2], Qinglei Gao[1], Yong Fang[1]

[1]Tongji Hospital, Tongji Medical College, Wuhan, China,[2]Department of Cell, Development and Cancer Biology, Oregon Health and Sciences University, Portland, OR

Background: DNA double strand breaks (DSB) results in the accumulation of abnormal nucleic fragments in the cytosol, which activates nucleic acid sensors such as cGAS, DHX9, and AIM2, leading to innate immune responses. Intriguingly, these sensors can influence DNA damage repair (DDR) within the nucleus conversely, which might indicate an unexpected feedback loop between these sensors and their functions in both the cytosol and nucleus. ZBP1, is also a classic nucleic acid sensor, which leads to programmed cell death and innate immune responses. Previous studies have demonstrated that ZBP1 plays a significant role in the downstream of DNA damage. However, it remains largely unclear whether ZBP1 exerts upstream feedback effects on DDR.
Methods and Results: ZBP1 was overexpressed in two human tumor cell lines, and its expression was induced in mouse L929 cell lines by IFN-γ. Subsequently, γ-H2AX foci were detected through immunofluorescence staining after DNA damage induced by etoposide, indicating that DNA damage repair was decelerated in cells expressing ZBP1. Immunohistochemical staining on ovarian cancer (OV) tissues demonstrated that the expression level of ZBP1 was positively correlated with that of γ-H2AX. Additionally, Co-IP assay revealed that ZBP1 bound with γ-H2AX, indicating ZBP1 localized to the DSB site. Then the DR-GFP and EJ5/GFP reporter system showed that ZBP1 inhibited Homologous Recombination (HR), but had no significant effect on Non-homologous End Joining (NHEJ). Subsequently, immunofluorescence and chromatin fractions extraction proved that ZBP1 affected DNA end resection. Co-IP assays verified that ZBP1 affected HR by binding to MRE11 and inhibiting MRE11 recruitment to chromatin. Furthermore, a kinase-specific phosphorylation site-prediction program, GPS 6.0, and western blot assay demonstrated that ZBP1 was phosphorylated at Ser106 by ATM, functioning as the initial signal for ZBP1 to inhibit downstream HR. Truncated mutants of ZBP1 for the binding site with MRE11, as well as a dephosphorylation mutation at Ser106, both attenuated the effect of ZBP1 in HR. In Addition, the results of flow cytometry and CCK8 assay on multiple ovarian cancer discovered ZBP1 overexpression cells displayed an enhanced sensitivity to PARP inhibitors. Moreover, the data from NANT study also indicated OV patients with high expression level of ZBP1 have better outcomes.
Conclusions: This study reveals that ZBP1 is binding on the DSB site upon the exogenous DNA damage, where it undergoes phosphorylation at ser106 by ATM and subsequently binds to MRE11 to prevent downstream end resection and inhibit HR, ultimately enhancing the synthetic lethality effect of PARPi. These findings indicates a cellular protective mechanism that prevents excessive repair mediated by ZBP1 and also suggests that PARPi could be an effective treatment strategy for OV with elevated ZBP1 expression.

#2921 SNV5686 a differentiated inhibitor of Werner helicase with potent activity against both WT WRN and WRN-C727S mutant proteins for treatment of MSI-H tumors.

Phillip C.C. Liu, Jeffrey Yang, Daniele Ferrante, Lin You, Mingming Gao, Yu Bai, Qipeng Fang, Yu Li, Zhentian Li, Chunhong He, Liyang Wang, Fei Zhou, Robert Landman, Hewen Zheng, Ken Mukai, Sabiha Chowdhury, Colin Zhang, Chao Qi, Liangxing Wu, Wenqing Yao

Synnovation Therapeutics, Inc., Wilmington, DE

Tumors with defects in mismatch repair genes can present with microsatellite instability (MSI) characterized by expansions of short, repeated DNA sequences. Functional genomic screens revealed that MSI-high (MSI-H) cell lines were uniquely vulnerable to depletion of Werner (WRN) which encodes an ATP-dependent helicase. Importantly inhibitors of WRN phenocopy genetic depletion leading to selective inhibition of MSI-H tumor growth. SNV5686 is a novel, reversible inhibitor of WRN with potent inhibitory activity in biochemical and cellular assays. SNV5686 shows exquisite selectivity against related RECQ helicases. The viability of MSI-H cells is selectively inhibited by SNV5686 through a mechanism involving activation of the DNA Damage response, loss of WRN protein and time- and dose-dependent increases in DNA breaks. In vivo, oral administration of low daily doses of SNV5686 potently depletes WRN and induces p21 in tumors and leads to deep tumor regression in an MSI-H colorectal xenograft model.
Irreversible WRN inhibitors and the non-covalent inhibitor HRO761 leverage binding to CYS727 in the active site to attain potency and selectivity, and published data show that mutation of CYS727 severely abrogates their activity. SNV5686 in contrast retains potent inhibition of WRN-C727S in both biochemical and cellular assays thereby exhibiting a differentiated profile. Acquired resistance to covalent inhibitors against other cancer targets such as EGFR and BTK though mutation of the covalent-bonded CYS (EGFR-C797, BTK-C481) is a well-documented clinical phenomenon. By maintaining potency SNV5686 has the potential to be a best-in-class inhibitor of WRN through its activity against both WT and mutant WRN as well as favorable physical-chemical properties and excellent preclinical PK profile. Furthermore, toxicology studies with SNV5686 have not revealed adverse findings in hematology or clinical chemistry supporting the potential to combine with standard of care agents including chemotherapy. These data support the clinical investigation of SNV5686 for tumors characterized by MSI-H.

#2922 RAD51AP1 deficiency enhances the synthetic lethality of the PARP inhibitors in lung cancer.

Jabunnesa Khanom[1], Nanditi N. Thangaraju[1], Sonia Batan[1], Kunal Kumar[1], Snigdha Ganjikunta[1], Subash Sundaram[1], Nikhil Patel[2], Santhakumar Manicassamy[3], Puttur D. Prasad[1], Muthusamy Thnagaraju[1]

[1]Biochemistry and Molecular Biology, Augusta University, Augusta, GA,[2]Pathology, Augusta University, Augusta, GA,[3]Medicine, Augusta University, Augusta, GA

Lung cancer (LC) is the most common cause of cancer-related death in men and women. Currently, the 5-year survival rate for LC is ~15%. Non-small cell lung cancer (NSCLC) accounts for more than 80% of all LC cases. About two-thirds of all patients with newly diagnosed NSCLC have advanced disease (stage III or IV), and they can be managed using palliative chemotherapy if they cannot benefit from the targeted therapy. The standard primary treatment for these patients is a combination of platinum-based chemotherapeutic agents. However, the critical barrier to using platinum-based chemotherapy is that it has high toxicity, especially nephrotoxicity and myelosuppression, and acquired drug resistance. Therefore, the development of a new and effective therapeutic strategy is a major unmet medical need and should have a high clinical impact on the treatment of NSCLC. Recently, poly (ADP-ribose) polymerase (PARP) inhibitors, Olaparib (AZD2281) and Talazoparib (BMN 673) offer an attractive new therapeutic avenue for the treatment of NSCLC as they are largely less toxic than platinum-based drugs. Although PARP inhibitor treatment alone has a significant impact on the overall survival of NSCLC patients, PARP inhibitors should have more clinical benefit in patients with a deficiency in homologous recombination (HR). RAD51AP1, HR protein involved in DNA repair and chemotherapy resistance. Therefore, the RAD51AP1 deficiency should potentiate the anticancer potential of PARP inhibitors and have a high clinical impact on the treatment of NSCLC, including *KRAS*-mutant NSCLC patients. We found that *RAD51AP1* knockdown significantly enhances PARP inhibitor response in both *KRAS*-wildtype NSCLC cell lines (H1299 and HCC827) and *KRAS*-mutant NSCLC cell lines (H1734 and H358). However, *RAD51AP1* knockdown did not affect the normal lung epithelial cells (HEL299 and HSAEC). *Rad51ap1* knockout mice are resilient in the *KRAS* mutation-induced spontaneous mouse lung cancer (*Rad51ap1*$^{-/-}$*-KrasLA2*) and significantly enhanced PARP inhibitors, Olaparib and Talazoparib, response. However, PARP inhibitor treatment does not have a significant response in *Rad51ap1*$^{-/-}$*-KrasLA2*. *RNA*-seq analysis provides evidence that *Rad51ap1* deficiency enhances chemotherapy response by limiting signaling pathways that are associated with drug resistance and efflux. Overall, our results provide a mechanism-based novel therapeutic strategy for the treatment of NSCLC and the identification of RAD51AP1 inhibitor should have a significant clinical impact on the prevention and treatment of NSCLC

#2923 Targeting DNA repair mechanisms to overcome CIC::DUX4 undifferentiated sarcomas.

Zeinab Kosibaty, Cuyler Luck, Ross A. Okimoto

UCSF - University of California San Francisco, San Francisco, CA

Transcription factor (TF) fusion oncoproteins represent cancer specific alterations that arise from chromosomal rearrangements. Through target gene recognition, TF fusions can disseminate transcriptional responses that collectively work to drive tumorigenesis. Thus, identifying the molecular targets that operate as a disease driving network can potentially uncover key actionable dependencies. We have taken this strategy to dissect the underlying biological mechanism by which CIC::DUX4, a fusion oncoprotein associated with dismal outcomes, drives sarcomagenesis. We and others have defined a CIC::DUX4 fusion mediated network that dysregulates cell-cycle and DNA replication checkpoints. Specifically, CIC::DUX4-mediated *CCNE1* upregulation compromises the G1/S transition leading to high DNA replication stress and conferring a dependence on the G2/M checkpoint kinase, WEE1. WEE1 provides a molecular brake to enable effective DNA repair prior to mitotic entry. Importantly, the mechanism by which CIC::DUX4 regulates DNA repair remains unknown. Here we show that the catalytic subunit of DNA polymerase epsilon (POLE) is essential for DNA integrity and cellular division in CIC::DUX4 sarcoma. Mechanistically, POLE loss increases DNA damage and induces p21-mediated cellular senescence to limit CIC:DUX4 tumor growth *in vitro* and tumor formation *in vivo*. Collectively, we credential POLE as a CIC::DUX4 target and further characterize a functional network through which CIC::DUX4 operates to drive tumor progression and survival.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Growth Factor Receptors and Other Surface Antigens as Targets for Therapy 1

CSTONE Pharmaceuticals, Suzhou, China

Background: EGFR (also known as HER1) is an epidermal growth factor receptor with tyrosine kinase activity implicated in both tumorigenesis and tumor progression, and its overexpression in approximately 70% of colorectal cancer (CRC), 60% of lung cancers, and over 90% of head and neck squamous cell carcinoma (HNSCC) have been shown associated with advanced diseases. Approved anti-EGFR therapies, including cetuximab, pantitumumab, and necitumumab, are widely used in treating the aforementioned malignancies. Amivantamab, a bispecific antibody targeting EGFR and c-MET, has been approved for treating advanced NSCLC with EGFR mutations. HER3, another member of the HER family, is overexpressed in cancers including CRC and lung cancer. The upregulation of HER3 has been reported in tumors when treated with MAPK/PI3K inhibitors, EGFR TKIs, or hormone therapies. Daiichi's HER3-ADC, U3-1402, has shown promising clinical results in advanced EGFR-mutant NSCLC, confirming HER3 as a valid therapeutic target. CS2011 is a bispecific antibody composed of a potent anti-EGFR arm and a fully functional anti-HER3 arm. Unlike anti-EGFR, anti-HER2 or anti-HER3 mono-targeting antibodies, CS2011 inhibits almost all functional membrane dimers formed with HER members, and therefore acts as a broad epithelial growth factor signaling blocker to address tumor heterogeneity effectively.
Methods & Results: The lead molecule of CS2011, J17, was constructed with monovalent arms targeting EGFR and HER3. J17 showed high binding affinities to EGFR or HER3 respectively and dual binding to EGFR & HER3 concurrently, as assessed by BLI. Our data further demonstrated that J17 possessed single-digit nanomolar affinities to EGFR-positive and/or HER3-positive tumor cells, while demonstrating no binding activity to EGFR/HER3-negative cells. J17 induced faster and deeper internalization compared to anti-EGFR and anti-HER3 mono-targeting antibodies. J17 also effectively inhibited EGFR downstream signaling to levels similar to anti-EGFR antibodies. Furthermore, J17 inhibited NRG1 (HER3 ligand)-induced proliferation of A431 cells. *In-vivo* studies further demonstrated potent tumor growth inhibition by J17. J17 also demonstrated favorable stability and developability, achieving yields comparable to those of monoclonal antibodies. Pilot pharmacokinetic (PK) and toxicity studies in cynomolgus monkeys suggested a monoclonal antibody-like PK profile and favorable tolerability at 30 mg/kg.
Conclusion: CS2011 is a promising bispecific antibody for the treatment of various advanced solid tumors. Current preclinical data support further IND-enabling development and clinical research on CS2011.

#2928 Combination surface targeting strategies in relapsed small cell lung cancer (SCLC) to overcome intratumoral heterogeneity associated with treatment resistance.

C. Allison Stewart, Kavya Ramkumar, Runsheng Wang, Yan Yang, Bingnan Zhang, Yuanxin Xi, Lixia Diao, Qi Wang, Alberto Duarte, Ping Li, Azusa Tanimoto, Alejandra G. Serrano, Jody Vykoukal, Mukulika Bose, Loukia G. Karacosta, Luisa Solis Soto, Samir Hanash, Jing Wang, John V. Heymach, Lauren Averett Byers, Carl M. Gay

UT MD Anderson Cancer Center, Houston, TX

Small cell lung cancer (SCLC) is an aggressive neuroendocrine malignancy characterized by rapid onset of chemoresistance and poor clinical outcomes. Following decades of, at best, modest clinical advances, the recent FDA approval of tarlatamab, a DLL3 targeting bispecific T-cell engager (BiTE), alongside unprecedented response rates observed with multiple antibody-drug conjugates (ADCs), have ushered in a paradigm shift towards surface targeting strategies in relapsed SCLC patients. These same agents are demonstrating similar efficacy in more rare high-grade neuroendocrine carcinomas, both pulmonary and extrapulmonary; however, they are being largely tested in unselected populations. While providing much-needed optimism for SCLC patients, resistance, both *de novo* and acquired, is common and must be better characterized to maximize the potential of these new therapeutic classes. We hypothesize that combinatorial targeting of multiple surface proteins using distinct strategies (i.e., BiTEs, ADCs, etc.) represents a novel way to overcome intratumoral heterogeneity common to relapsed SCLC and enhance antitumor immunity engendered by ADC payloads (i.e., topoisomerase 1 [TOP1] inhibitor). To better define the surfaceome of relapsed SCLC, we performed surfaceome mass spectrometry analysis of SCLC cell lines, naïve and relapsed patient derived xenografts (PDXs), and PDXs treated with frontline chemotherapy until relapse occurred, and identified a number of novel and known surface proteins (i.e., TROP2, HER2, B7H3). Surface targeting strategies against HER2, TROP2, and DLL3 are effective in preclinical models (i.e., cell lines and xenograft models) resistant to other common SCLC therapies (i.e., platinum chemotherapy). In particular, ADCs with TOP1 inhibitor payloads were more effective in models with high SLFN11 and target levels, suggesting that sensitivity requires both surface target expression and SLFN11 positivity for greatest response. Notably, single-cell transcriptional profiling of relapsed patient biopsies revealed mutually exclusive expression of surface genes in distinct cell populations, including senescent, drug tolerant persister cells (DTPCs), representing an unique opportunity to target heterogeneous populations. We show that combination targeting against different surface proteins (e.g., DLL3, TROP2, HER2) using both immune (i.e., chimeric antigen receptor T-cells, BiTEs) and payload-based modalities (i.e., ADCs) was more effective than single-agent targeting in resistant, neuroendocrine-low models. Therefore, intratumoral heterogeneity associated with relapsed SCLC, which limits efficacy of single-agent surface targeting strategies, may be exploited with combinatorial therapies to target resistant cell populations, including DTPCs, using payload and immune-based methods.

#2929 LX-101, a novel, clinical stage, payload-bearing targeted therapy directed to the insulin-like growth factor receptor (IGF-1R), demonstrates potent anti-tumor activity in Ewing sarcoma animal models and desmoplastic small round cell tumor.

Matt Hoberman[1], Danh Dinh Truong[2], Roberto Cardenas Zuniga[2], **Joseph A. Ludwig**[2]

[1]Lirum Therapeutics, Inc., New York, NY,[2]MD Anderson Cancer Center, Houston, TX

Objective: Multiple aggressive cancers of unmet need have alterations involving the insulin-like growth factor 1 receptor (IGF-1R) pathway, including gene fusions and/or high IGF-1R expression, that correlate with poor outcomes. In Ewing sarcoma (ES) and desmoplastic small round cell tumor (DSRCT), the gene fusion-produced oncogenic proteins upregulate the IGF signaling pathway. Although prior attempts at inhibiting IGF-1R with non-payload bearing naked monoclonal antibodies or small molecules produced some tumor responses, none of these agents were ultimately approved, potentially due to suboptimal potency and escape mechanisms via redundant signaling. LX-101 is a next-generation, targeted therapy directed to the IGF-1R, consisting of a proprietary IGF-1 variant coupled to a cytotoxic methotrexate payload. LX-101 was previously evaluated in Phase 1 trials of adult patients with advanced, pretreated cancers, where it was well-tolerated and demonstrated single agent activity. Neither a dose limiting toxicity nor a maximum tolerated dose was reached, leaving room for additional dose and schedule optimization. Herein, we investigated the in vitro and in vivo anti-tumor activity of the payload-bearing agent LX-101 in ES and DSRCT.

Methods: ES and DSRCT cell lines were incubated with LX-101 (1 - 10,000 nM) for 72 h. Cell viability was assessed by CellTiter-Glo; IC_{50}s were calculated using GraphPad PRISM software. Pretreatment IGF-1R expression levels were analyzed by RNA-seq & Western blot. NOD-SCID mice bearing subcutaneous A-673 tumors were treated i.v. with vehicle or LX-101 (16 uEq/kg, twice a week, for 3 weeks). Tumor volume and body weight were measured 3 times a week.

Results: LX-101 displayed anti-tumor activity against ES and DSRCT cell lines, including EWSR1::FLI1+ cell lines A-673 (IC_{50} = 693 nM), ES-8 (IC_{50} = 354 nM), and TC-71 (IC_{50} = 199 nM), as well as the EWSR1::WT1+ cell line BOD-DSRCT (IC_{50} = 453 nM). IGF-1R mRNA levels correlated with LX-101 anti-tumor activity. In mice bearing A-673 tumors, LX-101 significantly inhibited tumor volume, in vivo, following twice a week treatment for 3 weeks (55% tumor growth inhibition relative to vehicle group on Day 21, $p < 0.01$). No adverse effects were observed, demonstrating that LX-101 was well-tolerated.

Conclusion: These results demonstrate that LX-101 has potent anti-tumor activity against ES, in vivo and in vitro, and DSRCT, in vitro, providing a differentiated approach from previous IGF-1R targeting agents. These data support further clinical development of LX-101 in ES, DSRCT, and other IGF-1R-involved cancers. Phase 2 clinical trials are expected to begin in 2025.

#2930 Intrinsic payload resistance governs responses to datopotamab deruxtecan, a TROP2 antibody drug conjugate, in pancreatic cancer model systems.

Panot Sainamthip, Kazuki Takahashi, Jiajia Chen, Junning Wang, Julien Dilly, Seema Chugh, David Lui, Andrew J. Aguirre, Harshabad Singh

Dana-Farber Cancer Institute, Cambridge, MA

Introduction-TROP2, a transmembrane glycoprotein encoded by the TACSTD2 gene, is overexpressed in pancreatic cancer (PC) and contributes to cancer progression. Datopotamab deruxtecan (Dato-DXd) is an antibody-drug conjugate targeting TROP2, utilizing a novel linker technology that is only cleaved following internalization. It has demonstrated clinical activity in breast and lung cancers and is under investigation in PC. Determinants of response and resistance to ADCs are not well studied. Here, we investigate predictors of Dato-DXd efficacy in PDAC using in vitro models. *Method*-Twenty six PC cell lines with varying TROP2 mRNA levels were tested using Dato-DXd, isotype control-DXd, and naked toxin DXd in 96-well plates using CellTiter-Glo®. Drug sensitivity was correlated with mechanism based predictors using Pearson's correlation. Cell surface TROP2 was quantified using QIFIKIT; antibody internalization was analyzed using iQue® Human Antibody Internalization Reagent and quantified with Quantum™ MESF microsphere kit. Cathepsin B activity was measured with the Magic Red® Fluorescent Cathepsin B Assay Kit.*Result*-To identify factors influencing response and resistance, we used the ratio of AUC (Area Under the Curve) of Dato-DXd to AUC of Isotype-DXd (AUC Dato/Isotype) as a standardized measure of efficacy. AUC Dato/Isotype approaching 1 indicate no activity of Dato-DXd over isotype control, and lower values signify selective cytotoxicity mediated by Dato-DXd. We noted no activity of Dato-DXd in cell lines lacking surface expression of TROP2 (n = 4), whereas responses varied among TROP2+ lines. To explore predictors of Dato-DXd response in TROP2+ cell lines (n = 22), we examined the relationship of TROP2 mRNA levels, TROP2 surface expression, Dato-DXd internalization, and Cathepsin B activity with Dato-DXd sensitivity, using Pearson correlation. AUC of the DXd (payload) is highly correlated with the Dato-DXd sensitivity ($r = 0.63$, $p = 0.002$). Further review of sensitivity of to DXd showed natural separation of tested models into DXd sensitive and resistant models at 1nM DXd concentration. Lines resistant to DXd at 1 nM showed significantly higher resistance to Dato-DXd (two-tailed t-test, $t = 7.34$, $p < 0.0001$). *Conclusion*-PC in vitro models reveal a range of sensitivities to Dato-DXd. We found that TROP2 expression is necessary but not sufficient for sensitivity to Dato-DXd and intrinsic resistance to payload is highly correlated with resistance to Dato-DXd. Ongoing analyses to identify additional predictors of response to Dato-DXd using whole transcriptome profiles of tested models will be presented.

#2931 AXL-directed surface targeting approaches in recalcitrant pulmonary high-grade neuroendocrine carcinomas.

Kavya Ramkumar, C. Allison Stewart, Yan Yang, Bingnan Zhang, Qi Wang, Yuanxin Xi, Runsheng Wang, Alejandra G. Serrano, Luisa M. Solis Soto, Jing Wang, John V. Heymach, Carl M. Gay, Lauren A. Byers

UT MD Anderson Cancer Center, Houston, TX

High-grade neuroendocrine carcinomas of the lung (hgNECs), which include small cell lung cancer (SCLC) and pulmonary large-cell neuroendocrine carcinoma (LCNEC), are characterized by poor prognoses, limited treatment options and rapid emergence of resistance. While recent surfaceome-directed approaches targeting DLL3, SEZ6, and TROP2 using chimeric antigen receptor T cells (CAR-Ts), bispecific T cell engagers (BiTEs) and antibody drug conjugates (ADCs) show considerable promise in hgNECs, novel strategies to target the heterogenous resistant disease are needed. AXL, a TAM family receptor tyrosine kinase, is known to mediate resistance to chemotherapy, radiation and targeted therapies in SCLC and other cancers, through its roles in epithelial to mesenchymal transition (EMT), DNA damage repair and replication stress tolerance. We hypothesize that targeting cell surface AXL would provide an effective therapeutic strategy in hgNECs, especially for relapsed disease. We analyzed the transcriptomic (bulk and single-cell RNA sequencing) and proteomic (immunohistochemistry) expression profiles of AXL in treatment-naïve and relapsed SCLC, LCNEC and other extrapulmonary hgNECs patient tumors. High levels of AXL expression were seen in distinct tumor subsets. Notably, AXL-high tumors exhibited molecular signatures associated with resistance (higher EMT scores, lower replication stress and cisplatin response). To evaluate AXL as a viable surface target in hgNECs, we generated a preclinical CAR T cell against AXL. Anti-AXL CAR T cells were effective at inducing cytotoxicity in AXL-expressing SCLC and LCNEC cell lines. Similarly, an anti-AXL ADC also showed selective and potent cytotoxicity in AXL-positive models. These findings establish AXL as both a valuable biomarker and a promising target for the drug-resistant hgNECs, supporting the development of AXL-directed therapeutics such as anti-AXL CAR T cells and anti-AXL ADCs.

#2932 GNX1021, a novel ADC targeting glycans with branched Lewis B/Y, demonstrated preclinical tumor control activity in gastric cancer models and favorable safety.

Y.-Y. Chen, C.-C. Chang, W.-H. Lee, C.-K. Chen, Y.-R. Shen, Y.-T. Lin, C.-W. He, Y.-J. Wang, L.-Y. Liu, M.-C. Yang, T.-H. Chang; GlycoNex Inc., New Taipei City, Taiwan

Background: Branched Lewis B/Y (bLeB/Y) is a unique tumor-associated glycan antigen overexpressed in a wide panel of solid tumors including gastric cancer. GNX1021 is a novel bLeB/Y-targeting ADC, linked to the potent antimitotic agent Monomethyl auristatin E (MMAE) via an enzyme-cleavable linker. The mAb backbone of GNX1021 has established safety profile in Ph1 oncology study. Disease control was maintained over 4 months as stable disease in 4/46 advanced solid tumor patients. This study presents *in vitro* pharmacodynamics and *in vivo* anti-tumor activity of GNX1021 in multiple gastric cancer models as well as its safety profile in rats.
Methods: Target engagement was verified via ELISA, with detailed characterization of cell-binding, internalization, and cytotoxicity. Prevalence of bLeB/Y expression and other therapeutic targets are assessed through IHC over TMAs. Next, the *in vivo* efficacy was assessed in cell line-derived xenograft (CDX) models. MMAE-associated PD markers including Ki67 for cell proliferation and cleaved caspase-3 for apoptosis were characterized with IHC in the tumors isolated from CDX models. Nonclinical safety was evaluated in a pilot repeat-dose study of Sprague-Dawley (SD) rats.
Results: The mAb of GNX1021 showed specific binding to bLeB/Y glycans without cross-reactivity to other types of glycans in ELISA. Among the positive-stained solid tumors, bLeB/Y showed high prevalence in 50% to 60% of overall gastric tumors tested, whereas HER2 had a limited expression in less than 10% of the same cohorts. *In vitro* cytotoxicity and internalization of GNX1021 was positively correlated with target expression in gastric cancer cells. Moreover, single administration of GNX1021 at low doses exhibited significant *in vivo* tumor burden reduction activity in high bLeB/Y-expressing gastric models, with sustained efficacy to the study end. The intratumoral activation of cleaved caspase-3 and down-regulation of Ki67 was observed along with tumor control as expected. Furthermore, hematotoxicity of GNX1021 was not detected with weekly administration at a preclinically efficacious low dose over 4 weeks. A mild reduction in neutrophils and reticulocytes was noted as the weekly dose increased to more than the double, while no detectable lesion in bone marrow was correlated with this observation. No obvious sign of hepatic and renal toxicity was identified. In general, GNX1021 was well tolerated in SD rats.
Conclusions: GNX1021, a novel glycan-targeting ADC to branched Lewis B/Y, showed promising preclinical efficacy in gastric cancer models and favorable safety profile in SD rats. Through targeting such a unique glycan, GNX1021 demonstrated strong potential to address gastric cancer patients' unmet medical needs for novel targets.

#2933 IDP-001 is a potent bispecific ADC with in vivo activity against mouse xenograft tumor models expressing EGFR and CDCP1.

Hayley Ma[1], Sophia Romero[1], Anna de Regt[1], Clare Malone[2], Ben Setter[1], Brian Woodruff[1], Hengyu Xu[1], Rob Oslund[2], Niyi Fadeyi[2], Heath Klock[2], Ertan Eryilmaz[2], Pamela Holland[1], Scott Lesley[1]

[1]InduPro, Seattle, WA,[2]InduPro, Cambridge, MA

EGFR is a clinically-validated target that is overexpressed and activated in many human cancers and associated with poor prognosis. However, ADCs targeting EGFR exhibit toxicity due to expression on healthy tissue (1), and EGFR can show heterogeneous tumor expression (2). We utilized InduPro's proprietary MIntTM platform to identify proteins inherently proximal to EGFR on tumor cells. CUB domain-containing protein 1 (CDCP1) was identified as a TAPA (tumor associated proximity antigen) of interest. Like EGFR, CDCP1 is over-expressed in multiple cancers and plays key roles in oncogenic signaling and malignant transformation (3).

IDP-001 is a novel MMAE-conjugated EGFR-CDCP1 bispecific antibody with low DAR. Here we report the preclinical in vivo assessment of IDP-001 in established tumor cell line-derived xenograft (CDX) models representing a range of target expression (measured by flow cytometry and immunohistochemistry) across multiple solid tumor indications. We also generated isogenic pairs of tumor cell lines with CDCP1 knocked out. IDP-001, along with versions of varying EGFR affinity, or monospecific derivatives thereof, were administered I.V. at a single dose in tumor-bearing mice.

Unlike other EGFR ADCs, IDP-001 does not engage immune effector cells and has a serum half-life of ~16 hours in mice. It is well tolerated at all doses evaluated, with no signs of body weight loss. Robust, dose-dependent anti-tumor activity was observed in tumor models with dual-target expression, regardless of expression level. Activity is reduced but not absent in CDCP1 knockout tumors and mice treated with EGFR or CDCP1 monospecific ADC controls, demonstrating more selective anti-tumor activity through co-binding. The activity of IDP-001 was also evaluated in patient-derived xenograft (PDX) models of squamous lung carcinoma, where a high degree of target co-expression is observed in clinical samples. IDP-001 is a first-in-class bispecific ADC with the potential for broad therapeutic activity and best-in-class efficacy. These encouraging in vivo results support advancement of IDP-001 to non-human primate studies.

#2934 Novel hydrophilic CDH17-targeting antibody-drug conjugate exhibits anti-tumor efficacy in preclinical xenograft models.

Yang Ye, Yurong Qin, Xingxing Fang, Xiaoya Liu, Wanting Wang, Tingting Li, Chengze Ni, Chao Chu, Mi Ye, Guojin Wu, Jianming Sun, Yue Zhao, Xiao Huang, Jordan Zhu, Shoupeng Lai, Xiaoqiang Kang, **Hong Ling**

Nanjing Leadsbiolabs Co., Ltd., Nanjing, China

Background: CDH17 is a member of the cadherin superfamily, a group of calcium-dependent cell adhesion molecules critical for organ development, tissue integrity, and cancer progression. In normal tissues, CDH17 is highly restricted to the lateral membrane and hidden within intestinal tight junctions which is inaccessible. In contrast, it is overexpressed and redistributed in 50% to 90% of gastrointestinal cancers, leading to its exposure on the cancer cell surface, therefore becoming more accessible. This unique feature makes CDH17 a promising target for antibody-based therapies. Here, we describe the preclinical development of LBL-054, a novel CDH17-targeting antibody drug conjugate (ADC) that is developed from a humanized CDH17 IgG1 monoclonal antibody conjugated with our proprietary linker-payload platform.

Methods: LBL-054 targeting CDH17 monoclonal antibody was generated using mouse hybridoma technology. The binding affinity of mAb to CDH17 was determined using Fortebio and flow cytometry. The mAb internalization was assessed with anti-Fc-MMAE method. The internalization of both the mAb itself and LBL-054 was assessed by FACS method. Binding of LBL-054 to CDH17 was confirmed in human cancer cell lines and cells engineered to overexpress CDH17. Furthermore, plasma stability of LBL-054 was assessed with LC-MS methods. The killing activity of cancer cells was evaluated on CDH17 positive, negative and the mixed cancer cells. Finally, the anti-tumor effects of LBL-054 were evaluated in xenograft mouse tumor models with pharmacokinetics studies.

Results: LBL-054 exhibited proper affinity, and rapid internalization. In the killing assays with CDH17 positive cancer cells LBL-054 was more potent than LBL-054-Dxd conjugate while LBL-054 was less prone than LBL-054-Dxd conjugate to kill CDH17 negative cells. And also, LBL-054 exhibited stronger bystander effect than LBL-054-Dxd conjugate. LBL-054 was highly stable in plasma stability test. A single dose of LBL-054, which induced tumor regression, was more potent than LBL-054-Dxd conjugate in the xenograft models, and better PK than LBL-054-Dxd conjugate as well.

Conclusions: By conjugating with high potent/bystander/non-pgp substrate TOP1i payload exatecan with a cleavable/hydrophilic linker, LBL-054 targeting CDH17 demonstrates high stability in plasma, robust anti-tumor activity and good tolerability in the xenograft models, supporting clinical development of LBL-054 for patients with CDH17-expressing tumors.

#2935 Development of selective HER2 covalent inhibitors with brain penetration for effective treatment of CNS metastases.

Hyunjin Park, Yu-Yon Kim, Jiyoung Jeon, Sun Young Jang, Young Gil Ahn, Haemin Chon

Hanmi Pharmaceutical Co., Ltd., Hwaseong-si, Korea, Republic of

HER2 alterations, including amplification, overexpression, and mutations, are implicated in the development and progression of brain metastases (BM) and leptomeningeal metastases (LM) across various cancer types. In breast cancer, BM occurs in 15-25% of patients, with up to 50% of HER2-positive cases developing BM, underscoring the importance of HER2 amplification in metastatic progression. Similarly, HER2 alterations are positively associated with a higher risk of LM, affecting up to 25% of HER2-positive metastatic breast cancer patients. Although HER2 alterations are less common in lung cancer and melanoma, the high incidence of BM (20-40% in lung cancer and up to 50% in melanoma) and LM (3-5% in lung cancer and up to 23% in melanoma) highlights the importance of targeting HER2-driven pathways to manage these aggressive metastatic complications. The role of HER2 mutation and amplification in promoting metastatic progression establishes its significance as both a biomarker and target for tailored therapies. BM and LM are associated with poor prognosis and significantly reduced overall survival. Therefore, effective management of BM and LM requires addressing HER2-driven mechanisms, highlighting the unmet need for selective HER2 inhibitors with brain-penetrating properties capable of targeting both HER2 mutants and HER2WT amplification in HER2-altered BM and LM. Herein, we report the development of potent and selective covalent HER2 inhibitors, the Hanmi compounds, which exhibit strong anti-tumor activity in BM and LM models with high selectivity over EGFRWT. The growth-inhibitory effects of these compounds were evaluated in vitro using cell lines harboring HER2G776insVG/C mutations and HER2WT amplifications. Additionally, their anti-tumor efficacy was assessed in BM and LM mouse models. Hanmi compounds significantly reduced tumor burden and markedly improved survival in mice intracranially implanted with HER2WT-amplified N87 cells. Moreover, in the H1781 LM model harboring HER2G776insVG/C mutations, these compounds demonstrated superior efficacy by significantly increasing median overall survival (mOS) and inhibiting tumor growth compared to the approved HER2 targeting agent. These findings highlight the potential of Hanmi compounds as effective treatments for central nervous system (CNS) metastases, including BM and LM, addressing a critical unmet need in the management of HER2-altered metastatic diseases.

#2936 Preclinical characterization of XB371, a novel anti-tissue factor antibody-drug conjugate.

Kathleen Gogas[1], Brian A. Mendelsohn[1], Marlene Hennessy[1], Hui Zhao[1], Jeffrey Higaki[1], Maxine Bauzon[2], Fangjiu Zhang[2], Stepan Chuprakov[2], Robyn Barfield[2], Penelope Drake[2], Seema Kantak[1]

[1]Exelixis, Alameda, CA,[2]Catalent Pharma Solutions, Emeryville, CA

Background: Tissue factor (TF) is a transmembrane glycoprotein that plays an important role in the extrinsic coagulation cascade. TF is aberrantly expressed in various cancers, and its expression is generally associated with poor disease outcomes. XB371 is an anti-TF antibody-drug conjugate, developed using the SMARTag® platform, and is designed to deliver a cytotoxic payload to TF-expressing tumors while minimizing adverse events related to the disruption of TF function, notably bleeding. XB371 is composed of a tandem-cleavage topoisomerase inhibitor-based linker-payload conjugated to a monoclonal antibody that binds to TF with high affinity and does not interfere with the clotting cascade.1 Here, we describe the preclinical characterization of XB371, including its in vitro cytotoxicity, bystander, and immunogenic cell death (ICD) activity, and in vivo efficacy in cell line-derived xenograft (CDX) and patient-derived xenograft (PDX) models.

Methods: In vitro cytotoxicity of XB371 was evaluated in HPAF-II, BxPC3, and A431 cells using a luminescence assay. To evaluate bystander effect, the potency and maximal effect of XB371 on the viability of non-TF-expressing Jurkat cells were compared for a mono-culture of Jurkat cells and co-cultures with TF-expressing MDA-MB-231 cells. ICD activity was assessed by measuring immunostimulatory molecule release (HMGB1) in A431 cells, and monocyte activation and cytokine release in tumor cell/PBMC co-cultures following XB371 treatment. Tumor suppression was evaluated in HPAF-II, BxPC3, and A431 CDX models using a single dose level or a range of doses of XB371. Tumor growth inhibition was assessed in colorectal cancer (CRC) and non-small cell lung cancer (NSCLC) PDX models using a single dose of XB371 (10 mg/kg intravenously).

Results: XB371 displayed potent in vitro cytotoxic activity at subnanomolar concentrations. XB371 demonstrated in vitro bystander cell-killing effect and induced ICD in all assays evaluated. In vivo anti-tumor activity was observed following a single intravenous dose in the HPAF-II, BxPC3, and A431 xenograft models. In the HPAF-II CDX model, XB371 demonstrated dose-dependent anti-tumor activity, with significant increases in median survival and tumor volume quadrupling time at higher doses. A single dose of XB371 inhibited tumor growth in both CRC and NSCLC PDX models. Tumor regression and complete responses were observed in the NSCLC PDX model.

Conclusions: XB371 demonstrated in vitro cytotoxicity, bystander, and ICD activity, and in vivo efficacy across multiple xenograft cell lines and PDX models. Taken together, these preclinical results support further development of XB371; IND-enabling studies are ongoing.

#2937 Animal models for evaluating the efficacy of anti-human HER2 ADC alone or in combination with IO therapy.

Jean Huang, Chong Li, Ruili Lv, Qinjun Wang, Qingqing Xu, Heling Shen, Xiaofei Zhou

Biocytogen, Waltham, MA

Antibody-drug conjugates (ADCs) combine the targeting ability of antibodies with the killing power of cytotoxins, allowing for the release of highly toxic payloads within tumor cells, thereby enhancing therapeutic efficacy while reducing systemic toxicity. ADCs have demonstrated significant efficacy as monotherapy in the treatment of various tumors. However, like many cytotoxic agents, the issue of drug resistance limits the sustained efficacy they can achieve as standalone treatments. To overcome this challenge, the combined application of ADCs with other therapies is becoming a new focus of research. Among these, the combination of immuno-oncology inhibitors (IO) with ADCs has shown strong therapeutic potential in clinical settings. An appropriate preclinical evaluation model can effectively assess the therapeutic potential of ADCs.

Biocytogen developed a HER2-expressing MC38 cell line called B-hHER2 MC38 plus. The HER2 expression level of B-hHER2 MC38 plus is similar to that of the human cell line NCI-N87, and it can form tumors normally in B-hHER2 mice. In a syngeneic transplantation model of B-hHER2 mice with MC38 plus cells, the anti-HER2 antibody-drug conjugate (ADC) analogous to trastuzumab, MMAE, exhibited a dose-dependent tumor suppression effect. When combined with the anti-mPD-1 antibody, it demonstrated a higher tumor suppression rate. In another syngeneic transplantation model where B-hHER2 MC38 plus cells were inoculated into B-h4-1BB/hHER2 mice, the commercial product DS8201 showed significant tumor growth inhibition. In the xenograft models using a diverse array of human tumor tissues - including breast cancer tumor tissues (BP0818 and BP1056), colorectal cancer tumor tissues (BP0170 and BP0847), lung cancer tumor tissues (BP0508 and BP0638), as well as breast cancer cell lines (BT-474 and MDA-MB-231), and the gastric cancer cell line (NCI-N87) - the commercial product DS8201 demonstrated significant tumor growth inhibition.

#2938 Avaren-Fc: a novel lectin-Fc fusion protein for treatment of ovarian cancer.

Katarina Mayer[1], Noel Verjan-Garcia[2], Nobuyuki Matoba[3]

[1]Pharmacology and Toxicology, University of Louisville, Louisville, KY,[2]Center for Preventative Medicine, University of Louisville, Louisville, KY,[3]Pharmacology and Toxicology, Center for Preventative Medicine, and Brown Cancer Center, University of Louisville, Louisville, KY

Ovarian cancer (OVCA) is the deadliest gynecological malignancy and the fifth leading cause of cancer death in females in the United States. Despite advancements in the treatment options, current therapies lack specificity for tumor cells and fail to generate a robust anti-tumor immune response. In this study, we use a novel lectin-Fc fusion protein, named Avaren-Fc (AvFc), to target the abnormal, increased density of *N*-linked high-mannose-type glycans on the OVCA cell surface. Upon binding to clusters of these glycans on malignant cells, AvFc is postulated to induce antibody-dependent cell-mediated cytotoxicity (ADCC) by engaging Fc-bearing effector immune cells, such as natural killer cells. This study explores AvFc's therapeutic potential against OVCA utilizing *in vitro* experiments and *in vivo* evaluations using the syngeneic ID8 OVCA mouse model. AvFc's effects were evaluated utilizing flow cytometry and an *in vitro* luciferase-based ADCC reporter assay using a FcγRIIIa-expressing cell line, where AvFc exhibited dose-dependent binding and demonstrated a variable, yet significant degree of ADCC to four human (A2780, CAOV3, SKOV3, and SW626) and two murine (ID8 and ID8-VEGF-Def2b) OVCA cell lines. The antitumor effects of AvFc were evaluated in the ID8 OVCA model, where mice were intraperitoneally (i.p.) challenged with 2 million ID8 cells and 7 days later AvFc treatment was administered at 25 mg/kg i.p. every other day, for a total of 15 doses. The survival analysis revealed that, as of 28 days post-treatment, 75% of AvFc-treated animals remain alive, in contrast to 40% in the mutant AvFc control group and 0% in the vehicle control group. To assess the impact of this 15-dose regimen of AvFc on the tumor immune microenvironment in the ID8 OVCA model, immune cell profiling was performed at 36 days post-tumor challenge using cytometry by time-of-flight (CyTOF) on both the peritoneal fluid and spleen. CyTOF analysis revealed that AvFc treatment significantly increased total leukocytes ($p<0.05$; one way ANOVA with Tukey's multiple comparisons) including $TCR\gamma\delta^+$, $TCR\beta^+$, and $TCR\beta^+CD4^+$ T cells in the spleen compared to all other treatment groups. Additionally, AvFc treatment significantly increased $CD8^+$ T cells expressing the degranulation marker CD107a in the peritoneal fluid ($p<0.05$) relative to vehicle and healthy controls, suggesting that AvFc treatment induced a significant adaptive immune response against the murine ID8 OVCA challenge. These findings highlight AvFc's promising efficacy and immunostimulatory activity, supporting its potential as a novel targeted immunotherapeutic candidate for the treatment of OVCA.

#2939 The effect of cSNX1.3 on MMTV-PyMT tumor growth and metastasis.

Delina J. Denogean, Barbara Sands, Joyce Schroeder

Molecular and Cellular Biology, University of Arizona, Tuscon, AZ

The Epidermal Growth Factor Receptor (EGFR) belongs to a group of Receptor Tyrosine Kinases (RTKs) that are a part of the HER family. EGFR mediates many processes in the cell including proliferation, migration, and survival however its overexpression is correlated with poor prognosis in several epithelial cancers including Triple Negative Breast Cancer (TNBC). In healthy cells, EGF binds to EGFR dimerizes and undergoes transphosphorylation, and can then be intracellularly imported where it is taken to the early endosome and awaits ubiquitination. This signals readiness to be taken to the lysosome where it undergoes degradation or in some cases, gets recycled. In cancerous cells, however, ubiquitination gets inhibited due to their loss of polarity. This results in failure to signify readiness to be taken to the lysosome which allows EGFR to completely evade degradation and undergo nuclear localization. This process is initiated by the binding of Sorting Nexin 1 (SNX1), a protein responsible for the regulation of trafficking, to EGFR. Considering the interaction between Sorting Nexins and RTKs causes oncogenic activity, it was hypothesized in this lab that a therapeutic that can modify this interaction can alter tumor-specific retrotranslocation. In order to target these interactions, the therapeutic peptide, cSNX1.3, was developed. cSNX1.3 is a cell-penetrating peptide with a Protein Transduction Domain that allows for the delivery of peptides across the cell membrane and into the intracellular domain. cSNX1.3 interacts with EGFR when it's in the long-lived endosome and binds in competition with SNX1. When cSNX1.3 is bound to EGFR, it is able to inhibit the nuclear localization of the RTK and as a result, inhibit its oncogenic activity. In order to fully evaluate the tumor-regressing abilities of cSNX1.3, we used an immunocompetent model of transgenic Whey Acidic Protein - Transforming Growth Factor alpha (WAP-TGFα) mice, whose mammary gland tumors are EGFR dependent. These mice were treated with cSNX1.3 or the control drug, cPTD4, over the course of 4 weeks. After completion of treatment, it was determined that the tumors of the cPTD4-treated mice continued to grow whereas the tumors of the cSNX1.3-treated mice began to regress. We then decided to construct an additional study using another immunocompetent mouse model that would also demonstrate how cancer metastasis reacted to cSNX1.3 treatment, given that metastasis is typically what makes breast cancer fatal in humans. For these reasons, we decided to use a model of transgenic Mouse Mammary Tumor Virus - Polyoma Middle T (MMTV-PyMT) mice. Conducting an evaluation of cSNX1.3 using this model that closely resembles the function of metastatic breast cancer in humans, will allow us to better understand the future of cSNX1.3 as a breast cancer therapeutic for human applications.

#2940 Preclinical development of a next generation antibody drug conjugate (ADC) targeting CDH17 for treatment of solid tumors.

Wei Lian, Qing Zong, Chun Deng, Peng Zou, Liang Xiao, Tongtong Xue, Jiaqiang Cai

MediLink Therapeutics (Suzhou) Co., Ltd., Suzhou, China

Cadherin-17 (CDH17) is a membranous cell adhesion protein predominantly expressed in intestinal epithelial cells. High CDH17 expression is associated with metastatic progression in different cancers that mainly originate from gastrointestinal tracts. YL217 is a novel CDH17 -targeting antibody-drug conjugate (ADC) and built on MediLink's TMALIN® platform, which can release the payload both in the tumor cell and in the tumor microenvironment. This study evaluated efficacy, safety and pharmacokinetic profiles of YL217 in non-clinical studies. YL217 could specifically bind to CDH17 on tumor cell surfaces, followed with payload release both in the lysosome through internalization and in the tumor microenvironment. These translate *in vivo* where YL217 showed superior efficacy in causing tumor regressions and good tolerability in both cell lines and patient-derived xenograft (CDX and PDX) mouse models with low to high CDH17 expression levels. The *in vivo* pharmacokinetics in monkeys showed that YL217 is highly stable with less than 0.1% (molar ratio) payload released in circulation. These non-clinical data suggest the high stability of the linker in circulation as well as efficient payload release in tumors. Moreover, acceptable safety profiles were also noted in monkey GLP toxicity studies. Taken together, preclinical data suggest that YL217 could be further developed in the treatment of CDH17-positive cancer patients.

#2941 Physiologic epidermal growth factor modeling improves sensitivity of KRAS^{G12D}inhibitor MRTX1133.

Lauryn Elise Flannagan[1], Michela Cadarso[1], Eleanor Riedl[2], Md Shahadat Hossan[1], Ethan S. Lin[2], Jeremy D. Kratz[1]

[1]School of Medicine and Public Health, University of Wisconsin-Madison, Madison, WI,[2]University of Wisconsin-Madison, Madison, WI

Background: Pancreatic Ductal Adenocarcinoma (PDAC) remains a formidable cancer type with a median 5-year survival rate of 13%, largely due to ineffective systemic therapy. MRTX1133 is an emerging small molecule inhibitor of KRAS^{G12D} which has been shown to be effective across multiple treatment settings. Epidermal growth factor (EGF) is often integrated at supraphysiologic levels in models of luminal cancer types. Here, we evaluate KRAS^{G12D} targeting as a function of EGF supplementation to understand both sensitivity and selectivity across EGFR signaling.

Methods: Organoids were seeded in low volume 10uL 96 well plate (Ibidi, Inc) with a density of 500 cells per microliter across experimental groups. Organoids were treated with MRTX1133 in serial dilutions with either standard EGF concentrations (50 ug/mL) or physiological (0.5 ug/mL). Brightfield imaging was captured using time course data from 0h to 144h via Cytation 5. Viability was assessed 144 hours post treatment via Cell-Titer Glo assay, to calculate IC50 of MRTX1133 (n= 8). Response to MRTX1133 was tracked via effect size Glass's Delta, which is defined by difference between the mean of control and treatment group normalized to the standard deviation of the control. Protein analysis was performed by western blot for MAP kinase effector signaling.

Results: Removal of EGF in media lead to growth arrest over the course of 5 weeks (+17.8% v. + 120% in control; GΔ = 0.64). Indicating that its addition is required for proper organoid propagation. When established across 5 weeks, physiologic levels of EGF in cultures did not impact the growth of KRAS^{G12D} pancreatic organoids (+101.3% v. 102% in control; GΔ = 0.005). However, the use of physiologic EGF had improved sensitivity to MRTX1133 (IC_{50} 0.46± 11.03 nM) when compared to standard media (IC_{50}=33.6±3.40 nM), which shows a 60-fold decrease in sensitivity. At lower concentrations of MRTX1133 (0.5nM), resistance was observed in standard EGF conditions (+133.8% v. +106.4% in control; GΔ = 0.437), in comparison to physiological EGF media which reduced proliferation (+55.8% v. +85.7% in control; GΔ= -0.47). Western blot analysis revealed few changes between standard media conditions and physiologic when probing for effectors in Ras signaling, such as AKT and EGFR. Treatment of MRTX1133 (10nM) over 72 hours, also did not yield improved inhibition at either media conditions.

Conclusion: Physiologic EGF stimulation yielded improved sensitivity to MRTX1133 in a manner independent of organoid growth rate. While resistance to MRTX1133 can be observed in organoid models, understanding this as a function of accurate EGF stimulation remains a critical need particularly at informing relevant resistance mechanisms. Future work includes evaluating this across a diversity of KRAS^{G12D} cancer models and comparing physiologic EGF across therapeutic screening applications in combination.

#2942 Efficacy of a claudin 18.2/TGFβ bi-specific CAR-T in preclinical mouse models of gastric cancer.

Ralph F. Fleuranvil[1], Naryan Rustgi[1], Michael James[1], Zachary Hammer[1], Thomas J. Ryan[1], Jessica Reyes[2], Melanie L. Munguiam[2], Orit Foord[2], Jiajia Cui[2], Sandra Ryeom[1]

[1]Columbia University Irving Medical Center, New York, NY,[2]ImmPACT Bio, West Hills, CA

Gastric cancer (GC) is one of the 4th leading causes of cancer-related deaths worldwide. For decades, chemotherapy and surgery has been the primary treatment modality, however, the overall five-year survival rate for GC remains at 36% and new therapies are needed. Claudin 18.2, a tight junction protein that is expressed on the GC cell surface, has been validated as a bona fide target in GC with recent FDA approval of zolbetuximab, a Claudin 18.2 directed antibody. Chimeric antigen receptor (CAR)-T cell therapies are human T cells modified to express synthetic engineered receptors designed to target and eliminate cells expressing specific antigens. However, many barriers limit the therapeutic potential of CAR T cells in solid tumors. Our study examined the anti-tumor function of a bispecific Claudin18.2/TGFβ-targeting CAR T-cell candidate in preclinical orthotopic mouse models of GC in an immune competent background, as well as in GC patient-derived organoids (PDO) in an immunodeficient orthotopic mouse model. Our data indicate prolonged tumor suppression in our PDO GC model as well as in our murine gastric tumor-bearing mice treated with Claudin 18.2/TGFβ CAR T cells relative to mice treated with untransduced control T cells. We also demonstrate remodeling of the tumor immune microenvironment in our GC model in an immune competent background with an increase in CD19+ B cells in mice treated with our bispecific Claudin18.2/TGFβ CAR-T versus mice treated with untransduced T cells. Our data suggest that a bi-specific claudin18.2/TGFβ CAR T cell candidate may be an effective therapeutic approach for the treatment of gastric tumors that express Claudin 18.2.

#2943 SWY2321, a novel topoisomerase I inhibitor linked bispecific ADC targeting EGFR/cMet, exhibits potent anti-tumor efficacy.

J. Yang[1], J. Qiao[2], M. Dan[1], **X. Hui**[2], B. Yao[2], C. Yuan[2], M. Wei[1], X. Li[1], X. Lv[1];

[1]CSPC Pharmaceutical Group Ltd., Beijing, China, [2]CSPC Megalith Biopharmaceutical Co., Ltd., Shijiazhuang, China

EGFR and cMet are two important clinically validated targets in cancer therapy. They exhibit overexpression across various cancer types with a poor prognosis. The signaling pathways of EGFR and cMet demonstrate intricate interconnections, with evidence suggesting that activation of one pathway can trigger the other. These interactions contribute to augmented cell proliferation, survival, invasion, ultimately tumor growth as well as therapeutic resistance. Consequently, targeting both EGFR and cMet has the potential to improve treatment in patients with solid tumors characterized by EGFR and/or cMet dysregulated pathways. SWY2321 is comprised of a bispecific antibody against EGFR/cMet, a cathepsin B cleavable linker, and a novel topoisomerase I inhibitor agent. The ADC was constructed on the backbone of the clinically validated monovalent bispecific IgG platform and was engineered with fine-tuned affinity on EGFR and cMet, with the aim of enhancing tumor inhibition capacity while reducing EGFR and/or cMet-driven toxicity in normal tissues. SWY2321 demonstrated in vitro binding to all the tested cancer cell lines with various expression of EGFR and cMet, and showed higher internalization and cytotoxicity on the tumor cells co-expressing EGFR and cMet than single targeted ADC or first in class ADC. Furthermore, SWY2321 had potent efficacies on the tumor xenograft models of different malignant types including non-small cell lung cancer (NSCLC), gastric cancer (GC), cutaneous squamous cell cancer (CSCC), and with various expression levels of these two targets, including $EGFR^{High}cMet^{Low}$, $EGFR^{Low}cMet^{High}$, $EGFR^{moderate}cMet^{moderate}$ and $EGFR^{Low}cMet^{Low}$. The tumor inhibition efficacies of SWY2321 on these models were superior to first in class ADC, and superior to or equivalent to single-targeted ADCs given at the same dose with SWY2321. Especially in EGFR/cMet co-expressed NSCLC NCI-H1975 tumor model, SWY2321 showed excellent efficacy at 1.5 mg/kg single administration. In summary, the promising efficacy of SWY2321 supports that SWY2321 can be an effective treatment targeting multiple EGFR- or cMet- expressing solid tumors.

#2944 Synergistic lethality of combination treatment with Trop2-directed antibody-drug conjugate (IMMU-132) and Apo2L/TRAIL in triple negative breast cancer (TNBC).

Y. A. Addissie, M. Kundu, Y. E. Greer, S. Lipkowitz;
National Cancer Institute, Bethesda, MD

Background: Sacituzumab govitecan (IMMU-132) is an antibody drug conjugate targeting trophoblastic cell surface antigen 2 (Trop2) that's approved for treatment of patients with metastatic TNBC who have received two or more prior systemic therapies. The cytotoxic payload of IMMU-132 is a topoisomerase I inhibitor (SN-38) that kills cancer cells by causing DNA damage. Efforts to enhance the efficacy of IMMU-132 treatment include combination therapy with other agents. Apo2L/TRAIL interacts with death receptors on the cell surface to induce apoptosis in cancer cells, sparing normal cells. We previously have shown that TNBC is most sensitive to Apo2L/TRAIL. We investigated whether combination treatment with IMMU-132 and Apo2L/TRAIL synergistically inhibit TNBC cell growth.

Methods: Human TNBC cell lines treated *in vitro* with IMMU-132 and Apo2L were assessed for cell viability via a propidium iodide-based cell death assay and ATP cell viability assay. The mode of cell death elicited by combination treatment was also investigated by using inhibitors of apoptosis, necroptosis and ferroptosis. Effects of treatment on cell cycle arrest were explored using flow cytometry. *In vivo,* NCr athymic nude (nu/nu) female mice with HCC1806 TNBC xenografts were treated with IMMU-132 and Apo2L after which tumor growth and survival were monitored.

Results: Combination treatment with IMMU-132 and Apo2L synergistically induced cell death in triple negative breast cancer cell lines with high Trop2 expression (e.g. HCC1806, MDA-MB-468) but did not in the Trop2 low expressing MDA-MB-231 cell line. In some Trop2 low TNBC cell lines (e.g. BT-549, SUM-159), combination treatment also showed synergistic induction of cell death, suggesting extracellular deconjugation of the SN-38 cytotoxic payload and diffusion into cells. The synergy seen in Trop2 low TNBC cell lines was abrogated by limiting drug incubation periods - which minimizes the extracellular deconjugation. In contrast, the synergy seen in Trop2 high cells was maintained in these short incubation assays. Caspase activation assays and viability assays with caspase inhibitors showed that the primary mechanism of cell death for Apo2L and combination treatment with IMMU-132 is through apoptosis. Furthermore, flow cytometry-based cell cycle assays showed that IMMU-132 and combination treatment with Apo2L induce cell cycle arrest at the G2/M stage. A xenograft model investigating the effect combination treatment *in vivo* is ongoing.

Conclusions: The data suggest a synergistic effect of combination treatment with Trop2 antibody drug conjugate IMMU-132 and Apo2L/TRAIL in killing TNBC cells.

#2945 PLB-002 is a novel Claudin 6 antibody-drug conjugate for ovarian cancer and testicular germ cell cancer.

Haitao Pan*[1], Qing Zhang*[1], Ganyuan Xiao*[2], Guangchao Zhang[2], Jiaxin Li[3], Ling Xin[2], **Kia J. Puan**[1], Ling Xu[3], Yingdong Lu[2], Mao Yin[4]

[1]Biology, PrimeLink BioTherapeutics, Suzhou, China,[2]Chemistry, PrimeLink BioTherapeutics, Suzhou, China,[3]Analytical, PrimeLink BioTherapeutics, Suzhou, China,[4]R&D, PrimeLink BioTherapeutics, Suzhou, China

Background: Claudin 6 (CLDN6) is a clinically validated target for many solid tumors notably ovarian, endometrial, and testicular cancer. Its expression is restricted to tumor cells and fetal tissues with little or no detectable in normal tissues. As such, CLDN6 represents an attractive therapeutic target for the development of an antibody drug conjugate (ADC). Here, we describe the development and preclinical characterization of a novel ADC called PLB-002, which consists of a highly selective CLDN6 targeting antibody, PLB-002-ab7, conjugated to a FDA-approved microtubule inhibitor, eribulin, via a Primelink Biotherapeutics proprietary enzyme-cleavable linker with an optimized average drug-to-antibody ratio (DAR) of 4.0. PLB-002-ab7 is a novel humanized anti-CLDN6 single-domain antibody (Mw. 78.8 kDa) with highly binding affinity and selectivity to CLDN6 with barely binding to related CLDN family members (CLDN9, CLDN3, and CLDN4) in protein and cell based binding assays.
Methods: The in vitro binding affinity of the PLB-002 was determined by flow cytometry on OVCAR3, PA-1, OVCA429, OV90, and NEC-8 cells. Cell internalization effect was evaluated by an in-direct flow cytometry assay on OVCAR3, PA-1, and OV90 cells. In vitro cytotoxicity was measured using Cell-Titer Glo assay on OVCAR3, OV90, and NEC-8 cells. In vivo anti-tumor efficacy was investigated using several cancer cell derived xenograft (CDX) models of OVCAR3, OV90, and NEC-8 cells, as well as patient derived xenograft (PDX) models of ovarian cancer with CLDN6 high, moderate, low and negative expression. A dose-range finding (DRF) safety study of PLB-002 was performed in cynomolgus monkeys. Pharmacokinetics (PK) and pharmacodynamics (PD) data of PLB-002 in CDX mice were determined by LC-MS/MS method.
Results: PLB-002 exhibited strong binding, rapid internalization effect, and potent antitumor activity in vitro on OV90 (CLDN6 low expression) and OVCAR3 (CLDN6 high expression) cells with nano-molar range of IC50. When evaluated in OVCAR3 and OV90 CDXs of ovarian cancer, NEC-8 CDX of testicular germ cell tumor, and OV PDXs, PLB-002 showed strong tumor regression in a dose-dependent manner, which is consistent with the PK analyses showing high exposure, slow clearance and long half-life for both total antibody and conjugated drug. In a non-human primate study using cynomolgus monkey, PLB-002 showed favorable safety profile with no clinical symptoms of toxicities up to the highest tested dose.
Conclusions: These results show that PLB-002 has remarkable antitumor activity and support the clinical development as a therapeutic ADC for the treatment of ovarian cancer and other CLDN6 expressing solid cancer.
*, Equal contributions.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Growth Factor Receptors and Other Surface Antigens as Targets for Therapy 2
Poster Session

#2949 LX-101, a novel, clinical stage, payload-bearing targeted therapy directed to the insulin-like growth factor receptor (IGF-1R), demonstrates potent preclinical anti-tumor activity against multiple cancer types with elevated IGF-1R expression.

Matt Hoberman

Lirum Therapeutics, Inc., New York, NY

Objective: LX-101 is a next-generation, targeted therapy directed to IGF-1R. LX-101 consists of a proprietary IGF-1 variant coupled to a cytotoxic methotrexate payload. LX-101 was previously evaluated in Phase 1 trials of adult patients with advanced, pretreated cancers, where it was well-tolerated and demonstrated single agent activity. Neither a dose limiting toxicity, nor a maximum tolerated dose was reached, leaving potential room for additional dose and schedule optimization. Multiple aggressive cancers of unmet need harbor alterations affecting the IGF-1R pathway, including gene fusions and/or high IGF-1R expression, that correlate with poor outcomes, including certain subsets of cancers of the breast, head and neck, esophagus, stomach, and lung, as well as Ewing's sarcoma, osteosarcoma, and others. Prior attempts at targeting IGF-1R with non-payload bearing naked monoclonal antibodies or small molecules produced a range of clinical outcomes including some partial and complete responses. None of these agents, however, were ultimately approved, potentially due to redundant signaling, escape pathways, and/or the lack of enrichment for select tumor types with strong ties to the IGF-1/IGF-1R pathway. Herein, we investigated the anti-tumor activity of the payload-bearing agent LX-101 against IGF-1R-expressing cancer cell lines to overcome these past shortcomings.
Methods: Cell lines known to highly express IGF-1R were incubated with LX-101 (~1.6 - 2500nM). Cell viability was assessed by CellTiter-Glo after 4 days. IC_{50}s were calculated using GraphPad PRISM software.
Results: LX-101 displayed high levels of potency against lung cancer (A549, IC_{50} = 29 nM; NCI-H2122, IC_{50} = 10 nM; NCI-H526, IC_{50} = 23 nM), esophageal cancer (TE-1, IC_{50} = 16 nM; KYSE-70, IC_{50} = 7 nM), and stomach cancer (MKN74, IC_{50} = 19 nM; NUGC-4, IC_{50} = 30 nM).
Conclusion: These results demonstrate that LX-101 has potent preclinical anti-tumor activity against multiple cancer cell lines expressing IGF-1R. These data support further clinical development of LX-101 in IGF-1R-involved cancers. New clinical trials are planned.

#2950 Identification of sensitivity predictors and differentiators for HER2-directed ADCs.

Daphne J. F. Kluitmans, Jeffrey J. Kooijman, Janneke J. T. M. Melis, Sabine Wetemans, Jeroen A. D. M. de Roos, Mandy W. E. Drossaert-Smeets, Guido J. R. Zaman

Oncolines B.V., Oss, Netherlands

Antibody drug conjugates (ADCs) is a promising class of anti-cancer drugs that combines a monoclonal antibody with a small therapeutic agent for cell-specific delivery. With many ADCs in clinical trials and over 10 approvals by the U.S. Food and Drug Administration (FDA) since the beginning of this century, it is a rapidly expanding field. However, many clinical studies have been discontinued or terminated because of challenges such as low efficacy or off-target toxicity.

Trastuzumab emtansine (T-DM1, Kadcyla®) and trastuzumab deruxtecan (T-DXd, Enhertu®) are two ADCs approved for HER2-positive (HER2+) breast cancers that share the same anti-HER2 monoclonal antibody, but differ in their payload and linker chemistry. T-DM1 consists of trastuzumab and tubulin inhibitor emtansine (mertansine) connected by a non-cleavable linker, while T-DXd combines trastuzumab and topoisomerase I inhibitor deruxtecan with a cleavable linker. T-DXd is also approved for non-HER2+ breast cancers, which reflects that the ADCs have different effects on tumors even though they share the same antibody. Further insights into the cellular targeting of the two ADCs and their respective free payloads may help in better understanding important differences.

T-DXd and T-DM1 were profiled on 108 cancer cell lines in cell viability assays. Additionally, the free payloads, trastuzumab and the small molecule HER2 inhibitor tucatinib were profiled as single agents on the same cell lines. The cell line panel represents a broad range of tumor types including seven HER2+ cell lines. All cell lines were incubated with a 9-point dose range of each drug, followed by intracellular ATP readout to determine the cell viability. Half-maximum inhibitory concentrations (IC_{50}) were used for bioinformatic analyses to identify response predictors or differentiators based on genomic, transcriptomic and proteomic status of the cell lines.

Comparison of cell line responses between the ADCs and their free payloads showed a higher selectivity of the ADCs. Linking trastuzumab to deruxtecan or mertansine thus improves selectivity *in vitro*. Nonetheless, the ADCs targeted more cell lines than trastuzumab alone, showing that the ADCs also have non-antibody directed effects. Additionally, the HER2+ cell line SK-OV-3 showed striking resistance to T-DXd (IC_{50} > 10,000 ng/mL), while T-DM1 effectively targeted this cell line (IC_{50} = 393 ng/mL). Although a significant Pearson correlation between *ERBB2* (HER2) upregulation and sensitivity to T-DXd (r = -0.39) and T-DM1 (r = -0.63) was found, the results above show that HER2 status alone is not sufficient for response prediction of HER2-directed ADCs. Other sensitivity predictors were determined by bioinformatic analyses on resistant HER2+ and sensitive non-HER2+ cells. This study provides insights into sensitivity predictors and differentiators of the two HER2-directed ADCs and the small molecule HER2 inhibitor tucatinib.

#2951 Development of TNFR2, TNFR1 and LTBR humanized mouse model for evaluating anti-human LTBR antibodies.

Qiurong Wang, Chong Li, Zhixia Li, Zan Zhang, Jiansu Zhang

Biocytogen, Waltham, MA

The Lymphotoxin B receptor (LTBR) is primarily expressed on epithelial, stromal, and myeloid cells. LTBR signaling has diverse roles, including regulation of lymphoid organ development, induction of tertiary lymphoid structures (TLS), and promotion of liver regeneration. Recently, the therapeutic strategy of activating LTBR to induce and mature TLS has gained momentum, with LTBR-targeting antibodies now advancing into clinical trials. However, traditional preclinical models generally lack expression of human LTBR, which limits the progress of anti-human LTBR antibody development.

To address this, Biocytogen has developed a humanized mouse model expressing TNFR1, TNFR2, and LTBR through Biocytogen proprietary gene editing technology, known as B-hTNFR2/hTNFR1/hLTBR mice. In these mice, humanized TNFR1, TNFR2, and LTBR expression is detected in granulocytes, regulatory T cells, and macrophages, respectively. Testing of anti-human LTBR antibodies in this model has shown effective tumor growth control, underscoring the B-hTNFR2/hTNFR1/hLTBR mouse as a valuable preclinical platform for in vivo evaluation of anti-human LTBR antibodies.

#2952 The oncomucin MUC4 EGF domains: A new paradigm to target ErbB/HER and RTK receptors in pancreatic adenocarcinoma using inhibitory small molecules.

Tristan Girgin, Nicolas Stoup, Elsa Faillon, Maxime Liberelle, Nicolas Lebegue, Isabelle Van Seuningen

Inserm, Lille, France

Pancreatic adenocarcinoma is one of the deadliest cancers with an increasing incidence. It is mainly due to absence of diagnosis and no effective treatments, and a strong resistance to therapies. It is thus crucial for this devastating cancer to find new therapeutic alternatives. In this aim, we work on the interaction of the mucin MUC4 with receptor tyrosine kinases (RTK), and the targeting of MUC4 using small inhibitory molecules. MUC4, a large glycoprotein overexpressed at the surface of pancreatic cancer cells, is associated with poor prognosis of the tumor, increase of proliferation and migration as well as apoptosis and resistance to therapies. Moreover, we have shown that MUC4EGF domains interact with and upregulates the activity of ErbB2/HER2, this complex being a strong promoter of tumorigenesis. Use of small inhibitory molecules would circumvent the steric hindrance played by MUC4 glycosidic chains. We have now, using molecular dynamics and peptide library screening, identified a specific MUC4EGF domain inhibitory peptide (i) capable of inhibiting MUC4-ErbB2 complex formation and activity, (ii) having anti-proliferative activity and (ii) resensitizing pancreatic cancer cells to Trastuzumab and Pertuzumab ErbB2-targeted therapies.During these studies, we also observed that MUC4 interaction with ErbB2 led to the activation of the other members of the ErbB/HER family as well as other RTKs showing structural similarities with the ErbB/HER family. Our hypothesis is thus that MUC4 may play the role of an oncogenic interaction platform at the surface of pancreatic cancer cells. The interactions between MUC4 and the ErbB/HER family, Met, Axl, EpCAM, and IGF-1R were studied and characterized using Proximity Ligation Assay, MicroScale Thermophoresis, co-immunoprecipitation, GST pull-down. Our results show that MUC4 interacts directly via its EGF domains with and activate ErbB1,3,4, Met, Axl, IGF-1R and EpCAM. These interactions (i) are independent of ErbB2 expression and (ii) activate downstream oncogenic signaling pathways to maintain proliferation and migration capacities of pancreatic cancer cells. At this time, other drugs (tyrosine kinase inhibitors, mAbs) are currently being screened in association with our MUC4 inhibitory peptide to find the best therapeutic combination possible. Taken together, these results provide new paradigms on the inhibitory small molecule-based therapeutics targeting of ErbB/HER and RTK receptors as partners of the oncomucin MUC4 in pancreatic cancer but also in all epithelial cancers overexpressing these complexes.

#2953 CS5006: A novel integrin β4-targeted antibody-drug conjugate (ADC) with robust antitumor activity in preclinical studies.

Chuan Wang, Yamin Wang, Xinling Zhang, Ning Zhang, Yilin Huo, Yongwang Li, Xuelian Liu, Mengyao Zhu, Jingyu Sun, Yongli Yang, Yuxin Qian, Xueqin Dai, Fei Ma, Yi Sun, Jianxin Yang

CSTONE Pharmaceuticals, Suzhou, China

Background:The integrins are a family of cell surface receptors existing as heterodimers formed with one α subunit and one β subunit, and there are 24 heterodimers identified so far. These receptors play diverse roles in cellular adhesion, motility, and cytokinesis. Integrin β4 (ITGB4), also known as CD104, binds to integrin α6 (ITGA6) to form α6β4 integrin heterodimer that is recognized as a ligand of laminin and plays a critical role in strengthening and stabilizing the skin. The cytoplasmic tail of ITGB4 contains approximately 1000 amino acids which is longer than any other integrin β subunit. ITGB4 interacts with and plays important roles in multiple tumor-promoting signaling pathways including ErbB2, PI3K, FAK/AKT, and c-MET, and has been frequently reported as a potential prognostic and predictive marker in various cancers.
Methods & Results: Utilizing our proprietary AI-based target identification platform, ITGB4 was identified as a promising therapeutic target for multiple malignancies. Immunohistochemistry (IHC) staining confirmed high ITGB4 expression in tumor tissues from patients with colorectal carcinoma (CRC), non-small cell lung cancer (NSCLC), squamous carcinoma of head and neck (SCCHN) and esophageal squamous cell carcinoma (ESCC). CS5006, an ITGB4-targeted ADC, comprises a humanized anti-ITGB4 antibody, a proprietary CSL linker, and the well-validated topoisomerase 1 inhibitor exatecan (EXd). The plasma-stable, hydrophilic, beta-glucuronide CSL linker enables effectively tumor-selective toxin release. Both CS5006 and the humanized ITGB4-targeted antibody H86.2 exhibited selective binding to ITGB4 with high affinity, and triggered rapid, high-level internalization. *In vitro* cytotoxicity assays demonstrated CS5006's potent, target-dependent killing of ITGB4-expressing tumor cell lines. CS5006 also showed robust in vivo antitumor activity in CDX models originated from multiple cancer types, with minimal effective dose (MED) of 5 mg/kg. Pilot toxicity studies in non-human primate demonstrated a favorable safety and pharmacokinetics (PK) profile of CS5006.
Conclusion: CS5006 is a novel ITGB4-targeted ADC with robust preclinical efficacy and a favorable safety and PK profile. These findings support further IND-enabling and clinical evaluation of CS5006 as a promising ADC therapy for various advanced solid tumors.

#2954 CS5007: A novel EGFR and HER3 dual-targeted antibody-drug conjugate (ADC) with potent antitumor activity in preclinical studies.

Chuan Wang, Yamin Wang, Ning Zhang, Xinling Zhang, Yongwang Li, Yuxin Qian, Yongli Yang, Mengyao Zhu, Xuelian Liu, Yaxin Chen, Fei Ma, Yi Sun, Jianxin Yang

CSTONE Pharmaceuticals, Suzhou, China

Background: EGFR (also known as HER1) is an epidermal growth factor receptor with tyrosine kinase activity implicated in both tumorigenesis and tumor progression, and its overexpression in approximately 70% of colorectal cancer (CRC), 60% of lung cancers, and over 90% of head and neck squamous cell carcinoma (HNSCC) has been shown associated with advanced diseases. EGFR has been clinically validated as a therapeutic target for ADC. For instance, MRG003, an EGFR-targeted ADC, has shown encouraging clinical outcomes in NPC and HNSCC. HER3, another HER family member, is overexpressed in CRC and lung cancer. The upregulation of HER3 has been reported in tumors when treated with MAPK/PI3K inhibitors, EGFR TKIs, or hormone therapies. Daiichi's HER3-ADC, U3-1402, has shown promising clinical results in advanced EGFR-mutant NSCLC, confirming HER3 as a valid therapeutic target for ADC. Additionally, BL-B01D1, an EGFR/HER3 bispecific ADC, has shown encouraging phase 1 data in advanced cancers. CS5007 is designed to be a potential best-in-class, dual-targeted ADC with 1) fully functional EGFR/HER3 targeted arms to tackle tumor heterogeneity; 2) a proprietary, hydrophilic and stable beta-glucuronide linker to ensure mAb-like PK profile and tumor selective cleavage; and 3) a clinically validated, potent and well-tolerated topoisomerase 1 inhibitor exatecan (EXd).
Methods & results: CS5007 demonstrated high-affinity binding (single digit nM) to EGFR single-positive (A431), HER3 single-positive (SW620), and EGFR/HER3 double-positive (BxPC3, FaDu) tumor cells, comparable to its naked bispecific antibody. CS5007 also triggered high-rate internalization on these cells, resulting in efficient cell killing, thus posing the potential to address tumor heterogeneity by targeting tumor cells expressing either or both of EGFR and HER3. In the *in vivo* studies using CDX models, CS5007 demonstrated robust, antigen-dependent tumor growth inhibition across a range of EGFR and HER3 expression levels. Its efficacy was comparable or superior to the control ADCs composed of the same bispecific antibody with GGFG-DXd and to the monospecific (targeting EGFR or HER3) ADCs bearing GGFG-DXd. CS5007 was well tolerated in rodent with maximum tolerated dose (MTD) at 200 mg/kg and demonstrated a mAb-like PK profile. Its stability in circulation was confirmed in the human/cynomolgus monkey serum incubation assays. In pilot cynomolgus monkey studies, CS5007 was well tolerated at 30 mg/kg administered three times with two weeks interval, with toxicokinetic data confirming its excellent circulating stability.
Conclusion: CS5007 is a promising dual-targeted ADC that demonstrates potent antitumor efficacy with a favorable safety and PK profile. These preclinical findings support its further IND-enabling studies and clinical investigations for the treatment of various advanced solid tumors.

#2955 Preclinical development of TJ101, a potent bispecific ADC targeting EGFR and B7-H3 for the treatment of solid cancers.

Li Qi, **Shugaku Takeda**, Yangxin Zhang, Mao Huang, Dongdong Zhou, Yanli Mao, Zhaoyuan Chen, Siyi Hu

Phrontline Biopharma Co., Ltd, Shanghai, China

Antibody-drug conjugates (ADCs) have emerged as a promising class of targeted therapeutic agents; however, off-tumor toxicity and drug resistance remain as major challenges. Bispecific ADCs are designed to target two distinct antigens or different epitopes on the same antigen. Compared to monoclonal antibody ADCs, bispecific ADCs can enhance targeting to the tumors that co-express both antigens and reduce the likelihood of off-tumor toxicity. EGFR is a validated cancer therapeutic target that is upregulated in various solid cancers such as lung, head and neck, breast, and kidney cancers. Activation of EGFR through mutation, overexpression, or amplification drives proliferation, survival, and metastasis of tumor cells. The B7 family protein B7-H3, also known as CD276, is widely overexpressed in a range of solid cancers including non-small cell lung cancer (NSCLC), small cell lung cancer (SCLC), head and neck squamous cell carcinoma (HNSCC), prostate cancer, and breast cancer. Notably, B7-H3 expression is limited in normal tissues, making it an attractive target for ADC approaches. Interestingly, EGFR is co-expressed with B7-H3 in the majority of lung cancer and HNSCC cases (TCGA dataset) and in many solid cancer cell lines (DepMap Portal). TJ101 is a bispecific ADC directed against human EGFR and B7-H3. Its backbone is a natural IgG1 format bispecific antibody heterodimerized using knobs-into-holes (KIHs) technology. The affinity of the parental humanized anti-EGFR antibody is reduced to minimize on-target toxicity, while the anti-B7-H3 antibody retains high affinity. The warhead of TJ-101 is PY-4car2, a novel payload derived from camptothecin, conjugated with a cleavable linker. TJ101 exhibited synergistic internalization and cytotoxicity in multiple cancer cell lines expressing EGFR and B7-H3. Inhibition of antigen binding through pre-treatment with parental unconjugated antibody prevented the cytotoxicity of TJ101. TJ101 treatment in NSCLC, HNSCC, and colon cancer CDX models demonstrated potent, dose-dependent anti-tumor activity. Importantly, TJ101 also achieved significantly better anti-tumor activity than monoclonal anti-EGFR or anti-B7-H3 ADCs in EGFR/B7-H3 co-expressing models. Furthermore, single administration of TJ101 produced durable tumor regressions in PDX models derived from NSCLC, SCLC, HNSCC, breast cancer, and esophageal cancer. TJ101 was well-tolerated in a non-GLP toxicity study in cynomolgus monkeys with the highest nonseverely toxic dose (HNSTD) exceeding 30 mg/kg. In summary, TJ101 is a promising bispecific ADC with highly potent anti-tumor efficacy across multiple solid cancer types and preferable toxicity profiles, enabling an increased therapeutic index. Additionally, the dual-targeting approach of TJ101 offers a significant advantage in overcoming potential tumor resistance that may arise during future clinical applications.

#2956 Anti-tumor activity of camptothecin analog conjugate of a RSPO4-based peptibody targeting LGR4/5/6 in preclinical models of colorectal cancer.

Yukimatsu Toh[1], Ling Wu[1], Jianghua Tu[1], Zhengdong Liang[1], Adela M. Aldana[1], Li Li[1], Jake J. Wen[1], Sheng Pan[1], Julie H. Rowe[2], Martha E. Hensel[3], Carolyn L. Hodo[3], Rick A. Finch[3], Kendra S. Carmon[1], Qingyun J. Liu[1]

[1]Center for Translational Cancer Research, Brown Foundation Institute of Molecular Medicine, McGovern Medical School, University of Texas Health Science Center at Houston, Houston, TX,[2]Department of Internal Medicine, McGovern Medical School, University of Texas Health Science Center at Houston, Houston, TX,[3]Department of Comparative Medicine, Michale E. Keeling Center for Comparative Medicine and Research, University of Texas MD Anderson Cancer Center, Bastrop, TX

Antibody-drug conjugates (ADCs) have emerged as a major modality of targeted cancer therapy, yet no ADC has been approved for colorectal cancer (CRC). LGR4/5/6 (leucine-rich repeat containing, G protein-coupled receptor 4, 5, 6) are three related receptors that are expressed at high levels together or alternately in nearly all cases of CRC. ADCs targeting LGR5 have been shown to have robust anti-tumor potency, but not all CRC cells express LGR5 and LGR5-positive tumor cells may lose LGR5 expression due to cancer cell plasticity. R-spondin 4 (RSPO4) is a natural protein ligand of LGR4/5/6 with high affinity for all three receptors. We fused a mutant form of RSPO4 that retains high affinity binding to LGR4/5/6 to IgG1 Fc to create a peptibody designated R462. Conjugation of R462 with a camptothecin analog (CPT2) at eight drugs per peptibody led to the synthesis of R462-CPT2 that showed highly potent cytotoxic activity in vitro in CRC cell lines expressing any of LG4/5/6. In cell line xenograft and PDX models of CRC, R462-CPT2 demonstrated robust anti-tumor effect. Importantly, R462-CPT2 showed no major adverse effect at therapeutically effective dose levels. These results strongly support the use of RSPO ligand drug-conjugates that target LGR4/5/6 simultaneously for the treatment of CRC.

#2957 Establishing preclinical activity of topoisomerase I inhibitor (TOPO1i) antibody-drug conjugate AZD9592 in patient-derived xenograft (PDX) models of metastatic colorectal cancer (mCRC) in context of irinotecan pretreatment and resistance.

Mel Ehudin[1], Lara McGrath[2], Simon Christ[3], Italia Grenga[2], Fernanda Arnaldez[4], Frank Comer[4], Edward Rosfjord[4]

[1]Oncology R&D, AstraZeneca, Gaithersburg, MD,[2]Early Oncology R&D, AstraZeneca, Waltham, MA,[3]Computational Pathology, AstraZeneca, Munich, Germany,[4]Early Oncology R&D, AstraZeneca, Gaithersburg, MD

Background: Each year an estimated 1.9 million people are diagnosed with colorectal cancer worldwide and approximately 930,000 people die due to mCRC. The TOPO1i irinotecan is used frequently in combination chemotherapy regimens to treat mCRC that cannot be managed with surgery. Colorectal tumor cells often overexpress the cell membrane proteins epidermal growth factor receptor (EGFR) and mesenchymal-epithelial transition tyrosine kinase receptor (cMET). Overexpression of either EGFR or cMET is associated with cancer progression and poor clinical prognosis in mCRC. AZD9592 is a bispecific antibody-drug conjugate that binds EGFR and cMET and delivers a TOPO1i payload.

Methods: We evaluated a set of 9 colorectal PDX models with a broad range of EGFR and cMET protein expression. Eight of these models were mCRC obtained from tumors biopsied from the liver (n=7) or lung (n=1). We evaluated these models for a response to AZD9592 (administered in a single dose at 2, 4, or 8 mg/kg), irinotecan, or irinotecan plus oxaliplatin. We also examined whether AZD9592 induced responses in PDX models with tumors that progressed after irinotecan treatment. A response was defined as ≥30% tumor volume reduction from baseline.

Results: A single dose of AZD9592 resulted in responses in 100% (9/9) of tumors treated with 8 mg/kg, 67% (6/9) of tumors treated with 4 mg/kg, and 33% (3/9) of tumors treated with 2 mg/kg. A single dose of irinotecan resulted in a response in 33% (3/9) of tumors. Irinotecan plus oxaliplatin resulted in a response in 55% (5/9) of tumors. Subsequent dosing with AZD9592 was feasible in 4 of the PDX models that did not respond to irinotecan; responses to a single dose of AZD9592 were observed in 50% (2/4) and 75% (3/4) of these models treated with 4 or 8 mg/kg, respectively. A similar experiment was conducted in 2 of the 4 models that did not respond to irinotecan plus oxaliplatin; a response was observed in 1 of these models with subsequent AZD9592 dosing at both 4 and 8 mg/kg. We also evaluated the effect of multiple doses of AZD9592 on the magnitude and duration of response. In 22% of mCRC PDX models (2/9), multiple doses of AZD9592 increased the magnitude of response at 4 mg/kg compared to a single dose. In 78% of models (7/9), multiple doses of AZD9592 4 mg/kg increased the duration of response. Dosing AZD9592 every 3 weeks improved the magnitude of response in some models and increased the time until tumor relapse.

Conclusions: AZD9592 was effective in mCRC PDX models, even at the lowest doses tested. AZD9592 was effective in mCRC PDX models that did not respond to irinotecan-based treatment. Ongoing research is evaluating whether multiple doses of AZD9592 can induce resistance in PDX models, and potential resistance mechanisms are being assessed by molecular characterization.

#2958 SAR408701: An anti-CEACAM5-maytansinoid antibody-drug conjugate to treat CEACAM5-positive neuroendocrine prostate cancer (NEPC).

Loic Poiraudeau[1], Bigot Ludovic[1], Cedric Pobel[1], Naoual Menssouri[1], Marine Aglave[1], Catline Nobre[1], Alice Bernard-Tessier[1], Natacha Naoun[1], Anna Patrikidou[1], Claudio Nicotra[1], Maud Ngocamus[1], Benjamin Besse[1], Karim Fizazi[1], Jean-Yves Scoazec[1], Anne-Marie Lefebvre[2], Celine Nicolazzi[2], Nathalie Mace[2], Anne-Laure Bauchet[2], Yohann Loriot[1]

[1]Gustave Roussy, Villejuif, France,[2]Sanofi, Vitry sur Seine, France

Background: Neuroendocrine prostate cancer (NEPC) is a very aggressive subtype of metastatic castration-resistant prostate cancer (mCRPC), for which therapeutic strategies are currently lacking. NEPC is rare *de-novo* (<1% of the cases) but can represent 15 to 20% of cases after failure of the treatment targeting the androgen receptor (AR) axis (such as enzalutamide, abiraterone) in. Carcinoembryogenic antigen-related cell adhesion molecule 5 (CEACAM5) has been previously identified as an attractive NEPC cell surface antigen. Here, we investigate its expression in NEPC patient specimens and its therapeutic potential as a target for Antibody-Drug Conjugate (ADC) therapy.

Methods: Tumor biopsy specimens were obtained from the prospective trial MATCH-R (NCT02517892). Patient-derived xenografts (PDX) were established and both patient biopsies (n=59) and PDX (n=16) were characterized by RNAseq and immunohistochemistry (IHC). 5 PDX from our 16 models were selected based on their CEACAM5 expression for our pharmacological assay: 2 NEPC models with a high expression of CEACAM5, 1 NEPC model with a mild (weak) expression of CEACAM5, 1 NEPC model with no expression of CEACAM5 and 1 mCRPC with a luminal phenotype and no expression of CEACAM5. SAR408701, an anti-CEACAM5 ADC or an irrelevant ADC with no specific target was administrated to immunodeficient mice. Tumor growth and body weight were monitored twice a week for 21 days post-injection.

Results: 54 patient biopsies were collected for IHC and 59 for RNAseq analysis. 33 cases out of the 54 presented evidence of neuroendocrine differentiation (in IHC analysis)tusamitamab and 21 expressed synaptophysin in more than 50% of the tumor cells. CEACAM5 expression in tumor cells was detected in 12 cases which all expressed synaptophysin (>50%), suggesting a strong correlation between CEACAM5 expression and neuroendocrine differentiation. An unsupervised hierarchical clustering based on RNAseq analysis of patient samples showed an enriched neuroendocrine cluster, in which CEACAM5 was significantly overexpressed. In the 5 PDX models selected to test the activity of Tusamitamab Ravtansine based on CEACAM5 expression, a strong correlation between CEACAM5 expression in the PDX models and
response to Tusamitamab Ravtansine was observed, with Tusamitamab Ravtansine showing a strong antitumoral activity on CEACAM5 expressing PDX models and no efficacy in models lacking CEACAM5 expression.

Conclusion: Overall, these results demonstrate the efficacy and specificity of SAR408701 against NEPC tumors harboring CEACAM5.This study provides preclinical evidence of the antitumor activity of SAR408701 in CEACAM5-positive NEPC.

#2959 PF-08046031: A promising first-in-class antibody-drug conjugate for targeting novel tumor antigen in melanoma.

Raj Giraddi, Steven Jin, Devra J. Olson, Iliyana Mikell, Eliana Moskovitz, **Rebecca Mazahreh**, Sharsti Sandall

Pfizer, Inc., Bothell, WA

MFI2, also known as CD228, melanotransferrin, p97, MTf, or MELTF, is a GPI-anchored membrane protein that belongs to the iron-transporting transferrin family. CD228 expression is elevated in multiple solid tumors such as melanoma and non-small cell lung cancer (NSCLC) but has limited expression in normal tissues. Here, we have expanded our expression analysis and found that other solid tumors, including head and neck cancer (HNSCC) and esophageal cancer (ESCC), also show positivity rates of 86% and 94%, respectively. PF-08046031 is an antibody-drug conjugate (ADC) that consists of the anti-CD228 human IgG1 antibody conjugated with an average of 4 molecules of monomethyl auristatin E (MMAE) by a cleavable valine-citrine (vc) linker. The proposed mechanism of action (MoA) of PF-08046031 is to bind to CD228-expressing cells where it is internalized and transported to lysosomes to release MMAE, causing microtubule disruption and cytotoxic cell death. This drug-linker and conjugation methodology have been clinically validated and approved. In this study, pharmacological evaluations of antibody binding, internalization, cytotoxic cell death and in vivo anti-tumor activity were conducted using various in vitro and in vivo models. PF-08046031 specifically binds to human CD228 with high affinity in both high and low CD228-expressing tumor cells. In vitro studies showed that the ADC had strong cytotoxic effects on CD228-positive cell lines but not on CD228 negative or genetically modified CD228KO cells. The anti-tumor activity of PF-08046031 was tested in vivo using two cutaneous melanoma models derived from cell lines (A2058 and Colo853). After a single intravenous dose of PF-08046031 at 3 and 6 mg/kg, significant tumor growth inhibition (TGI) was observed in a dose-dependent manner compared to the untreated group. At the highest dose of 6.0 mg/kg, TGI reached 87% for A2058-derived tumors and 90% for COLO853-derived tumors. These findings support the clinical development of PF-08046031 for targeting multiple solid tumors.

#2960 MYTX-011: A pH-dependent anti-cMET ADC exhibits potent activity in multiple epithelial tumor models with clinically actionable mutations and varying levels of cMET expression.

Deepak Kanojia, Federico Colombo, William J. Israelsen, Vijay Ramesh, Nimish Gera, Thomas Chittenden, Brian P. Fiske

Mythic Therapeutics, Waltham, MA

Small-molecule inhibitors (SMI) of acquired genetic alterations in cancer-driver genes have advanced patient care, especially in non-small cell lung cancer (NSCLC). Tyrosine kinase inhibitors (TKI) targeting the cMET receptor currently benefit a subset of patients whose tumors are dependent on cMET signaling. However, tumors frequently become refractory to SMI therapy. Antibody-drug conjugates (ADCs) targeting cMET have shown promising efficacy in a subset of NSCLC patients whose tumors express high levels of cMET. MYTX-011, an investigational, pH-sensitive, vcMMAE-based ADC targeting cMET, is designed to benefit a broader set of patients whose tumors express low to moderate levels of cMET and are not dependent on cMET signaling, in addition to patients that express high levels of cMET. We previously demonstrated that MYTX-011, which is engineered to rapidly dissociate from cMET at the acidic pH of endolysosomes, drives increased net internalization and cytotoxicity in tumor cells expressing low or moderate levels of cMET compared to a matched non-engineered ADC. Moreover, MYTX-011 was efficacious in NSCLC, gastric, esophageal, and HNSCC xenograft models with various cMET adenocarcinoma/squamous histology. Here, we demonstrate by live cell imaging that the pH-dependent binding of the antibody component of MYTX-011 leads to its rapid dissociation from cMET in the early endosomal lumen, whereas the non-engineered antibody remains localized to the endosomal membrane. These data support a model where MYTX-011 avoids non-productive recycling to the cell surface thereby enhancing delivery to lysosomes, payload release and cytotoxicity. To further study the mechanism of MYTX-011 across multiple tumor mutational backgrounds, we showed potent efficacy of MYTX-011 in tumor xenografts harboring clinically relevant mutations such as MET exon 14 skipping (METex14), KRAS, and EGFR, demonstrating that pH-dependent binding of MYTX-011 translated to potent efficacy regardless of actionable mutation status. MYTX-011 was active in low or moderate cMET-expressing NSCLC KRAS mutant (G12C) xenografts as well as in TKI-resistant xenograft models bearing EGFR mutation (T790M), whereas a benchmark ADC was either inactive or had greatly reduced efficacy. We also show that MYTX-011 was highly active in a METex14 Hs746T cell line derived xenograft (CDX) and NSCLC patient-derived xenografts (PDX) including a model derived from a patient with acquired resistance to MET TKI. Further, there were no antagonistic effects of combining MET TKI and MYTX-011 in METex14 PDX models, indicating the potential of MYTX-011 in combination with approved MET TKIs. Together, these findings highlight the potential of MYTX-011 as a therapeutic candidate for treating a broad range of cMET-expressing cancers with clinically actionable mutations.

#2961 AZD9592, an EGFR/cMET bispecific antibody-drug conjugate (ADC), demonstrates target-dependent efficacy in colorectal cancer (CRC) patient-derived xenograft (PDX) models.

Ying Zheng[1], Edward Rosfjord[1], Simon Christ[2], Stephanie Zalesak-Kravec[3], Italia Grenga[4], Fernanda Arnaldez[1], Frank Comer[1], Lara McGrath[4]

[1]Early Oncology R&D, AstraZeneca, Gaithersburg, MD,[2]Computational Pathology, AstraZeneca, Munich, Germany,[3]Translational Medicine - CBD, Early Oncology, AstraZeneca, Gaithersburg, MD,[4]Early Oncology R&D, AstraZeneca, Waltham, MA

Background: AZD9592 is a bispecific ADC designed to target both epidermal growth factor receptor (EGFR) and mesenchymal-epithelial transition tyrosine kinase receptor (cMET), delivering a topoisomerase 1 inhibitor payload to tumor cells. Despite recent advances in ADC development for CRC, such as the use of trastuzumab deruxtecan to treat HER2-positive CRC, a significant unmet need remains for novel therapeutic approaches, particularly for patients with limited targeted treatment options.

Methods: We evaluated the antitumor efficacy of AZD9592 and explored biomarker-response relationships in CRC PDX models across a range of very low to high EGFR expression (optical density of membrane [OD] 6.7-162.6) and cMET expression (OD 18.5-142.6) measured by immunohistochemistry-quantitative continuous score (IHC-QCS), as well as other molecular features like oncogene drivers. Responses were defined as ≥30% tumor volume reductions from baseline.

Results: AZD9592 demonstrated dose-dependent efficacy, with responses observed in 34.5% of models at 8 mg/kg and 14.8% at 4 mg/kg. Biomarker analyses of tumors revealed a significant association between cMET expression levels by IHC-QCS and responses at 8 mg/kg. cMET levels were significantly higher in AZD9592-responsive models than in antibody-responsive and isotype control-responsive models ($p<0.02$ for both). An optimized cMET expression cutoff had a predictive performance with an area under the curve of 0.73. Compared to wildtype tumors, response rates were not significantly different in tumors harboring mutations in oncogenes that share signaling pathways with EGFR and cMET and where clinical activity of EGFR antibody therapies is limited, including KRAS and BRAF. Moreover, response rates were not significantly different across tumors derived from patients with or without prior irinotecan treatment, a chemotherapy that also inhibits topoisomerase I. Proteomics identified additional molecular features associated with response.

Conclusions: AZD9592 demonstrated dose-dependent antitumor activity in CRC PDX models, including KRAS-mutant and KRAS-wildtype tumors. These responses suggest opportunities for clinical development of AZD9592 in CRC and the potential for biomarker-guided patient selection.

#2962 Enhanced HER2 internalization by clathrin-dependent endocytosis in non-small cell lung cancer positive for *HER2* mutations.

A. Shimauchi[1], E. Iwama[1], R. Ibusuki[1], H. Tsutsumi[1], D. Shibahara[1], K. Otsubo[1], Y. Yoneshima[1], K. Tanaka[2], H. Inoue[3], I. Okamoto[1]; [1]Kyushu University, Fukuoka, Japan, [2]Kagoshima University, Kagoshima, Japan, [3]Fukuoka University Hospital, Fukuoka, Japan

Introduction: Mutations in the gene for human epidermal growth factor 2 (HER2) result in constitutive phosphorylation of the protein and are driver alterations in cancer. HER2 mutations are present at a frequency of 1% to 4% in non-small cell lung cancer (NSCLC), with exon-20 insertion mutations such as A775_G776insYVMA and G776delinsVC being among the most common of these latter mutations. Although HER2-targeted ADCs have shown marked efficacy for HER2 mutation-positive NSCLC, the detailed molecular mechanisms underlying such efficacy are not well understood.

Methods: The intracellular trafficking and dimerization patterns of HER2 were examined in cells expressing wild-type (WT) or mutant forms of the protein with the use of live cell imaging and an in situ proximity ligation assay, respectively. Proteins that preferentially associate with mutant HER2 were identified by liquid chromatography and tandem mass spectrometry to shed light on the pathway of HER2 trafficking in HER2-mutated cells.

Results: HER2 internalization was enhanced in NSCLC cells expressing mutant forms of HER2 compared with those expressing HER2(WT). Homodimers of HER2(WT) were localized mainly at the cell surface, whereas those of mutant HER2 were present mostly in the cytoplasm. Although siRNA interference of EGFR or HER3 effectively suppressed the HER2 internalization in cells stably expressing WT forms of HER2, such internalization was not affected in the cell lines expressing mutant forms of HER2. The enhanced internalization of mutant HER2 was mediated by clathrin-dependent endocytosis, as was reflected by increased binding of the ubiquitin ligase c-Cbl to mutant HER2 and its consequent ubiquitination. Zongertinib, a HER2-specific tyrosine kinase inhibitor, attenuated HER2 phosphorylation, the binding of c-Cbl to HER2, and HER2 internalization in HER2-mutated cells.

Conclusions: Upregulation of HER2 phosphorylation promotes internalization of mutant forms of HER2 mediated by clathrin-dependent endocytosis, which may contribute to the efficacy of HER2-targeted ADCs in NSCLC positive for HER2 mutations.

#2964 SCR-A002, a novel FGFR2b-targeting ADC for solid tumors.

Yayuan Fu, Yuanjie Ge, Xiaohui Shao, Qi Deng, Chunlei Xia, Renhong Tang

Simcere Zaiming Pharmaceutical Co., Ltd., Shanghai, China

Background: FGFR2b (fibroblast growth factor receptor 2 IIIb), an isoform of transmembrane tyrosine kinase FGFR family, is overexpressed in various cancers, including gastric, esophageal, breast, hepatocellular, pancreatic, ovary, uterine, cervical, endometrial, lung, colorectal cancers. Bemarituzumab (FPA144) is an afucosylated humanized IgG1 monoclonal antibody targeting FGFR2b with enhanced ADCC activity, which had promising clinical efficacy in phase 2 study of FGFR2b-selected gastric or gastroesophageal junction adenocarcinoma. Simcere Zaiming has developed a potential first-in-class FGFR2b-targeting ADC (SCR-A002) at IND-enabling status, displaying significantly superior anti-tumor potency compared to Bemarituzumab.
Methods: Using hybridoma technique, anti-FGFR2b antibody was generated from immunization of FGFR2b protein in mice. SCR-A002 was comprised of a humanized anti-FGFR2b IgG1 monoclonal antibody conjugated through a cleavable linker to proprietary TOPO1 inhibitor payload (DAR 8). Binding activity and cytotoxicity were assessed in FGFR2b+ tumor cell line. And anti-tumor efficacy was evaluated in several CDX and PDX models.
Results: SCR-A002 specifically bound to FGFR2b on tumor cells and could be internalized, and the TOPO1 inhibitor could be cleaved intracellularly and then exhibited potent cytotoxicity to tumor cells. And tumor regression was achieved after single-dose administration of SCR-A002 in different FGFR2b expression level CDX and PDX models, even with big-size tumor or Bemarituzumab resistance.
Conclusion: SCR-A002 showed remarkable anti-tumor efficacy in preclinical data, suggesting that SCR-A002 is expected to provide a new treatment option as single agent or combo with SoC for patients with FGFR2b-overexpressing solid tumor.

#2965 SCR-A006, an innovative and potential best-in-class EGFR/cMet bispecific antibody-drug conjugate.

Yayuan Fu, Chaochao Cen, Lei Jiang, Xiaohua Yan, Chuanchuan Lu, Qian Wang, Ye Hong, Renhong Tang

Simcere Zaiming Pharmaceutical Co., Ltd., State Key Laboratory of Neurology and Oncology Drug Development, Simcere Pharmaceutical Group, Shanghai, China

Background: EGFR and cMet are widely co-expressed in solid tumors, and there is crosstalk between their signaling pathways, which is the general escape mechanism for each other in clinic. Although various drugs targeting EGFR and/or cMet have been approved or are in clinical development, primary and acquired resistance limits their prolonged efficacy. There still remains a large unmet need in solid tumor therapy. SCR-A006 is an antibody-drug conjugate (ADC) comprising a bispecific mAb targeting EGFR&cMET conjugated to a topoisomerase 1 inhibitor (TOP1i) via a cleavable and hydrophilic linker, which potentially benefits a broad population of solid tumor patients.

Methods: Physiochemical and biological properties of SCR-A006 were evaluated. The binding affinity and cytotoxicity of SCR-A006 were investigated *in vitro* using cancer cell lines containing different target expression levels, tumor types (lung, head and neck, breast, gastric, colorectal and pancreas), as well as genomic landscapes. *In vivo* pharmacodynamic studies were conducted in several CDX and PDX models with different EGFR expression levels or mutations. Preclinical PK studies and tissue distributions were performed by intravenous injection of SCR-A006 at 5mg/kg single in WT mice and tumor cell xenograft mice.

Results: SCR-A006 exhibited strong cytotoxicity against a broad range of tumor cell lines with higher potency than benchmark ADC, but did not enhance toxicity to normal cells, suggesting a larger therapeutic window. *In vivo*, SCR-A006 demonstrated dose-dependent tumor inhibition and was more effective than benchmark ADC in xenograft models regardless of tumor types and genetic profiles. SCR-A006 also showed good efficacy and was superior to benchmark ADC in amivantamab resistant xenograft models. Excitingly, we found complete response and prolonged efficacy in NSCLC PDX model. To figure out the mechanism of better efficacy compared to benchmark ADC, PK and cleavage efficiency in tumor or normal tissue from CDX model of SCR-A006 were carried out, which showed better tumor penetration and higher cleavable efficiency in tumor homogenate than benchmark ADC but very limited cleavage in normal tissue. SCR-A006 also displayed higher hydrophilicity and more excellent plasma stability than Benchmark ADC. All of above performance potentially resulted the better efficacy and good safety of SCR-A006.

Conclusions: Taken together, these findings highlight the potential of SCR-A006 as a therapeutic candidate for broad treatment of solid tumors and with a larger therapeutic window than other EGFR/cMET BsADCs. IND enabling studies of SCR-A006 are currently underway, and planned to initiate clinical study in 2025.

#2966 The anti-tumor activity of a novel anti-Her2 and anti-c-Met bispecific antibody-drug conjugate.

Hongyan Zhong, Daniel Li, Daniel Guo, Phuong Nguyen, **Ming Yang**

Bright Biologics LLC, Sunnyvale, CA

Background: Her2 and c-Met, two tumor-associated antigens (TAAs), are well-established cancer targets, as evidenced by the approval of several anti-Her2 antibody-drug conjugates (ADCs), a bispecific anti-c-Met/EGFR antibody, and promising Phase 2 efficacy of an anti-c-Met ADC. Her2 and c-Met are expressed separately or co-expressed in various cancer types, including lung, pancreatic and kidney cancers, reflecting the heterogeneity of tumor TAA expression. Dual TAA-targeting may reduce the probability of cancer escape, commonly seen in the treatment of single TAA-targeting ADCs, due to the heterogeneity of TAA expression.
Methods: We developed a novel bispecific anti-Her2/anti-c-Met ADC, BB-205. BB-205 was engineered using humanized anti-Her2 and anti-c-Met VHH fragments, fused with a human IgG1 Fc, and conjugated with vc-MMAE. Whole cell binding assays were conducted to determine the binding affinity of BB-205 to TAAs. *In vitro* cytotoxicity assays were performed to evaluate the cytotoxic effects of BB-205 on various cancer cell lines. The *in vivo* efficacy of BB-205 was tested in HPAC and NCI-H1975 xenograft mouse models.
Results: BB-205 maintained the high binding affinities of its parental VHH-Fc antibodies to Her2 and c-Met. It exhibited remarkable cytotoxic effects on cancer cells that express either Her2 or c-Met, or both. Its cytotoxic potency was comparable to Trastuzumab-MMAE (T-MMAE) in Her2-high expressing cancer cells and to Telisotuzumab vedotin (Teliso-V) in c-Met-high expressing cancer cells. BB-205 demonstrated superior cytotoxicity than either reference ADC or combination of both reference ADCs in dual TAA-expressing cancer cells with low to medium level of expression. Additionally, BB-205 showed higher internalization compared to either reference ADC in cancer cells. In the *in vivo* HPAC xenograft model, where HPAC cells express medium levels of c-Met and low levels of Her2, both BB-205 and Teliso-V significantly inhibited tumor growth, achieving 100% and 91% tumor growth inhibition (TGI), respectively. In contrast, treatments with T-MMAE had a low efficacy in suppression of tumor growth. At the end of study, 50% of mice in the BB-205 group were tumor-free, whereas no mice in other groups were tumor-free. BB-205 was also tested in an NCI-H1975 xenograft model, where NCI-H1975 cells express medium levels of Her2 and c-Met. Treatment with either BB-205 or T-MMAE significantly reduced tumor size. Four weeks after a single dose, 50% mice in BB-205 group and 25% mice in T-MMAE group were tumor-free. While Teliso-V initially shrank tumors, the tumors gradually regrew in the fifth week post-treatment. No obvious side effects were observed in both *in vivo* studies.
Conclusions: The novel anti-Her2/anti-c-Met bispecific ADC BB-205 demonstrates superior anti-tumor activity in preclinical studies. BB-205 shows promising therapeutic potential as a first-in-class ADC drug candidate.

#2967 Bone voyage: FGFR1, stemness, and the Wnt trail to prostate cancer metastasis.

Agustina Sabater[1], Pablo Sanchis[1], Nicolas Anselmino[2], Juan Bizzotto[3], Jun Yang[2], Jiabin Dong[2], Peter D. A. Shepherd[2], Paul G. Corn[2], Elba Vazquez[4], Christopher J. Logothetis[2], Nora Navone[2], Geraldine Gueron[4], Estefania Labanca[2]

[1]Universidad de Buenos Aires (UBA) - IQUIBICEN - CONICET - Universidad Argentina de la Empresa (UADE), CABA, Argentina. MD Anderson Cancer Center, Houston, TX,[2]MD Anderson Cancer Center, Houston, TX,[3]Universidad de Buenos Aires (UBA) - IQUIBICEN - CONICET - Universidad Argentina de la Empresa (UADE), CABA, Argentina,[4]Universidad de Buenos Aires (UBA) - IQUIBICEN - CONICET, CABA, Argentina

Prostate cancer (PCa) lethality largely stems from the progression to castration-resistant PCa (CRPC) bone metastasis. We previously reported that fibroblast growth factor receptor 1 (FGFR1) is overexpressed in a subset of human CRPC bone metastases, and that FGFR1 overexpression of both α and β isoforms drives bone metastases and reduces survival in experimental metastatic murine models with intracardiac PCa cells injection, posing its blockade as a promising therapeutic strategy for advanced PCa. An on-going clinical study at our department at MD Anderson is currently evaluating erdafitinib, an FGFR inhibitor, for treating men with CRPC bone metastases (ClinicalTrials.gov Identifier: NCT04754425). However, the dynamics behind FGFR-driven PCa progression remain elusive. As FGFR signaling has previously been linked to the development and proliferation of PCa stem-cells, we hypothesized that FGFR promotes PCa bone metastasis by modulating cell plasticity. *In vitro* assays confirmed that FGFR1α- and FGFRβ-expressing PCa cells exhibited increased colony formation and confluency, and a more stem-like phenotype, evidenced by altered morphology, smaller cell size, elevated aldehyde dehydrogenase (ALDH) levels, and enhanced tumorsphere formation ($p<0.0001$). Consistently, RNA-seq analysis of PCa cells and MDA PCa patient-derived xenografts (PDX) showed a significantly positive correlation between FGFR1 levels and stem-cell markers ($p<0.05$). Furthermore, PCa patients from TCGA-PRAD (497 primary PCa) and SU2C (81 metastatic CRPC) datasets with enrichment of FGFR-correlated stem-cell categories exhibited increased risk of progression (log-rank $p<0.05$). Among the stem-categories that correlate with FGFR expression, genes from Wnt signaling, a pathway involved in stem-cell traits regulation and implicated in PCa, emerged prominently (*FERMT2*, *FZD7*, NES, *CORO1C*, *BMP4*, *MEF2C*, *GJA1*, *SFRP1*, *WNT2B*, *CDH2*). Bioinformatics analysis also revealed significant correlation between TCF/LEF factors and FGFR1 in TCGA-PRAD patients. FGFR1-expressing PCa cells showed increased *TCF* reporter activity, indicating Wnt activation, and nuclear β-catenin immunostaining in FGFR1-expressing PDXs and human CRPC bone metastases further confirmed this activation. Overall, our findings suggest that FGFR1 drives PCa progression through Wnt signaling-induced stemness, conferring cancer cells the plasticity to adapt to the bone microenvironment. Future studies aim to further characterize the FGFR1-induced stemness and dedifferentiation mechanisms underlying PCa bone dissemination and evaluate FGFR-targeted therapies.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Identification of Molecular Targets 1

[1]XenoSTART, San Antonio, TX,[2]XenoSTART, Madrid, Spain,[3]XenoSTART, Grand Rapids, MI,[4]START San Antonio, San Antonio, TX,[5]START Madrid, Madrid, Spain,[6]START Midwest, Grand Rapids, MI

Background: Somatic mutations in the human epidermal growth factor receptor 2 (HER2) gene occur in several cancer types, including bladder, colorectal, lung and cervical. Multiple antibody-drug conjugate (ADC) molecules and small molecule treatments targeting HER2 have been approved; however, comparative in vivo sensitivity of these therapies toward known and novel HER2 mutations is unclear. To better understand the effects of these targeted therapies on specific HER2 variants, we established and characterized a panel of XPDX models harboring various HER2 mutations and benchmarked in vivo sensitivity to targeting ADCs and small molecule therapies.
Methods: 18 XPDX models were included in this study. Models representing the S310F mutation in the extracellular domain included ST174 (bile duct), ST524 (colorectal), ST1243 (lung) and ST5025B (bladder) and one cervical model (STM602) with a reported S310Y variant. Models harboring an R678Q mutation in the juxtamembrane domain included ST022 (ovary), ST026 (colorectal) and STF001 (pancreas). Models with mutations in the kinase domain included ST5960 breast (Y735C), STF117 lung (L755F), ST1616B breast (D769Y), ST2594 colorectal (D769Y), ST427 colorectal (V777L), ST4295 ovary (S792F), and ST1456 breast (V842I). Two models ST3107 (lung) and STF059 (colorectal), harboring a YVMA insertion, and the ST3013 (lung) with a 776-777 G/LC indel were also evaluated. Models were characterized for HER2 expression by immunohistochemistry and profiled using WES and RNA_{seq}. For in vivo studies, T-DXd, T-DM1, neratinib, tucatinib, and afatinib were evaluated at standard treatment regimens. Study endpoints included tumor volume and time from treatment initiation with %T/C values and tumor regression reported at study completion; a %T/C of ≤ 20 versus control was considered sensitive. Tumor regression (%T/C<0%) versus Day 0 tumor volume was also reported.
Results: The majority of models stained for HER2 at 2+ or 3+ and RNA based expression correlated with IHC results. In vivo, T-DXd or T-DM1 treatment resulted in regressions in ST1243 and ST3013 but were ineffective toward ST5025B. Neratinib reported activity toward ST5025B (%T/C=-80%), ST3107 (%T/C=1%), and ST3013 (%T/C=2%) while tucatinib was found efficacious toward ST5025B (%T/C=12%) and STF117 (%T/C=13%). Afatinib treatment resulted in regressions toward ST427 (%T/C=-25%) and was active in ST3013 (%T/C=8%).
Conclusion: We have established and characterized a panel of XPDX models harboring various HER2 mutations and benchmarked in vivo sensitivity toward targeting ADCs and small molecule therapies. This data and model panel can be utilized as a valuable tool in better understanding the utility of HER2-targeting therapies in HER2-mutated cancers.

#2972 Trabectedin exerts its potent and selective antitumor effects by irreversibly covalently bonding to duplex stem loops in G-quadruplexes.

Alena Safarova[1], Marta Martinez Diez[2], Raquel M. Altares[2], Pablo M. Aviles[2], Marcelo Lima Ribeiro[2], Carmen Cuevas[2], **Laurence H. Hurley**[1]

[1]University of Arizona, Tucson, AZ,[2]Pharma Mar, S.A., Madrid, Spain

Trabectedin, a marine-derived anti-tumor agent from the ecteinascidin family, shows effectiveness when treating cancers such as Ewing Sarcoma, small cell lung cancer (SCLC) and ovarian cancer. It features a unique carbinolamine group that forms reversible bonds with the N2 position of guanine, distinguishing it from typical DNA alkylating agents. Structurally, trabectedin also includes a C-subunit that widens the DNA minor groove, inducing transcriptional replication stress and genome instability. Given the sensitivity of Ewing Sarcoma to trabectedin and the role of G-quadruplexes (G4s) in binding EWSR1—especially those with longer stem loops—this study aims to redefine trabectedin's molecular target by exploring its potential interaction with G4 structures. Building on these insights, we designed experiments using trabectedin in combination with wild-type (WT) and mutant MYCN G4s to assess whether trabectedin could irreversibly bond covalently to a consensus sequence within a duplex stem loop associated with a G4. Circular dichroism (CD) analysis confirmed that trabectedin stabilized a G4 containing a consensus covalent bonding site within the associated hairpin loop. Mass spectrometry (MS) demonstrated that a guanine in the trabectedin consensus binding site is essential for this irreversible covalent binding. Additionally, CD and MS showed that when trabectedin was bound covalently to the hairpin stem loop, it displaced GSA0932, a molecule that binds non-covalently to both the core structure and stem loop. Finally, we observed that trabectedin treatment significantly increased G4 frequency within cells. On a final note, trabectedin irreversibly binds to the N2 of guanine within a duplex stem loop of a G4, fully accounting for its downstream effects on transcription-dependent replication stress and genomic instability. While this data specifically pertains to trabectedin, other members of the ecteinascidins, which possess structurally distinct C-subunits, appear to exhibit varied downstream effects, such as on transcription. These differences may arise from variations in sequence selectivity at the stem-loop level, leading to the targeting of distinct G-quadruplex structures.

#2973 Discovery of novel synthetic lethal targets for effective and safe colorectal cancer therapies.

Andrzej Mazan[1], Marcin Duleba[1], Eliza Zimolag[1], Joanna Szuszkiewicz[1], Marcin Serocki[1], Joanna Krawczyk[1], Oleksii Bryzghalov[1], Agata Stachowicz-Walaszek[1], Izabella Wieckowska[1], Marcelina Chmiel[1], Alexander Kurzejamski[1], Barbara Lipert[1], Katarzyna Sarad[1], Michal Mikula[2], Rafal Dziadziuszko[3], Tomasz Rzymski[1], Andrew Thomason[1], Krzysztof Brzozka[1]

[1]Ryvu Therapeutics, Krakow, Poland,[2]Maria Skłodowska-Curie Institute of Oncology, Warsaw, Poland,[3]Medical University of Gdansk, Gdansk, Poland

Colorectal cancer (CRC) poses a significant global health burden, highlighting the urgent need for innovative and effective treatment options. This study focuses on the discovery and validation of novel therapeutic targets, particularly synthetic lethal (SL) interactions, to exploit specific genetic vulnerabilities in CRC cells and enable the development of safer and more effective therapies. We employed a comprehensive strategy integrating healthy cells, genetically engineered isogenic cancer models derived from human intestinal stem cells (hISCs) with patient-derived xenografts (PDXs) and primary cell cultures. Using CRISPR/Cas9 technology, we introduced key CRC-associated mutations into the hISCs to replicate disease-specific contexts. Transcriptome profiling, coupled with machine learning, validated these models as robust, clinically relevant representations of tumor biology by aligning them with clinical datasets. Genome-wide CRISPR/Cas9 screenings conducted across the isogenic and patient-derived models revealed actionable vulnerabilities, including the identification of genes that are synthetically lethal with APC and KRAS mutations. Discovered SL targets were rigorously validated *in vitro* and *in vivo* using patient-derived cells with matching mutational profiles. This integrative approach bridges preclinical and clinical research, ensuring translational relevance. By identifying and validating SL targets tailored to CRC mutational landscapes, we provide a robust foundation for the development of novel treatment options for CRC patients.

#2974 Bortezomib resistant multiple myeloma shows a specific dependency on Ecm29 in vitro and in vivo.

Andrej Besse[1], Lenka Besse[2], Sara C. Stolze[3], Marianne Kraus[4], Ondrej Slaby[2], Hirofumi Nakagami[3], Christoph Driessen[4]

[1]Dept. of Biology, Masaryk University, Brno, Czech Republic,[2]Masaryk University, Brno, Czech Republic,[3]Max Planck Institute for Plant Breeding Research, Cologne, Germany,[4]Cantonal Hospital St. Gallen, St. Gallen, Switzerland

Background: Resistance to proteasome inhibitors (PI) bortezomib (BTZ) is a major obstacle to the successful treatment of multiple myeloma (MM). Thus, the identification of a specific target in PI-resistant MM is an unmet medical need. The highly specialized and adapted nature of PI-resistant MM may offer novel areas of vulnerability. Using genome-wide CRISPR/Cas9-based functional screening in BTZ-adapted cell lines *in vitro* we identified the proteasome adaptor and scaffold protein Ecm29 as an essential survival factor for BTZ-adapted cells under BTZ treatment. We aimed to characterize its function in myeloma *in vitro* and *in vivo*.
Methods: Genome-wide CRISPR/Cas9 screening was used in BTZ-resistant cells to identify overlapping BTZ sensitivity candidates, which were further validated in a set of four BTZ-resistant cells. Viability was determined by CCK8 viability assay. Cell cycle, apoptosis induction, and aggresome formation after BTZ treatment were determined by flow cytometry. NGS, LC-MS/MS, and SILAC were used to determine major changes in Ecm29 knock-down (KD) or knock-out (KO) cells. RT-PCR and westernblot were used to determine unfolded protein response. Two *in vivo* orthotopic mouse models were used to determine the effect of Ecm29 on BTZ resistance.
Results: Ecm29 was identified as a consistent candidate for BTZ sensitivity in two independent screens with BTZ-adapted MM cell lines exposed to BTZ. Validation with specific Ecm29 KD or KO sensitized BTZ-adapted cells to BTZ, in contrast to BTZ-naïve parental cells. Pull-down of proteins bound to Ecm29 in BTZ-adapted cells, in contrast to BTZ-naïve cells, showed significant changes, related to Ecm29 and proteasome localization towards the cytoskeleton and vacuolar compartment. Following, Ecm29 silencing induced changes in the cytoskeleton and vesicular trafficking, decreased protein synthesis and diminished the accumulation of poly-ubiquitinated protein. BTZ treatment caused accumulation of poly-ubiquitinated proteasome substrate proteins, induction of the unfolded protein response, induction of chaperones and aggresome formation, G2-phase cell cycle arrest, and apoptosis in Ecm29-silenced cells, in contrast to BTZ-adapted control cells. Ecm29 depletion significantly reduced the growth of two independent BTZ-adapted cells *in vivo* in murine bone marrow, following BTZ treatment.
Conclusion: The proteasome adaptor and scaffold protein Ecm29 controls proteasome trafficking and localization. It is of central importance in BTZ-adapted MM cells undergoing BTZ treatment due to dependance on different proteasome localization. Ecm29 may therefore represent a novel therapeutic target to specifically re-sensitize PI-resistant MM cells to PI treatment.

#2975 Characterization of the RAC1/CDC42 inhibitor MBQ-167 to assess its utility as a tool for interrogating Rho GTPase biology.

Szilvia Barsi, Arpad Varga, Csaba Szantai-Kis, Maria Victoria Ruiz-Perez, Ivan Fekete, Imre Gaspar, Csilla Polner-Szundi, Boldizsar Elek, Magdolna Djurec, Nora Ordasi, Istvan Taisz, Amrik Basran, **Daniel Veres**

Turbine Simulated Cell Technologies Ltd., Budapest, Hungary

The Simulated Cell platform highlighted RAC1 as a target with great antitumor potential. RAC1 is a small Rho GTPase with roles in cell polarity and migration, and contributes to cancer metastasis. To identify good chemical tools for RAC1, we evaluated multiple RAC1 inhibitors, and selected MBQ-167 as a potent RAC/CDC42 inhibitor with publicly available efficacy data.

We analyzed the *in silico* effects of individual and dual RAC1/CDC42 inhibitors using the Simulated Cell. *In vitro* we studied MBQ-167 using viability, apoptosis and scratch assays. Viability of RAC1 KO cells treated with MBQ-167 was also analyzed. Post-treatment RNA-Seq and bioinformatics analysis of pathway activity signatures revealed MBQ-167 downstream effects. The SignalChem kinase assay was used to validate off-target identification.

Our simulations revealed that, beyond their role in cytoskeleton, RAC1 and CDC42 exert effects through apoptosis signaling, with a stronger contribution of RAC1. *In vitro*, we confirmed the activity of MBQ-167 against RAC1 and CDC42. We observed a negative impact of MBQ-167 on cell migration and an induction of apoptosis. However, RAC1 KO did not affect sensitivity to MBQ-167, suggesting that effects of MBQ-167 on cell viability are not dependent on RAC1.

Post-treatment RNA-Seq analysis of MBQ-167 treated cells and calculation of the similarity scores with LINCS consensus signatures, revealed that the MBQ-167 signature is highly similar to those of various kinase KOs and inhibitors targeting PLKs, AURKA, MET, CDK1, MAPK14, FLTs, RET and PDGFRs. RAC KOs were not involved. A kinase off-target panel validated that MBQ-167 inhibits the aforementioned kinases. It inhibited PLK2 and AURKA with an IC50 of around 200 nM, similar to its primary described targets. Other kinases were also inhibited in the nanomolar range, such as CDK1, MET and PLK1.

Targeting RAC proteins and CDC42 holds great anti-tumoral potential. We investigated MBQ-167 *in vitro* and showed that it does not exert its effects on cancer cell viability through RAC1. Besides RAC and CDC42, this compound can inhibit cancer-relevant kinases such as AURKA and PLK2. Simulations helped understanding that MBQ-167 is not a specific inhibitor and therefore not adequate as a tool for interrogating the biology of interest. Further studies are needed to find additional inhibitors against RAC/CDC42 and to understand the effects of MBQ-167 on cancer cells and as a clinical asset tested in Phase I clinical trials as a single agent against advanced breast cancer.

#2976 XPR1 and SLC34A2 (NaPi2B)- A tale of targeting the phosphate homeostasis in cancer cells.

Mansi Babbar[1], Dion Daniels[1], Katie Vowell[1], Rajesh Sundaresan[1], Shuzhen Wu[2], Feng Wang[1], James Lin[1], Jenny Laraio[1], Justin Munro[1], Joseph Kozole[1], John Kreeger[1], Geeta Sharma[2], Bryan Joosse[1], Florence Patel[1], Joseph Tomlinson[1], Katherine Welbeck[3], Richard Priest[3], Jennifer Percival-Alwyn[3], Trevor Wattam[3], Gurjinder Heer[1], Iain Moal[3], Sreenivas Nannapaneni[1], Benjamin Schwartz[2], Biju Mangatt[1], Anthony Mazurek[1]

[1]GlaxoSmithKline, Collegeville, PA,[2]GlaxoSmithKline, Cambridge, MA,[3]GlaxoSmithKline, Stevenage, United Kingdom

SLC34A2 is overexpressed in 61% of ovarian cancer and 18% of uterine cancer tumors. SLC34A2 overexpression is believed to be driven by the aberrant activity of the essential PAX8 transcription factor in these tumors. Overexpression of SLC34A2, a phosphate importer, sensitizes the cells to the genetic depletion of XPR1, the sole phosphate exporter. Importantly, pharmacologic inhibition of XPR1 by XRBD, a peptide molecule that binds the extracellular domain 3 (ECL3) of XPR1 to antagonize its function, phenocopies the lethal impact of XPR1 knockdown on SLC34A2 overexpressing cancer cells. This observation supported the hypothesis that an antibody that binds to XPR1 will antagonize its function and selectively kill cancer cells that overexpress SLC34A2. There are no XPR1 therapeutics reported in clinical development indicating a first-in-class opportunity for an XPR1 therapeutic antibody. The goal of this program was to identify an antagonist antibody that inhibits XPR1 phosphate export function as a novel therapy for ovarian and uterine cancers patients with tumors that overexpress SLC34A2 (SLC34A2-high). We utilized XRBD to understand XPR1 biology in SLC34A2-high and low expressing cancer cell line models. Mechanistically, in SLC34A2-high expressing cell lines, genetic or pharmacologic inhibition of XPR1-dependent phosphate efflux led to the toxic accumulation of intracellular phosphate. XPR1 inhibition in these cell lines also resulted in increased cellular nucleotide triphosphate levels. Interestingly, we found altered mitochondrial gene expression and metabolism upon XPR1 inhibition and/or loss. Further, XPR1 inhibition induced gamma H2AX suggesting increased DNA damage. This finding was also supported by synergistic growth inhibition and cytotoxicity when XPR1 inhibitor was combined with cisplatin. On our path to therapeutic XPR1 antibody discovery, we identified antibodies that bound to overexpressed and endogenous XPR1, however they did not induce expected pharmacodynamic responses or efficacy against SLC34A2 -high expressing cancer cell lines. These results indicate that the binding of these antibodies to XPR1 does not recapitulate the antagonistic activity of XRBD against the viability of SLC34A2 overexpressing cancer cells.

#2978 PSMD6 is a promising therapeutic target in multiple myeloma.

Minxing Wang, Arghya Ray, Teng Fang, Xueping Wan, Ting Du, Sindhu C. Pillai, Md Abu Musa, Yan Song, Kenneth C. Anderson

Dept of Medical Oncology, LeBow Institute for Myeloma Therapeutics and Jerome Lipper Myeloma Center, Dana-Farber Cancer Institute, Boston, MA

Background: The 26S proteasome is essential for maintaining protein homeostasis by degrading misfolded or unneeded proteins regulating critical cellular processes such as the cell cycle, apoptosis, and immune response. It consists of 20S catalytic core particle and 19S regulatory particle, with the PSMD family playing a key role in proteasome assembly. Multiple myeloma (MM), a plasma cell malignancy characterized by abnormal immunoglobulin production, heavily depends on proteasome function. While proteasome inhibitors (PIs) are commonly used in MM treatment, resistance to inhibitors targeting the 20S subunit frequently develops. Targetting the PSMD family of ubiquitin receptors upstream of the proteasome in the ubiquitin proteasome cascade represents a promising therapeutic target to overcome PI resistance. This study aimed to identify key PSMD subunits as therapeutic targets in MM, with a focus on validating PSMD6.

Methods: Gene expression and cell line dependencies were analyzed using the Gene Expression Omnibus datasets and DepMap portal. Kaplan-Meier plotter was used to assess the correlation between PSMD expression and MM patient survival. PSMD6 was knocked down via siRNA or CRISPR/Cas9 in MM cell lines, followed by immunoblotting to evaluate K48 polyubiquitinated protein accumulation, apoptosis, endoplasmic reticulum (ER) stress, and cell cycle progression.

Results: 1) DepMap identified that PSMD1-4, PSMD6-8, and PSMD11-14 as essential for MM cell line survival. 2) PSMD3, PSMD5-13, and PAAF1, are highly expressed in MM patients (GSE6691, GSE6471, GSE153380). 3) Elevated expression of PSMD1-3, PSMD6, PSMD8, PSMD9, PSMD11, and PSMD13 was correlated with poor MM patient survival. 4) Our real-time PCR and immunoblot analysis confirmed higher PSMD6 expression in MM patient samples and cell lines compared to normal controls. 5) Functional studies revealed that PSMD6 KD significantly inhibited proliferation of MM cell lines (AMO1, KMS11, H929, and RPMI-8226), independent of p53 status. 6) To assess whether PSMD6 KD disrupt proteasome function, a ubiquitin-GFP reporter cell line was used, where GFP is constitutively degraded by the proteasome. Immunoblot analysis revealed significant accumulation of GFP in PSMD6 KD cells. This was further confirmed by live-cell imaging using the IncuCyte system. 7) Mechanistic studies showed that PSMD6 KD led to increased apoptosis (early and late apoptotic phases), G0-G1 cell cycle arrest, accumulation of K48-linked polyubiquitinated proteins, caspases activation, and induction of the ER stress pathway.

Conclusion: Our study highlights the potential of PSMD subunits, particularly PSMD6, as therapeutic targets in MM. Our data validate targeting PSMD6 to enhance cytotoxicity and overcome PI resistance in MM and provide the preclinical rationale for developing PSMD6 inhibitors to improve patient outcomes in MM.

Keywords: PSMD6, proteasome, multiple myeloma, therapeutic target

#2979 Deletion of p53-related protein kinase (TP53RK) suppresses solar UV-induced photocarcinogenesis by inhibiting PDL1 expression and enhancing CD8+ T cell infiltration.

Qiushi Wang[1], Eunmiri Roh[2], Asad Khan[1], Sally Dickinson[3], Georg T. Wondrak[3], Ann Bode[1], Clara Curiel-Lewandrowski[3], Tianshun Zhang[1]

[1]The Hormel Institute, University of Minnesota, Austin, MN,[2]Department of Cosmetic Science, Kwangju Women's University, Gwangju, Korea, Republic of,[3]The University of Arizona Cancer Center, The University of Arizona, Tucson, AZ

Nonmelanoma skin cancers (NMSCs), including cutaneous squamous cell carcinoma (cSCC), are primarily caused by solar ultraviolet (UV) exposure and represent the most common cancers in the United States. TP53RK (p53-related protein kinase, also known as PRPK) is a protein kinase involved in multiple cancer progression such as colon cancer, myeloma and skin cancer. In this study, we generated epidermal-specific TP53RK knockout mice using CRISPR/Cas9 technology in SKH1 hairless mice with loxP-flanked TP53RK alleles, crossed with keratin 14-Cre (K14.Cre) mice. Our findings reveal that epidermal-specific deletion of TP53RK significantly suppresses tumor growth in solar-simulated light (SSL)-induced NMSC. Mechanistically, TP53RK deletion inhibits proliferating cell nuclear antigen (PCNA) and programmed death-ligand 1 (PDL1) expression, as well as the transcription factors c-Myc, c-Jun, and NF-κB, which mediate PDL1 expression. Using a 3D culture system, we further demonstrate that TP53RK deletion suppresses cSCC cell growth. Flow cytometry analysis indicates that TP53RK deletion enhances CD8+ T cell infiltration into the tumor microenvironment. This is accompanied by significant reductions in IL-6, MIP-2, and VEGF levels, reprogramming the tumor microenvironment to support CD8+ T cell infiltration. In summary, our study demonstrates that TP53RK deletion suppresses solar UV induced photocarcinogenesis by inhibiting PDL1 expression and enhancing CD8+ T cell infiltration, highlighting its potential as a therapeutic target for NMSC.

#2980 Therapeutic potential of combined targeting of casein kinase 1 alpha (CK1 alpha) and CDK7/9 with the inhibitor BTX-A51 in human liposarcomas.

Renyan Liu[1], Nicole L. Solimini[1], Caoibhne McSweeney[1], Patrick Bhola[1], Daryl Griffin[1], Tim B. Branigan[1], Michael J. Wagner[1], Audrey Turchick[1], Ricardo de Matos Simoes[1], Joshua M. Dempster[2], Jie Hao[1], Xin Wang[1], Roshen Alharthi[1], Michael Yorsz[1], Shaili Soni[1], Cing-siang Hu[3], Irit Snir-Alkalay[4], Francisca Vazquez[2], Prafulla C. Gokhale[3], Constantine Mitsiades[1], Anthony Letai[1], Yinon Ben-Neriah[4], George D. Demetri[1], Geoffrey I. Shapiro[1]

[1]Dana-Farber Cancer Institute, Boston, MA,[2]Broad Institute of MIT and Harvard, Boston, MA,[3]Experimental Therapeutics Core, Dana-Farber Cancer Institute, Boston, MA,[4]The Lautenberg Center for Immunology and Cancer Research, Institute of Medical Research Israel-Cana, Hebrew University-Hadassah Medical School, Jerusalem, Israel

Introduction: Liposarcomas (LPS) are mesenchymal cell malignancies that are diagnosed in more than 3500 patients in the US each year. LPS are characterized by DNA amplifications of *MDM2* (100%) and *CDK4* (90+%) genes on neochromosomes, generally with wild-type *TP53*. Management of metastatic or surgically unresectable LPS remains purely palliative. Recent clinical trials targeting MDM2 or CDK4/6 with small-molecule inhibitors have shown modest activity but have generally failed in phase 3 trials. The development of new therapeutics is greatly needed to improve outcomes for patients with LPS.
Results: To identify unique liposarcoma-specific vulnerabilities, we utilized the Dependency Map (DepMap) database to analyze gene-specific dependencies of 9 LPS cell lines as compared to non-LPS cancers and identified *CSNK1A1* as one of the top essential genes preferentially for LPS. siRNA-mediated depletion of *CSNK1A1* confirmed that CK1α negatively regulates p53 and is critical for the proliferation and survival of LPS cells. DepMap analyses identified *CDK7* and CDK9 as two additional top LPS-essential genes. Three CDK9 inhibitors suppressed LPS cell growth and induced apoptosis by decreasing MDM2 levels while inducing expression of p53 and PUMA. The cytotoxic effects of CDK9 inhibitors were enhanced upon CK1α depletion. Furthermore, we quantitatively determined synergism between CDK7 and CDK9 inhibitors in LPS cells. These data led us to examine combined targeting of CK1α and CDK7/9 in LPS with the novel small molecule inhibitor BTX-A51, which has previously also been shown to inhibit CK1α, CDK7, and CDK9 with nanomolar potency in acute myeloid leukemia (AML) models. BTX-A51 treatment significantly reduced expression of MDM2 with marked induction of p53, resulting in increased PUMA expression and profound apoptosis of LPS cells. Through CRISPR/Cas9-mediated *TP53* knockout, we established that BTX-A51-treatment-induced apoptosis was in part mediated in a p53-dependent manner, which was further validated transcriptionally using RNA-Seq based pathway analysis. BTX-A51 also reduced expression of the apoptosis inhibitor MCL1 and primed LPS cell lines and PDX-derived cells for BIM/PUMA-induced apoptosis. Importantly, *in vivo* experiments in
two LPS PDX models demonstrated that BTX-A51 is well-tolerated with anti-tumor efficacy.
Conclusions: These data have confirmed CK1α, CDK9, and CDK7 as essential for LPS cells and indicate that BTX-A51 has potent preclinical efficacy in LPS, through combined inhibition of CK1α, CDK9, and CDK7. Our data form the scientific foundation for our ongoing pilot clinical trial evaluating BTX-A51 in patients with advanced WDLPS or DDLPS (NCT06414434).

#2981 Glioblastoma reduced sensitivity to tumor treating fields (TTFields) is associated with changes in electrical membrane properties of tumor cells.

Michele Mazzanti[1], Francesca Cianci[1], Guido Rey[1], Sara Torabi[1], Elisa Meraviglia[1], Davide Ceresa[2], Paolo Malatesta[2], Kerem Wainer-Katsir[3], Tullio Florio[2], Dietmar Krex[4]

[1]University of Milan, Milano, Italy,[2]University of Genova, Genova, Italy,[3]Novocure, Haifa, Israel,[4]6Klinik und Poliklinik fur Neurochirurgie, Universitatsklinikum Carl Gustav Carus der Technischen Universitat Dresden, Dresden, Germany

Glioblastoma (GBM) is recognized as the most aggressive type of brain tumor, and current treatments generally fail to prevent recurrence. Tumor-treating fields (TTFields) is an innovative therapy that improves patients' life expectancy. Although the initial application of TTFields slows tumor progression, it typically does not prevent tumor relapse in most patients. To model tumor recurrence after surgical intervention, we exposed patient-derived GBM primary cultures to continuous electric field stimulation. Remarkably, three days of uninterrupted TTFields stimulation completely halted the proliferation of tumor cells. However, the surviving cells eventually become less sensitive to TTFields, and rescue proliferation at their maximum rate within 8 to 10 days. In this study, we analyzed transcripts of several patients' tumor tissues derived from primary and secondary surgical resection. Eight of these patients received TTFields treatment between the two surgical interventions. Their transcriptomic profile was compared with those who received the standard therapy but not TTFields between the surgeries. The tumor samples collected during initial surgeries and untreated GBM cells displayed significant inter-heterogeneity in their transcript profiles. These differences were less pronounced following TTFields application, which unveiled several commonly altered cytosolic pathways including inhibition of proliferation. Many of the upregulated pathways are not viable therapeutic targets, as they involve positive or negative modulations of physiological cellular functions. In addition, RNA extracts from human glioblastoma primary cultures were matched with those of patients treated with TTFields. After the TTFields application, several stemness pathways were significantly upregulated in isolated cells and human biopsies. Previous studies demonstrate that glioblastoma stem cells are enriched in transmembrane Chloride Intracellular Channel 1 (tmCLIC1) and its inhibition slows down tumor cell proliferation. CLIC1 transcript does not appear to be modulated in patients by electric field stimulation. However, following prolonged TTFields exposure in primary cell lines we observed a significant increase in the membrane protein activity. This indicates that tmCLIC1 could serve as a valuable target for a combined antitumoral therapy alongside TTFields to impair glioblastoma development.

#2982 Accelerating antigen-targeting therapy discovery with a scalable pan-cancer bioinformatics platform.

Eleonore Fox, Lea Meunier, Guillaume Appe, Abdelkader Behdenna, Lucas Hensen, Akpeli Nordor, Solene Weil, Camille Marijon

Epigene Labs, Paris, France

Cancer drug discovery is lengthy and nearly 90% of clinical trials fail due to efficacy or safety concerns. Identifying safe and effective drug targets using data-driven approaches in the earlier stages of research is critical to improve success rates. Over 40 antigen-targeting therapies have been FDA-approved in the past three decades but have yet to reach their full potential, especially in solid tumors where selecting the right antigen targets is a major challenge. To address this, we developed a comprehensive and scalable translational bioinformatics platform leveraging underutilized public omic data to discover, and prioritize novel antigen targets across various cancers.We integrated 168 microarray datasets using our AI-powered, human-supervised clinical data curation and transcriptomic data normalization pipeline. These were aggregated into 18 indication-specific cohorts encompassing 7,885 tumor and 1,569 healthy samples, and profiling 20,347 genes. We leveraged our proprietary target discovery pipeline, starting with a differential gene expression analysis, followed by proteomic filters selecting cell surface proteins with transmembrane or glycosylphosphatidylinositol -anchored domains. We further prioritized targets using a proprietary framework incorporating bulk and single cell transcriptomic data, proteomic, biological and pharmacological data metrics into a weighted scoring system designed to anticipate clinical relevance. Metrics were classified into 3 categories (efficacy, safety and novelty) and weights were optimized using FDA-approved targets.We identified an average of 216 potential antigen targets per indication, ranging from 41 to 556. Among these, we successfully rediscovered FDA-approved targets across several indications, including CD19 and CD22 in acute lymphoblastic leukemia, ERBB2 and TACSTD2 in breast invasive carcinoma, PDL1 in skin melanoma, PSMA in prostate cancer and FOLR1 in ovarian serous carcinoma, alongside targets currently in clinical trials for antigen-based therapies. Our prioritization framework was then applied to our candidate targets and revealed novel antigen targets exhibiting characteristics similar to those of FDA-approved targets. For example in breast invasive carcinoma, we identified 16 highly promising targets with efficacy scores matching or exceeding FDA approval benchmarks, including 9 with better predicted safety and 2 with high novelty scores in this indication. Additionally, 14 of these promising targets were identified in two or more indications, highlighting their tissue-agnostic potential. Our platform integrates unbiased data-driven tools with cancer biology insights to streamline antigen target discovery, from data integration to target prioritization. Scalable to any cancer type or antigen-targeting modality, it offers a robust framework for accelerating oncology drug discovery.

#2983 BUB1B is an inactive kinase required for survival of chromosomally unstable cells.

Nazario Bosco[1], Rafael S. Depetris[1], Jasmina Prabhakara[1], Akanksha Verma[1], Jared L. Johnson[2], Lewis C. Cantley[2], Scott Drutman[1], Shinsan M. Su[1], Rumin Zhang[1], Derek A. Cogan[1], Christina H. Eng[1]

[1]Volastra Therapeutics, New York, NY,[2]Department of Cell Biology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA

Chromosome instability (CIN) is a prevalent hallmark of aggressive cancers that is largely absent in normal cells. Targeting tumors with CIN is a therapeutic strategy that is rapidly advancing. Volastra Therapeutics has undertaken multiple orthogonal approaches to target CIN as a cancer vulnerability. One such approach that relies on the Cancer Dependency Map (DepMap) identified BUB1B (BUB1 Mitotic Checkpoint Serine/Threonine Kinase B) as a top scoring gene required for survival of cell lines with increased genomic instability. BUB1B, a core component of the spindle assembly checkpoint that functions in cell cycle progression and chromosome segregation, was also highlighted in published screens as a major cancer vulnerability in cells with aneuploidy and whole-genome duplication.

To corroborate the dependency of chromosomally unstable cancer cells on BUB1B, we used three independent cell models: 1) an isogenic CIN system based on modulating kinetochore-microtubule dynamics, 2) a Cas9-engineered system to induce dicentric chromosomes through telomere deprotection and 3) a non-isogenic cell line model based on differential levels of aneuploidy and micronuclei. Data in these three orthogonal systems confirmed that chromosomally unstable cells rely heavily on BUB1B for survival.

We next explored the development of BUB1B small molecule inhibitors. The C-terminus of BUB1B is responsible for chromosome congression and contains the putative kinase domain, suggesting that catalytic activity may be responsible for CIN suppression. Whether BUB1B possesses enzymatic activity has been controversial, with some groups reporting low but inhibitable BUB1B kinase activity, while others indicate that BUB1B lacks key kinase residues and is catalytically inactive.

To probe the function of BUB1B, we generated full-length and kinase domain recombinant proteins. Both constructs showed very weak ATPase activity comparable to published and commercially available proteins. Efforts to boost the kinase activity through improved substrate specificity or enhanced phosphorylation were not successful, and additional purification resulted in further loss of kinase activity. Furthermore, modeling of the BUB1B kinase domain suggests that ATP binding to the ATP cleft is physically hindered by bulky residues. Finally, substrate sequence mapping did not match sequences predicted for BUB1B. Together the data suggest that BUB1B is not enzymatically active and that the measured low ATPase activity may be attributable to a co-purifying kinase.

Our work confirms chromosomally unstable cells have greater dependency on BUB1B. However, the protein lacks catalytic activity and thus cannot be targeted with a kinase inhibitor strategy. BUB1B's function as a protein interaction hub with specific partners could permit alternative therapeutic strategies that may result in effective treatments for patients with chromosomally unstable cancers.

#2984 High throughput drug screening of patient-derived organoids reveals the ATR-mediated DNA damage response pathway as an esophageal cancer vulnerability.

Wataru Hirose[1], Samuel Flashner[1], Yasuto Tomita[1], Kento Kawasaki[1], Masaki Morimoto[1], Izabella Pacheco[1], Nour Kandil[1], Christian Lee[1], Cecilia Martin[1], Charles Karan[2], Joel T. Gabre[1], Anil K. Rustgi[1], Hiroshi Nakagawa[1]

[1]Columbia University Herbert Irving Comprehensive Cancer Center, New York, NY,[2]Department of Systems Biology, JP Sulzberger Columbia Genome Center, New York, NY

Introduction: Esophageal squamous cell carcinoma (ESCC) is common worldwide and the deadliest of all squamous cell carcinomas (SCC). Standard-of-care chemotherapy and immune checkpoint inhibitors offer limited survival benefits, highlighting the need for novel therapeutic strategies to combat ESCC. Patient-derived organoids (PDO) recapitulate therapy response and are powerful tools to meet this need; however, current PDO drug screening protocols are limited to fewer than 100 drugs, restraining their use in high-throughput screening (HTS) campaigns.

Methods: We developed a novel protocol enabling HTS of therapy-naïve ESCC (n=7) and normal esophageal mucosa (n=4) PDOs with >10,000 bioactive compounds. We validated our results by preforming a dose response assay to determine the IC50 of select drugs using three representative ESCC PDO lines. We further validated our results in an orthogonal model of murine-derived organoids (MDO) generated from mice bearing normal mucosa, preneoplasia and ESCC, the latter two induced by esophageal carcinogen 4-nitroqunoline-1-oxide. We analyzed DNA damage response (DDR) genes in the Cancer Genome Atlas, ESCC human tissue microarrays, and MDO. We evaluated DNA damage in tissues and organoids by alkaline comet assay and γH2AX staining. We depleted ATR by CRISPR interference (CRISPRi) in MDO.

Results: We identified 222 drugs (many FDA-approved) that killed (viability <80%) the majority of ESCC PDO (≥4 of 7) at 10 μM. We next selected drugs based on their pharmacodynamic properties. First, we selected drugs with IC50 values significantly lower than their Cmax values, the maximum plasma drug concentration documented in patients. We then selected 19 drugs that killed ESCC PDO significantly more (≥three-fold, $P<0.05$) than normal PDO, highlighting a potential therapeutic window for these strategies. Four of such ESCC-selective killers target the DDR regulators ATR, CHK1, and WEE1. We found that in DDR genes were significantly upregulated in ESCC patient tissue (n=88) relative to normal adjacent mucosa (n=11). Moreover, we determined that γH2Ax was significantly elevated in ESCC (n=215) relative to normal mucosa (n=93). We confirmed our results in MDO: γH2Ax labeling index, comet tail moments, and expression of DDR genes were significantly increased during ESCC pathogenesis. CRISPRi-mediated ATR depletion killed ESCC but not normal MDO.

Conclusions: Through an innovative HTS campaign in PDOs, we determined that ESCC are addicted to DDR genes to combat endogenous DNA damage that would be lethal to cancer cells if left unrepaired. ATR and other DDR checkpoint kinases are therefore promising therapeutic targets for selectively killing ESCC cells, and possibly other SCC, underscoring the translational utility of PDO in precision cancer medicine.

#2985 UHRF1 drives small cell lung cancer progression and immune evasion via epigenetic regulation.

Yijun Gu, Claudia Benavente

University of California, Irvine, Irvine, CA

Small cell lung cancer (SCLC) is a highly aggressive subtype of lung cancer, with a five-year survival rate of less than 8%. This poor prognosis stems primarily from rapid tumor growth, early metastasis, and an immunologically “cold” tumor microenvironment. A hallmark of SCLC is the near-universal inactivation of the RB transcriptional corepressor 1 (RB1), yet therapeutic advancements have been hindered by the lack of targetable oncogenic mutations. Our research has identified ubiquitin-like containing PHD and RING Finger domains 1 (UHRF1) as a direct downstream target of the RB pathway and a key protein overexpressed in RB-deficient cancers, including SCLC. Elevated UHRF1 expression correlates with poor survival outcomes in SCLC patients, but its specific role in disease progression remains poorly understood. We hypothesized that UHRF1 overexpression is critical for SCLC tumor progression. To test this hypothesis, we employed CRISPR-Cas9 and shRNA to disrupt UHRF1 expression in human SCLC cell lines. We assessed changes in tumor cell proliferation, clonogenicity, migration, and invasion in vitro, alongside primary tumor growth, metastasis, and survival in vivo. Additionally, we developed genetically engineered mouse models of SCLC to explore Uhrf1’s role of in tumor development, particularly its interaction with the immune microenvironment. Our findings reveal that UHRF1 overexpression drives a more aggressive tumor phenotype by promoting SCLC proliferation, angiogenesis, and maintaining an immune “cold” environment. Loss of UHRF1 in both human and mouse models led to significantly improved survival outcomes. These results underscore UHRF1’s critical role in SCLC progression and highlight its potential as therapeutic target. To elucidate the molecular mechanisms behind UHRF1’s oncogenic roles, we performed transcriptomic analysis using bulk RNA-seq, further validated by RT-qPCR. Upon UHRF1 KO, we observed significant gene expression changes, including downregulation of ST6GALNAC5 and upregulation of MAGEA4, RERG, and TGFBI. Pathway analysis suggests that UHRF1 modulates these downstream targets epigenetically, potentially through DNA methylation. In conclusion, our study identifies UHRF1 as an oncogenic driver in SCLC, facilitating tumor growth, metastasis, and immune evasion via epigenetic regulation. These findings provide a foundation for developing targeted therapies aimed at UHRF1 or its key downstream effectors to improve outcomes for SCLC patients.

#2986 Genomic amplification of MCL1 as a therapeutic target for osteosarcoma.

Satoshi Takagi, Tianyi Huang, Ryohei Katayama

Japanese Foundation for Cancer Research, Tokyo, Japan

Osteosarcoma (OS) is the most common primary malignant bone tumor that predominantly occurs in children, adolescents, and young adults. The treatment for OS that combines surgery with chemotherapy, which consists of a four-drug combination of doxorubicin (DOX), cisplatin (CDDP), high-dose methotrexate (MTX), and ifosfamide, was established in 1970s, and it is still used as a standard therapy. The lack of progress in drug development for OS is partly due to unidentified actionable oncogenic drivers common to OS. In this study, we demonstrate that copy number gains of MCL1 frequently occur in OS, leading to increased vulnerability to therapies based on Mcl-1 inhibitors. Fluorescence in situ hybridization analysis of formalin-fixed paraffin-embedded specimens revealed MCL1 amplification in 46.3% of patients with OS at the JFCR hospital (N = 41). Furthermore, analysis of the TARGET OS dataset, which comprises pediatric patients with OS (N = 81), found that the frequency of MCL1 amplification was notably higher, at 70.4%. Genetic inhibition of MCL1 induced significant apoptosis in MCL1-amplified OS cells. Pharmacological inhibition of MCL1 demonstrated a negative correlation between MCL1 copy numbers and sensitivity to Mcl-1 inhibitors, including MIK665 and AZD5991, with a Pearson's r value of -0.65 ($p = 0.03$) across OS cell lines. The chromosome 1q21.2-3 region, where MCL1 is located, contains multiple genes related to the IGF-1R/PI3K pathway, including PIP5K1A, TARS2, OUTD7B, and ENSA, which also showed increased copy numbers in MCL1-amplified OS cells. Additionally, the combination of MIK665 with IGF-1R inhibitors, including OSI906, AEW541, and AZD3463, induced synergistic cell death by overcoming drug tolerance conferred by the activation of IGF signaling in OS cells. In a NOS-10 (which has 16 copies of MCL1) xenograft model, MIK665 significantly suppressed tumor growth, and its antitumor effect was remarkably enhanced by combining with OSI906. This trend was also observed in a NOS-1 (with 5 copies of MCL1) xenograft model, but the enhancement was more modest than in the NOS-10 model. Moreover, the combination therapy of AZD5991 with OSI906 also reduced tumor growth in the NOS-10 xenograft model. These results suggest that genomic amplification of MCL1 in the 1q21.2-3 region, observed in nearly half of OS patients, may act as a predictive biomarker for combination therapy with an Mcl-1 inhibitor and an IGF1-R inhibitor.

#2987 Role of EIF4G1 network in non-small cell lung cancers (NSCLC) pathogenesis and development of targeted therapy.

Z. Qin[1], S. R. Post[1], H.-y. Li[2], L. Dai[1];

[1]University of Arkansas for Medical Sciences, Little Rock, AR, [2]University of Texas Health San Antonio, San Antonio, TX

Although the Eukaryotic Translation Initiation Factor 4 Gamma 1 (EIF4G1) has been found overexpressed in a variety of cancers, its role in non-small cell lung cancers (NSCLC) pathogenesis, clinical relevance and therapeutic potential remain largely unknown. By using cancer patients tissue assays, our results indicate that EIF4G1 expressional levels are much higher in NSCLC tissues than in adjacent or normal lung tissues, which are also associated with NSCLC patient survival. By using an RNA-Sequencing based pipeline, the data show that EIF4G1 has a significant association with immune checkpoint molecules such as PD-1/PD-L1 in NSCLC. Protein array results identify the signature of proteins controlled by EIF4G1 in NSCLC cells, in which new candidates such as MUC1 and NRG1 are required for NSCLC survival and tumorigenesis with clinical relevance. EIF4G1 small-molecule inhibitors effectively repress NSCLC growth in cell culture and xenograft animal models. To further improve the specificity of EIF4G1 targeted therapies, we recently have designed and synthesized O'PROTAC-based EIF4G1 specific degraders which showing effective anti-NSCLC activities. Taken together, these results demonstrate the immunoregulatory functions, clinical relevance and therapeutic potential of the EIF4G1 network in NSCLC, which may represent a promising and novel target to improve lung cancer treatment.

#2988 Patient-survival linked *TTLL12* isoform switching event sensitizes EAC cells to standard-of-care chemotherapy agents via chaperone-mediated autophagy.

Y. Zhang[1], R. Israel[1], B. Vandenburg[1], S. Barnett[1], J.-J. Riethoven[2], J. Clarke[2], M. P. Lee[1], D. A. Ntsiful[1], K. H. Lagisetty[1], J. Lin[1], R. M. Reddy[1], C. Ekeke[1], A. C. Chang[1], D. Odell[1], L. A. Kresty[1];

[1]University of Michigan, Ann Arbor, MI, [2]University of Nebraska - Lincoln, Lincoln, NE

Esophageal adenocarcinoma (EAC) represents a growing health problem characterized by rising incidence and poor prognosis, despite current multimodal therapy. Although EAC has a high mutational burden, it lacks highly prevalent oncogenic drivers that can be therapeutically targeted, as *TP53* mutation accounts for over 80% of mutational events in EAC. Recently, our group characterized isoform switching events, defined as a change of dominant gene isoforms between conditions, associated with EAC progression and identified 75 isoform switching events between Barrett's low-grade dysplasia (BE.LGD) and Barrett's high-grade dysplasia (BE.HGD) patient samples. Herein, we further investigated whether isoform-switching events may offer prognostic or therapeutic value in EAC. Isoform switching analysis was performed using RNA-seq data derived from 57 patient samples comparing BE.LGD to BE.HGD combined with EAC (BE.HGD+EAC) alone or in combination with *TP53* mutations. Patients were further stratified into tertiles based on isoform expression levels, followed by survival analysis. Forty-two isoforms were significantly ($P<0.05$) linked with all-cause mortality, comparing BE.LGD with BE.HGD+EAC, whereas 39 isoforms were identified when *TP53* mutation status was included. Among those identified to be significantly associated with all-cause mortality comparing BE.LGD with BE.HGD+EAC, isoforms of tubulin tyrosine ligase like 12 (*TTLL12*), a gene linked with aberrant cell proliferation, oxidative stress and cancer progression in other targets, were among the top isoforms switched. Isoform-specific genetic knockdown was performed via siRNA to target the protein-coding isoform of *TTLL12* in two EAC cell lines (OE19 and OE33). Knockdown of the *TTLL12* protein-coding isoform significantly inhibited cell viability and migration in both cell lines. In addition, synergistic effects on cell viability were observed for *TTLL12* knockdown of EAC cells treated with standard-of-care chemotherapeutic agents (Paclitaxel and Carboplatin), suggesting a role for specific isoform-switching events in therapeutic sensitization. Protein-interaction prediction using STRING and immunoblot analysis further supported that TTLL12 is linked with the regulation of chaperone-mediated autophagy (CMA), as evidenced by the induction of LAMP2A and HSC70 in EAC cells. Because CMA is linked with the regulated degradation of CHK1 and mutant TP53 in other cancers, we are currently assessing the role of CMA in regulation of CHK1 and degradation of TP53 in EAC. Future directions include using FDA-approved agents to target CMA in EAC. In conclusion, isoform switching may provide fresh insight for the identification of prognostic markers and inform new potential therapeutic targets for EAC treatment or prevention.

#2989 PIM1 contributes to tumor progression, immune evasion and metastasis of triple-negative breast cancer.

Chandrajeet Singh[1], Patrick Faughnan[1], Wasif A. Mohi[1], Bao Le[1], Jason M. Foulks[2], Golam Mohi[1]

[1]University of Virginia, Charlottesville, VA,[2]Sumitomo Pharma America, Inc, Marlborough, MA

Triple-negative breast cancer (TNBC), which is characterized by the absence of expression of estrogen, progesterone and HER2/Neu receptors, is the most aggressive subtype of breast cancer and associated with poor prognosis. Due to the absence of definitive molecular targets, chemotherapies are commonly used to treat TNBC, but these patients eventually develop resistance to chemotherapies. Therefore, there is a critical need to develop novel targeted therapies for TNBC. Analysis of the TCGA gene expression datasets and CCLE breast cancer cell line database revealed that PIM1 expression is significantly elevated in TNBC patients and TNBC cell lines. We also observed increased levels of PIM1 expression in metastatic breast cancer patients. Furthermore, high expression of PIM1 is associated with poor survival in TNBC patients. PIM1 belongs to the PIM family of serine/threonine kinase that controls cell growth and survival. Depletion of PIM1 by shRNA-mediated knockdown or CRISPR/Cas9-mediated genome editing significantly reduced the proliferation, migration, invasion and 3D tumor sphere formation of TNBC cells. To study the *in vivo* roles of PIM1 in breast cancer progression and metastasis, we crossed the MMTV-PyMT metastatic breast cancer mouse model with Pim1 knockout mice. Genetic ablation of Pim1 significantly inhibited breast tumor growth and reduced lung metastasis in these mice. Treatment of TP-3654, a novel second generation PIM1 kinase inhibitor, also significantly reduced proliferation, migration, invasion and tumor sphere formation in TNBC cells, and reduced breast tumor growth and lung metastasis in MMTV-PyMT mice. Genetic deletion or pharmacologic inhibition of Pim1 also resulted in a significant reduction of tumor-associated macrophages (TAMs) and cancer stem cells (CSC) while increased the infiltration of cytotoxic and helper T cells in the mammary tumors of MMTV-PyMT mice, suggesting a role of Pim1 in the maintenance of tumor microenvironment and immune evasion. Mechanistically, we show that deletion or inhibition of PIM1 significantly inhibited the activation of mTORC1 signaling pathway and reduced the expression of Slug, Vimentin and c-Met in TNBC cells. Additionally, we performed RNA-sequencing analysis on MDA-231 TNBC cells without or with PIM1 deletion or TP-3654 treatment to identify which pathways were affected by PIM1 deletion or inhibition. Gene Set Enrichment Analysis (GSEA) revealed significant downregulation of genes related to cell proliferation, translation, EMT and metastasis in PIM1-deleted or TP-3654-treated TNBC cells compared to control TNBC cells. Collectively, our results suggest that PIM1 plays an important role in tumor progression, immune evasion and metastasis of TNBC, and inhibition of PIM1 with TP-3654 might be potentially useful for treatment of TNBC.

#2990 Single-slide FFPE proteomic profiling enables therapeutic target quantification and molecular subtyping in non-Hodgkin's lymphoma and bone marrow tumor biopsies.

Matthew Loya[1], Tine Casneuf[2], Helene Bon[2], Manling Ma-Edmonds[1], Angelo Harris[1], Daniel Martin[1], Anantharaman Muthuswamy[1], Dominique Kamber[3], **Martin Mehnert**[3], Amaury Lachaud[3], Yuehan Feng[3], Mark Fereshteh[1], Omar Jabado[1]

[1]Genmab, Plainsboro, NJ,[2]Genmab, Utrecht, Netherlands,[3]Biognosys AG, Schlieren, Switzerland

Molecular profiling of formalin-fixed paraffin-embedded (FFPE) tumors in clinical research is performed with low-plex immunohistochemistry or genome-wide transcriptomics. The application of unbiased, highly multiplexed proteomics to FFPE is limited by sample input requirements, assay throughput and complex bioinformatics. Here we report a proteomic method amenable to low-input FFPE profiling which complements transcriptomics.

We applied Biognosys' mass-spectrometry platform (TrueDiscovery, DIA-MS) to samples encountered in routine histopathology laboratories (e.g. B-cell malignancies [n = 35], and breast, pancreatic and colorectal tumors [n=8]). FFPE samples were deparafinzed, de-crosslinked followed by trypsin digestion, and resulted peptides were analyzed by directDIA. Impact of tissue staining by Hematoxylin and Eosin (H&E) and acid decalcification was also assessed. We compared a deep-proteome workflow on a Thermo Scientific Orbitrap Exploris 480 to a novel high throughput workflow on a Bruker timsTOF HT.

The deep-proteome workflow with single-slide FFPE tissues (median area 35mm^2) generated comprehensive proteome coverage: ~12,000 proteins detected overall and ~7,000 detected in the majority of samples. The high throughput Bruker workflow delivered similar data with 80% less input in 20% of the time. Proteomes from H&E stained, cover-slipped slides were nearly identical to adjacent unstained tissue. Interestingly, proteomics profiling was successful in acid decalcified leukemia bone marrow biopsies whereas RNA was not recoverable. To assess the detection of key tissue biomarkers for therapeutic decision-making, we compiled a list of FDA approved antibody based therapeutic targets and found 20 of 21 were detectable in our samples (e.g. PDL1, PD1, LAG3, CD19, CD20 and CD38). Similarly, >80% of 55 immuno-oncology targets undergoing clinical development were detected. A key effector function of antibody therapeutics is complement-dependent cytotoxicity. The presence of complement components was confirmed by proteomics, however, some were undetectable by transcriptomics. Diffuse Large B-cell Lymphoma samples in this study were molecularly subtyped for a key prognostic, Cell of Origin (COO), using a CLIA validated RNA assay (Lymph2Cx). Well studied proteins (e.g. MUM1 and CD10) showed expected distribution based on patient COO, demonstrating proteomics can recapitulate established subtyping methods.

We demonstrate that proteomics profiling can be conducted on single FFPE slides even with pre-processed tissue. This high-throughput workflow enables real-time analysis of Phase I trials or large tissue banks. Furthermore, proteome profiling provides an opportunity to consolidate testing for multiple therapeutic targets instead of serial IHC assays, maximizing the use of precious tissue biopsies.

#2991 Systematic discovery of regulators of adoptive T-cell therapeutic resistance using *in vivo* CRISPR screening.

Chenlin Zhao[1], Sharif Ahmed[2], Xiyue Hu[1], Ranjit S. Atwal[1], Zongjie Wang[3], Sophie Xiao[1], Shana O. Kelley[1]

[1]Biochemistry and Molecular Genetics, Feinberg School of Medicine, Northwestern University, Chicago, IL,[2]Department of Chemistry, Northwestern University, Chicago, IL,[3]Department of Biomedical Engineering, McCormick School of Engineering, Northwestern University, Evanston, IL

Background: Adoptive T-cell therapy has emerged as a promising approach for the treatment of several malignancies, including melanoma. Despite promising outcomes, therapeutic resistance remains a significant challenge, with limited or transient responses observed in many patients. The molecular mechanisms driving resistance pathways have not been thoroughly studied *in vivo*. Systematic characterization of the genetic regulators of adoptive T-cell therapeutic resistance is thus critical for designing next-generation of synergistic combination therapies and treatment regimens to enhance efficacy and durability.

Methods: We developed an *in vivo* CRISPR knockout screening system to identify genetic factors mediating resistance to adoptive T-cell therapy in a melanoma mouse model. To explore potential synergistic therapeutic combinations, we opted to target the easily druggable subset of the human genome, encompassing all known kinases. CRISPR-edited B16-GFP-OVA cells transduced with a mouse CRISPR KO library (Brie: comprising 2,852 sgRNAs targeting 713 mouse kinase genes) were engrafted into C57BL/6J mice. The mice were divided into two groups: a PBS control group (n=6) and a T-cell treatment group (n=14). Tumors were harvested either at an early (Day X) or later time points (Day Y) for genomic DNA extraction and next-generation sequencing (NGS)-based guide RNA enrichment analysis. Deep sequencing data were analyzed using the MAGeCK pipeline. Functional validation of our top candidates was performed by generating single clones of single-gene CRISPR knockouts and conducting functional profiling using orthogonal assays, including flow cytometry, LDH cytotoxicity assay, and pharmacological inhibition studies to assess target engagement and efficacy.

Results: The CRISPR screen identified two key regulators of adoptive T-cell resistance, termed NU-ATCTr-101, NU-ATCTr-102. Single-gene knockouts of these targets significantly enhanced T-cell-mediated killing *in vitro*. Pharmacological inhibition of NU-ATCTr-101 demonstrated a dose-dependent increase in cytotoxicity and enhanced T-cell response. Mechanistic studies revealed alterations in antigen presentation, PD-L1 expression, and T-cell activation pathways. Bulk RNA sequencing and additional pathway analyses are ongoing to further elucidate precise molecular mechanisms underpinning these enhanced therapeutic outcomes.

Conclusion: Our findings identify NU-ATCTr-101 and NU-ATCTr-102 as potential therapeutic targets to overcome resistance to adoptive T-cell therapy. Synergistic pharmacological interventions targeting these kinases may serve as promising adjuvants towards the development of effective immunotherapeutic strategies. Future studies will focus on validating these findings across additional human cancer model systems to evaluate and expedite their translational potential.

#2992 Uncovering metabolic dysregulation and therapeutic targets in aneuploid models of squamous cell carcinoma.

Nadja Zhakula[1], Sejal Jain[2], Laura Byron[3], Joan J. Castellano[4], Matthew L. Meyerson[5], Alison M. Taylor[4]

[1]Genetics and Development, Columbia University Irving Medical Center, New York, NY,[2]Medical Oncology, Dana-Farber Cancer Institute, Boston, MA,[3]Cell and Developmental Biology, Rutgers University, New York, NY,[4]Pathology and Cell Biology, Columbia University Irving Medical Center, New York, NY,[5]Genetics and Medicine, Harvard Medical School, Boston, MA

Squamous cell carcinomas (SCCs) arise from epithelial tissues in the lung, head and neck, esophagus, bladder, and cervix. SCCs lack canonical oncogenic mutations and urgently need targeted therapies. Aneuploidy—chromosomal losses or gains, is rare and poorly tolerated in normal cells but occurs in 90% of tumors in tissue-specific patterns. SCCs are characterized by near-universal early chromosome 3p deletion and 3q gain, which correlate with poor prognosis and metastasis. To study effects of 3p deletion in human cells, we used CRISPR-Cas9 to delete a copy of 3p in human immortalized lung epithelial cells, representing the basal cell (lung SCC cell-of-origin). In a subset of clones with 3p deletion, we observed whole chromosome duplication of the unaltered chromosome 3 copy. As a result, these cells transitioned to a state of 3q gain, providing us models for 3p loss, 3q gain, and 3 disomy.

To uncover vulnerabilities associated with chromosome 3 arm aneuploidies, we performed drug-repurposing and CRISPRi screens in our engineered cells. In 3q gain cells, the top genetic hit was sterol regulatory element-binding factor 1 (SREBF1), a key regulator of cholesterol and fatty acid biosynthesis. Compared to cells without 3q gain, 3q gain cells were more sensitive to knockdown of SREBF1, co-factor SCAP, and downstream target HMG-CoA reductase (HMGCR), the rate-limiting enzyme in cholesterol synthesis. HMGCR inhibitors (several statins, including mevastatin) were top chemical hits, inducing higher cell death in 3q gain cells. Chemical inhibition of SREBF1 using fatostatin recapitulated effects seen with genetic knockdown. Rescue with mevalonate or geranylgeranyl pyrophosphate (GGPP, a product of the mevalonate pathway involved in protein prenylation) demonstrated the toxicity of pathway inhibition are on-target. Transcriptomic and lipidomic profiling suggest that increased statin sensitivity of 3q gain cells is due to their reduced activation of SREBF1 and HMGCR, causing increased cell death upon inhibition of the mevalonate pathway. Ongoing mechanistic studies will investigate how aneuploidy alters lipid metabolism and contributes to cancer.

Statins have been shown to induce tumor-specific apoptosis and reduce cancer risk, though these effects can be highly variable and context-dependent. Preliminary studies in organoid cultures and SCC cancer cell lines suggest that 3q gain is a biomarker of statin response and sensitivity in SCCs. Mevastatin and fatostatin co-treatment, inhibition at two points in the mevalonate pathway, showed synergy, suggesting statin potentiation that could be beneficial in cancer therapy. Additionally, 3q gain cells showed increased toxicity in response to other cholesterol-lowering compounds. Understanding aneuploidy-induced vulnerabilities will reveal how aneuploidies promote tumorigenesis and help identify precision medicine targets for SCCs with 3q gain.

#2993 Loss of p53 sensitizes cancer cells to oxidative phosphorylation agonism.

Jianhuang Lin[1], Dimitra Georgopoulou[2], Shuzhen Wu[3], Svaty Sachania[2], Rebecca Saunders[2], Biju Mangatt[1], Geeta Sharma[3], Euan Stronach[2], **Anthony Mazurek**[1], Fiona M. Behan[2], Benjamin Schwartz[3], Brendan A. Veeneman[3]

[1]GSK, Collegeville, PA,[2]GSK, Stevenage, United Kingdom,[3]GSK, Boston, MA

Large scale efforts using CRISPR based gene loss-of-function screens have produced comprehensive catalogs of gene essentiality in hundreds of well annotated cancer models. The equivalent catalogs have not been generated for gene gain-of-function. While loss-of-function (LOF) mutations in *TP53* are frequent in cancer, targeting these mutations pharmaceutically remains challenging. To explore synthetic lethalities with p53 LOF we performed genome-wide CRISPR activation screens in wildtype and *TP53* knockout isogenic cancer cell lines. We discovered a cluster of genes associated with oxidative phosphorylation (OxPhos) whose overexpression were synthetic lethal with p53 loss. This is consistent with the literature describing a metabolic switch from OxPhos to glycolysis after p53 mutation/loss. Our screen results suggest that this metabolic switch could be a protective action for cancer cells with mutant p53 if OxPhos activation is synthetic lethal with functional p53 deficiency. Indeed we found that overexpression of two of the top OxPhos gene hits from the screen, namely ADCK3 and SCO2, were synthetic lethal with p53 loss *in vitro*. Moreover, overexpression of ADCK3 resulted in significant growth inhibition of tumors with p53 loss *in vivo*. Mechanistically, overexpression of either ADCK3 or SCO2 significantly induced cellular ROS production and mitochondrial DNA damage in cancer cells with p53 loss. Our results suggest a model that wildtype p53 is important for maintaining the homeostasis between OxPhos and glycolysis. In the absence of p53 cells cannot tolerate the ROS generated by OxPhos and they switch to glycolytic metabolism. Our results are consistent with the model that hyperactivation of ADCK3, a critical component for electron transport chain, results in an increase in OxPhos and subsequently ROS which in the context of p53 deficient cells is lethal. Similar to p53 deficient cells, cancer cells with hotspot *TP53* mutations have been reported to undergo a similar OxPhos to glycolysis metabolic shift and are deficient in the repair of mitochondrial DNA damage caused by OxPhos generated ROS. Our results support that an ADCK3 agonist therapeutic could be an effective strategy to target mutant p53 cancers.

#2994 Co-targeting the HER family and mutant KRAS is efficacious in colorectal cancer.

Mary Kate Kilroy[1], Cecilia Wischmeier[2], Briley SoYoung Park[3], Rosalin Mishra[4], Wasim Feroz[1], Joan T. Garrett[1]

[1]Pharmaceutical Sciences, University of Cincinnati, Cincinnati, OH,[2]University of Cincinnati, Cincinnati, OH,[3]Dana Farber Cancer Institute, Boston, MA,[4]MedPace, Cincinnati, OH

We are investigating the role of naturally co-occurring HER3 and KRAS mutations in colorectal cancer, as about 6% of all colorectal cancers contain a HER3 mutation and 41% contain a KRAS mutation. After investigating the frequency of co-occurring mutations in publicly available data sets, we observed that there is a statistically significant co-occurrence of HER3 in KRAS mutations while there is mutual exclusivity with mutations in the other members of the HER family (EGFR, HER2, HER4) and mutant KRAS. We have found that there is a striking increase in total HER3 levels in SNU-407, LS180, LS513 cells and 572918-348-R and 172845-121-B patient derived organoids (PDOs) when treated with the $KRAS^{G12D}$ inhibitorsMRTX1133 and RMC9805, creating an adaptive response that could limit the efficacy of a KRAS inhibitor as a single agent. We next aimed to determine if this was biologically meaningful by genetically knocked down HER3, KRAS or the combination in SNU-407 and LS-513 cells. We have found that genetic knockdown of both KRAS and HER3 with siRNA targeting KRAS and HER3 in the CRC cell lines SNU-407 ($HER3^{V104M}$,$KRAS^{G12D}$) and LS513 ($HER3^{WT}$, $KRAS^{G12D}$) results in a statistical reduction in cell proliferation in comparison to genetic knockdown with only KRAS or HER3. Next, we examined HER3 binding partners in a panel of CRC and observed HER3 bound to EGFR in SNU-407 cells and HER3 bound to MET in LS513 cells. Co-targeting EGFR and mutant KRAS resulted in a slight synergistic effect in $KRAS^{G12D}$ mutant cell lines usingMRTX1133 in combination with sapitinib, afatinib or peltinib. Currently, we are assessing if there is a synergistic effect directly targeting HER3 with a HER3 antibody-drug-conjugate in combination with a KRAS inhibitor in CRC cells. Our findings may present a new paradigm for targeted combination therapies in colorectal cancer with the eventual goal of increased overall patient survival.

#2995 Inhibition of pyrimidine synthesis and the cell cycle in mesothelioma.

George Scaria, Marian Kratzke, Stephen Porter, Betsy Kren, **Mark A. Klein**

Minneapolis VA Health Care System, Minneapolis, MN

Introduction: Novel approaches to the treatment of advanced mesothelioma are needed, as mesothelioma is considered incurable in the vast majority of cases. Targeting 1) pyrimidine biosynthesis via inhibition of dihydroorotate dehydrogenase (DHODH) and 2) DHODH in combination with inhibition of select cyclin-dependent kinases (CDKs) are potential approaches for treating mesothelioma, as the cell cycle is altered most mesothelioma cells.

Methods: We conducted cell proliferation assays in mesothelioma cell lines to determine the IC_{50} for the DHODH inhibitor BAY2402234 as compared with the older generation DHODH inhibitor brequinar. BAY2402334, brequinar, or control were incubated with mesothelioma cells for 72 hours and cell viability was determined using a Cell Counting Kit-8 spectrophotometric assay. Experiments were conducted with and without uridine at 100 mM to determine the effect of “uridine rescue” on the IC_{50} values for each DHODH inhibitor. We also determined mRNA expression via RNA-sequencing (RNA-Seq) and protein expression via immunoblotting of key mRNA transcripts and corresponding proteins. We then conducted cell proliferation assays to determine if the combination of BAY2402234 plus dinaciclib (inhibitor of CDKs 1, 2, 5, and 9) could be additive or synergistic.

Results: BAY2402234 exhibited a significant degree of potency against 4 mesothelioma cell lines with IC_{50} values ranging from 55 picomolar (pM) to 4.63 nanomolar (nM). Uridine rescue resulted in a significant shift in the fitted curves (suggesting decreased efficacy of BAY2402234 due to uridine supplementation), which supports the notion that DHODH is a major mechanism of BAY2402234 as anticipated. Overall, BAY2402234 was between 59 to 1,811 times more potent than brequinar against mesothelioma cells. After exposure to BAY2402334 or control for 48 hours, H2373 cells were evaluated via RNA-Seq and immunoblotting. Of note, PD-L1 mRNA increased approximately 7-fold, and PD-L1 protein expression increased 1.5-2-fold. In addition, mRNA expression of CDKN1A (p21 protein), Cyclin D1, Cyclin A1, and CDK1 increased. Cytokine pathway interactions also increased. For several concentration combinations, the combination index was < 1, suggesting a synergistic effect of that combination of drugs on decreasing cell proliferation.

Conclusions: BAY2402234 is an extremely potent inhibitor of cell growth in multiple mesothelioma cell lines and 59-1,881 times more potent than brequinar; 2) BAY2402234 and dinaciclib act synergistically, suggesting an interaction between pyrimidine biosynthesis and one or more of the following CDKs: CDK1, CDK2, CDK5, and/or CDK9; and 3) BAY2402234 results in increased PD-L1 expression and increased cytokine pathway mRNA expression, suggesting the potential for enhancement of immune checkpoint blockade.

#2996 TNG462, an MTA-cooperative PRMT5 inhibitor, demonstrates strong efficacy in combination with clinically relevant targeted therapies in MTAP-null preclinical models.

Minjie Zhang, Alice Tsai, Kevin M. Cottrell, Brian B. Haines, Alan Huang, Jannik N. Andersen, Adam S. Crystal, **Kimberly J. Briggs**

Tango Therapeutics, Boston, MA

TNG462 is a clinical-stage, MTA-cooperative PRMT5 inhibitor currently being evaluated in an ongoing phase I/II clinical trial for solid tumors with MTAP loss. Approximately 10-15% of all human cancers exhibit MTAP deletions, including 10-15% of lung cancer and more than 20% of pancreatic adenocarcinomas. MTAP deletion frequently co-occurs with other genetic alterations: ~30% of MTAP-deleted lung adenocarcinomas and ~92% of MTAP-deleted pancreatic ductal adenocarcinomas (PDAC) also harbor KRAS mutations, while ~20% of MTAP-deleted lung adenocarcinomas are also EGFR mutant. Although TNG462 monotherapy drives deep and durable tumor regressions in MTAP-null preclinical models, we investigated its potential in combination with therapies targeting actionable genetic alterations. In relevant models, the combination of TNG462 with either KRAS or EGFR inhibitors led to significant tumor regressions, surpassing the effects of either agent alone. This supports our clinical development plans for TNG462, which include targeted combinations with two RAS(ON) inhibitors, RMC-6236 and RMC-9805 from Revolution Medicines, as well as the EGFR inhibitor osimertinib from AstraZeneca. Additionally, nearly all MTAP-deleted cancers are also CDKN2A-deleted due to the proximity of the two genes on chromosome 9p, resulting in de-repression of the cyclin D-dependent CDK4/6 complexes, which creates a susceptibility to CDK4/6 inhibition. Significant efficacy was observed in preclinical models with the combination of TNG462 and CDK4/6 inhibitors, supporting a potential development path in GBM for our next generation CNS penetrant PRMT5 inhibitor, TNG456, with abemaciclib. Lastly, MTAP loss also sensitizes cells to MAT2A inhibition, providing strong rationale for combining PRMT5 inhibitors with MAT2A inhibitors. Preclinical data demonstrated significant efficacy when subtherapeutic doses of both agents are combined. However, TNG462 monotherapy at a clinically relevant dose achieved comparable benefits to the combination. Collectively, these findings strongly support evaluating TNG462 in combination with other targeted therapies in clinical trials for patients with cancers that exhibit MTAP loss.

#2997 Cell-based assay platforms for NLRP3 inflammasome drug discovery.

Jianghong Wu, Li Liang, Peter Gallagher, Yong Wan, Haiching Ma

Reaction Biology Corporation, Malvern, PA

Inflammasomes have recently emerged as the exciting and promising drug targets for inflammatory disease therapy. The best characterized is the NLRP3 inflammasome. The NLRP3 inflammasome is associated with onset and progression of various diseases, including metabolic disorders, multiple sclerosis, inflammatory bowel disease, cryopyrin-associated periodic fever syndrome, as well as other auto-immune and auto-inflammatory diseases. The NLRP3 inflammasome is a cytosolic multiprotein complex composed of the innate immune receptor protein NLRP3, adapter protein ASC, and inflammatory protease caspase-1 that responds to microbial infection, endogenous danger signals, and environmental stimuli. The assembled NLRP3 inflammasome can activate the protease caspase-1 to induce gasdermin D-dependent pyroptosis and facilitate the release of IL-1β and IL-18, which contribute to innate immune defense and homeostatic maintenance. We have established cell-based Caspase-Glo 1 Inflammasome Assay and NanoBRET target engagement intracellular NLRP3 assay for high throughput screening of inflammasome inhibitors. MCC950 is a cell-permeable, bioavailable, non-toxic sulfonylurea-derived compound. Here, we demonstrate that MCC950 inhibits LPS/Nigericin-induced caspase-1 activation and pyroptotic cell death in dose response mode in PMA primed THP-1 cells in Caspase-Glo 1 inflammasome and CellTiter-Glo viability assays. Our NanoBRET target engagement NLRP3 assay results show that MCC950 binds to cellular NLRP3 within 2 hours of incubation. Interestingly, NanoBRET NLRP3 residence time analysis in living cells indicates that a slow dissociation kinetics (long residence time) is observed for MCC950. Furthermore, Western blot analysis confirms that MCC950 blocks LPS/Nigericin-induced caspase-1 cleavage and activation in PMA primed THP-1 cells. Taken together, our results indicate Caspase-Glo 1 inflammasome and NanoBRET target engagement NLRP3 assays serve as great cell-based assay platforms to facilitate inflammasome drug discovery against inflammatory diseases.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Kinase and Phosphatase Inhibitors 2
Poster Session

#3000 Targeting ERK and PI3K signaling in pancreatic ductal adenocarcinoma.

Gauthami Nair, Katie Reindl, Mohiuddin Quadir

North Dakota State Univ., Fargo, ND

Pancreatic ductal adenocarcinoma (PDAC) remains one of the deadliest malignancies, with a dismal five-year survival rate of only 13%. The high mortality is largely due to late-stage diagnosis, limited surgical options (available in just 10-20% of cases), and the failure of current chemotherapy regimens, which are often plagued by toxicity and drug resistance. Therefore, innovative therapeutic strategies targeting key signaling pathways driving tumor progression are urgently needed. Mutations in the *KRAS* gene, present in approximately 95% of PDAC cases, lead to hyperactivation of the KRAS protein and downstream pathways, including extracellular signal-regulated kinase (ERK) and phosphatidylinositol 3-kinase (PI3K). In this study, we hypothesized that simultaneous inhibition of these critical pathways could effectively suppress PDAC cell proliferation. Using SCH772984 (an ERK 1/2 inhibitor) and pictilisib (a class I PI3K inhibitor), we evaluated their combined effects on human PDAC cell lines (MIA PaCa-2 and PANC-1) and a patient-derived xenograft (PDX) cell line. Our results demonstrate significant synergy between these two inhibitors, as evidenced by reduced cell viability and colony formation in clonogenic assays compared to single-agent treatments. Western blot analysis confirmed that SCH772984 was able to inhibit its target ERK 1/2 and pictilisib was able to inhibit AKT, that is downstream of PI3K. These findings suggest that dual targeting of ERK and PI3K pathways effectively disrupts PDAC cell growth. Future studies will focus on formulating these inhibitors into nanoparticle-based drug delivery systems to enhance solubility, stability, and tumor-specific delivery. Additionally, preclinical testing in animal models will provide critical insights into the therapeutic potential of this combination. This approach represents a promising avenue for improving PDAC treatment outcomes and addressing unmet needs in this aggressive disease.

#3001 Highly selective and oral bioavailable PI3Kγ inhibitor for cancer immunotherapy by targeting myeloid-derived suppressor cells in tumor.

Hanning Wen, Shuai Mao, Mahamadou Djibo, Chengyi Li, Jinsong Tao, Hongyi Zhao, Qiyan Wang, Weijia Zheng, Bo Wen, Wei Gao, Duxin Sun

University of Michigan, Ann Arbor, MI

Introduction: Phosphoinositide 3-kinases (PI3Ks) are crucial for cell growth, survival, and metabolism, with dysregulated signaling common in cancer. The PI3K family includes four isoforms—PI3Kα, PI3Kβ, PI3Kδ, and PI3Kγ—each with distinct roles, where pan-PI3K inhibition often results in toxicity due to broad isoform expression. Existing various PI3K isoform inhibitors, despite *in vitro* specificity, often act as pan-inhibitors at high *in vivo* clinical effective concentrations (1μM to 5μM). We developed a highly selective PI3Kγ inhibitor that retains its specificity even at therapeutic *in vivo* levels, effectively targeting tumor immunosuppressive environment to inhibit tumor growth, while reducing toxicity associated with pan-PI3K inhibitions.

Methods: Newly synthesized compounds were screened for PI3K isoform selectivity by kinase binding assays. After oral administration (p.o.), tissue distribution studies compared lead compounds with IPI-549 across various tissues, including tumor, spleen, tumor-draining lymph nodes (TDLNs), plasma and liver. The lead PI3Kγ inhibitors were further evaluated *in vivo* using MC38 colon cancer model and MMTV-PyMT breast cancer model, in both monotherapy (p.o.) and combination therapy with paclitaxel (PTX) or anti-PD-1 antibody (aPD-1). Immune cell profiling in tumor microenvironment was analyzed by flow cytometry post-treatment.

Results: The lead compounds, SH-315 (γ IC_{50}110.4nM, δ IC_{50}>10000nM, β IC_{50}>10000nM, α IC_{50}3212nM) and SH-327(γ IC_{50}297.4nM, δ IC_{50}>10000nM, β IC_{50} >10000nM, α IC_{50}2438nM), demonstrated significantly higher selectivity for PI3Kγ compared to IPI-549 (γ IC_{50} 5.5nM, δ IC_{50} 968.8nM, β IC_{50} 1566nM, α IC_{50} 1248nM). Concentrations of SH-315 and SH-327 were higher in target tissues (tumors, spleen, TDLNs), while plasma levels were lower than IPI-549, potentially reducing PI3K inhibitor-related side effects. In MMTV-PyMT model, SH-327 and SH-315 at 20 mg/kg, combined with PTX and aPD-1, led to significantly smaller tumors compared to IPI-549. In MC38 model, SH-315 at 10mg/kg combined with PTX and aPD-1 achieved Complete Response (CR) in 60% mice, where SH-327 at 20mg/kg achieved CR in 75% mice. SH-315 at 10mg/kg decreased CD11b+Ly6C+ myeloid-derived suppressor cells (MDSCs) in MC38 tumor by 24% compared to IPI-549 and increased CD8+ T cells in tumor by 41% than IPI-549, suggesting enhanced immune activation and reduced immunosuppression.

Conclusion: The PI3Kγ inhibitors SH-315 and SH-327 demonstrated superior anti-tumor efficacy compared to IPI-549. Treatment with SH-315 and SH-327 reduced immunosuppressive MDSCs and increased cytotoxic CD8+ T cell activity, highlighting their potential to drive anti-tumor responses through targeted immune modulation and supporting their further development for cancer immunotherapy.

#3002 GSC002639, a brain penetrating and mutant-selective PI3Kα inhibitor, exhibits potent mono- and combination therapy against PI3CA mutant tumors.

Xing Fan, Sheng Zhao, Hang Xu, **Biao Lu**, Yuanfeng Xia, Fanglong Yang

Changchun GeneScience Pharmaceutical Co., Ltd., Shanghai, China

Background: PIK3CA gene mutation is recognized as a significant driver of oncogenesis in various human cancers. Approximately 30% of breast cancers, 25% of endometrial cancers, 15% of colorectal cancers, 10% of ovarian cancers, and 5% of lung cancers exhibit mutations in the PIK3CA gene. The approvals of Alpelisib and Inavolisib have demonstrated the therapeutic benefits of PI3Kα inhibition for patients with PIK3CA mutations. However, their inhibition of wild-type PI3Kα leads to side effects such as hyperglycemia with insulin resistance, rash, and diarrhea, which limit their efficacy.
Material and methods: The suppressive effects on cell proliferation and phosphorylated AKT were analyzed across cellular models harboring various PIK3CA mutations. The capacity of GSC002639 to inhibit the isoforms PI3Kβ, PI3Kγ, and PI3Kδ, along with additional kinases, was determined through in vitro kinase activity tests. CDX model were used for in vivo efficacy evaluation. Furthermore, the pharmacodynamic properties of GSC002639 and its impact on glucose imbalance were investigated following established procedures. Preclinical toxicology studies were conducted with GSC002639 over 28 days of dosing in rats and dogs.
Results: GSC002639 exhibited nanomolar potency against PI3Kα hotspot mutations while maintaining approximately 30-fold selectivity over the wild-type PI3Kα. Furthermore, GSC002639 displayed excellent selectivity over other PI3K isoforms, including PI3Kβ, δ, and γ. GSC002639 showed favorable pharmacokinetic properties and strong antitumor activity against cancer cells that express the PI3Kα H1047X mutations, without causing elevated plasma insulin levels, even at high dosages. Our study also revealed a notable observation: In an HR-positive and HER2-negative PI3Kα H1047X CDX model, the combination of GSC002639 with Fulvestrant exhibited greater efficacy than the combinations of either Alpelisib or Inavolisib with Fulvestrant. In addition, GSC002639 showed good brain penetrating capability with a brain/plasma ratio of 0.26. In preclinical toxicology studies, GSC002639 demonstrated excellent therapeutic safety window in F/M rats with 14.6/12.7 folds and in F/M dogs with15.3/28.1 folds, respectively.
Conclusions: In this report, we present the identification and characterization of GSC002639, a selective inhibitor targeting the PI3Kα H1047X mutation. GSC002639 demonstrates high specificity, the ability to cross the blood-brain barrier, and robust in vivo efficacy, while avoiding the insulin elevation. The promising pharmacokinetic and toxicological profiles of GSC002639 suggest its potential as a safe and effective cancer therapy. GSC002639 is undergoing IND-enabling studies, with plans for its clinical evaluation as both a single-agent therapy and in combination regimens for patients with PI3Kα mutant cancers by early 2025.

#3003 Targeting mechanisms of adaptive resistance to the PI3Kαmutant selective inhibitor RLY-2608 in HR+/PIK3CA mutant breast cancer.

Fabiana Napolitano[1], Chang-Ching Lin[1], Khushi Ahuja[2], Dan Ye[1], Maria Rosario Chica-Parrado[1], Yasuaki Uemoto[1], Pamela Luna[1], Yuki Matsunaga[1], Saurabh Mendiratta[1], Nisha Unni[1], Jeon Lee[2], Ariella B. Hanker[1], Carlos L. Arteaga[1]

[1]Harold C. Simmons Comprehensive Cancer Center, Dallas, TX,[2]Lyda Hill Department of Bioinformatics, University of Texas Southwestern Medical Center, Dallas, TX

The *PIK3CA* gene is mutated in ~40% of HR+/HER2- breast cancers. Alpelisib and inavolisib are currently FDA approved for treatment of *PIK3CA*-mutant breast cancers, although neither is selective for mutant *PIK3CA*. Inhibition of wild-type PI3K results in multiple adverse events, including hyperglycemia, which limit the dose and duration of treatment. Further, inhibition of PI3K/AKT relieves feedback suppression of receptor tyrosine kinase (RTK) expression and activity, thus limiting complete inhibition of PI3K/AKT signaling in cancer cells and resulting in adaptive drug resistance. Whether PI3K mutant-selective inhibitors can more potently block this compensatory adaptive resistance is unclear. In this study, we interrogated early adaptive resistance mechanisms to the PI3Kα mutant-selective inhibitor RLY-2608 in HR+ breast cancer cells with *PIK3CA* mutations. Phospho-RTK arrays of MCF7 and T47D cells treated with the IC_{75} of RLY-2608 for 0-48h revealed feedback activation of the ERBB family of RTKs (EGFR, HER2, HER3, HER4) at 24 h. These results were confirmed by immunoblot analysis with phospho-specific antibodies. After an initial inhibition of MAPK and PI3K/AKT signaling at 6 h, we found rebound activation of pERK1/2, pAKT1, and pS6 at 24 h, which was maintained for 48 h, suggesting a potential mechanism of adaptive resistance. To identify the ERBB RTKs causing this adaptation, we tested the TKIs erlotinib, neratinib, and tucatinib, and the HER3 antibodies patritumab and zenocutuzumab, each in combination with RLY-2608. RLY-2608 combined with the pan-HER TKI neratinib and the HER2-selective TKI tucatinib most effectively reduced pERK1/2, pAKT1 S473, and pS6 at 48 h, suggesting inhibition of HER2 could block this adaptive mechanism. In short and long-term proliferation assays, neratinib and tucatinib also synergized better with RLY-2608 compared to the other inhibitors. GSEA of RNA-seq data from MCF7 and T47D cells treated with RLY-2608 for 48 h revealed upregulation of pathways related to tyrosine kinase signaling, extracellular matrix, and redox signaling. FoxO signaling was one of the top upregulated KEGG and Reactome pathways, suggesting that activation of FoxO transcriptional activity may compensate for PI3K/AKT inhibition. The Hallmark Estrogen signaling pathway was also upregulated following RLY-2608 treatment; this was validated by immunoblot analysis, showing that ERα levels increased in T47D and MCF7 cells treated with RLY-2608 over a time course. Other upregulated Hallmark pathways in both cell lines included Myogenesis, Hypoxia, and KRAS signaling down. These findings suggest that, in addition to RTK activation, adaptive resistance to RLY-2608 may involve metabolic reprogramming, increased oxidative stress, and hypoxia signaling, highlighting the need for combination strategies to overcome resistance and enhance treatment efficacy.

#3004 Preclinical characterization of CGT6297, a novel PI3Kα H1047R mutant-selective inhibitor.

Aaron C. Smith, Ben Arwood-Levine, Abiezer Blandon, Alexandra Born, Richard Brizendine, Payal Chatterjee, Mark J. Chicarelli, Michael L. Conner, Brad Fell, Jennifer Fulton, Anna Guarnieri, Hannah Hubert, Ravi Jalluri, Hailey Knox, Keith Koch, Daniel Krischlunas, Vijay Kumar, Sara Kuzbiel, Matt McDonald, Colin McHugh, Brent Mclean, Kelsey W. Nassar, Paul Larsen, Brad Newhouse, Scott Niman, Rob Rieger, John Robinson, Mareli Rodriguez, Leah Salituro, Vinny Scarato, Lee Stunkard, Francis Sullivan, Patrick Sutter, Roy Turton, Rob Van Gulick, Brooklynn Venteicher, Logan Vine, Shannon Winski, Shannon Winski, Hannah Work, Yeyun Zhou

Cogent Biosciences, Inc., Boulder, CO

PIK3CA encodes the p110α catalytic subunit of PI3-kinase alpha (PI3Kα) and is the most frequently mutated kinase in human cancer with common mutations occurring in the kinase domain (H1047R) and helical domain (E542K/E545K). The approved PI3Kα inhibitor, alpelisib, shows promise for this targeted class of agents with improvements in progression-free survival in ER+/Her2- breast cancer patients in combination with fulvestrant. However, toxicities attributed to the inhibition of wild-type PI3Kα, such as hyperglycemia, gastrointestinal issues, and skin reactions, lead to sub-optimal target engagement due to requisite dosing modifications. A PI3K mutant inhibitor that spares WT PI3K is predicted to be better tolerated, require fewer dosing modifications, and therefore, have the potential to provide improved clinical benefit. Herein, we present the preclinical characterization of CGT6297, a wild type sparing PI3Kα H1047R inhibitor.

#3005 Discovery of a potential therapeutic mechanism for selected tumors via targeting PI3K and DDR pathways simultaneously with a novel orally available small molecule.

W. Chen, W. Xu, Y. Wang, Z. Zhou;
LittDD Medicines Ltd, Hangzhou, China

The genomic instability and hyperactivation of PI3K pathway have been observed in many types of tumors. Targeting some of the key proteins among these pathways such as ATR or mTOR individually has been studied in many clinical trials with various small molecular drug candidates, but so far these efforts have failed to deliver therapeutic benefits to patients. One of the key challenges for targeting these targets is the lack of therapeutic window due to their significant toxicities in clinical trials. It has been evidenced that both PI3K and DDR pathways can be activated simultaneously in many tumor types. We hypothesize that targeting both mTOR and ATR simultaneously could generate synergistic effect to lower the toxicities while maintaining the efficacy in selected tumors. Through rational design, we discovered a novel orally available small molecule LIT-00814 which solely inhibits both mTOR and ATR with great selectivity against other kinases. In preclinical studies, LIT-00814 demonstrates much larger therapeutic window while maintaining good efficacy in selected tumor models with higher DDR mutations and PI3K pathway activities. A specific Akt1-S473 phosphorylation antibody LIT-A0001 has also been developed to precisely stratify patients in clinical trials which is critical to eliminate Akt2 and Akt3 signals and identify right patients for LIT-00814. The clinical phase I trials for LIT-00814 were initiated and the preliminary results hold promise to deliver beneficial therapy to selected cancer patients. In summary, we have discovered a novel orally available small molecule LIT-00814 targeting both mTOR and ATR with novel therapeutic mechanisms of action which could deliver beneficial therapy to selected cancer patients.

#3006 Efficacy of novel CDK9/CDK4/6/PI3K triple inhibitors, LCI133 and LCI139, in Ewing sarcoma.

Kaitlyn H. Smith[1], Cody C. McHale[2], Kenzie Wells[1], Krishnaiah Maddeboina[2], Kimberly Q. McKinney[1], Poornima Gourabathini[1], Jeffrey S. Huo[1], Donald L. Durden[2], Javier Oesterheld[1]

[1]Pediatric Oncology Research Laboratory, Atrium Health, Charlotte, NC,[2]Molecular Targeted Therapeutics Laboratory, Atrium Health, Charlotte, NC

Introduction: The survival rate of patients with Ewing sarcoma (ES) has seen slow improvement over the past several decades and remains dismal for those with recurrent or metastatic disease. Initial clinical trials in relapsed/refractory ES with single agent targeted therapies, or combinations of single agents, have not yet improved patient outcomes. To overcome this barrier, the Molecular Targeted Therapeutics Laboratory has developed by *in silico* design “first in class” small molecule multikinase inhibitors (MKIs) which simultaneously target multiple tumor-promoting pathways with a single drug at nM potency. LCI133 (CDK4/6/CDK9) and LCI139 (PI3K/CDK4/6/CDK9) potently inhibit key kinases that control mitogenic signaling, proliferation, and transcription. The purpose of this study is to evaluate the potency, efficacy, and toxicity of LCI133 and LCI139 in ES model systems.
Methods: ES cell lines and normal human skeletal muscle cells (SkMC) were treated with MKIs in logarithmic fashion and IC_{50}s were determined by CellTiter-Glo 2.0 viability assays. Incucyte® Annexin V Dye was used to evaluate apoptosis over time by Incucyte® S3 following MKI treatment. Cell cycle analysis was performed over time using Incucyte® Cell Cycle Lentivirus Reagent and analyzed using an Incucyte® S3. Western blot and qPCR analysis was used to assess protein and RNA expression changes, respectively, of targeted pathways to confirm on-target activity of these MKIs following 3-24 hr treatment.
Results: LCI133 and LCI139 were nanomolar potent in ES cell lines TC71 (392.5nM/312nM) and A673 (471.5nM/407.4nM), while only LCI139 was nanomolar potent in the RDES (262.2nM) cell line. Critically, LCI133 and LCI139 were less toxic against SkMC compared to single agent CDK9 inhibitors. In TC71 and A673 cells, both compounds induced statistically significant dose-dependent apoptosis, as well as G1 phase cell cycle arrest. Three hr LCI133 and LCI139 treatment decreased expression of CDK9-RNA polymerase II response genes *MCL1* ($P \leq 0.001$) and *MYC* ($P \leq 0.001$). 24 hr treatment had differential effects on pRb and pAKT levels. pRpb1 and MCL-1 were reduced in all cell lines by LCI139 and/or LCI133. Increased cleaved PARP (cPARP) was observed in all cell lines following 24 hr treatment with LCI133 and LCI139 confirming the induction of apoptosis.
Conclusion: Novel small molecule MKIs allow for the simultaneous targeting of multiple pathways while mitigating the toxicity of single agent combination therapy. This is a promising potential treatment strategy for ES patients for whom new treatment approaches are desperately needed. These studies provide preclinical evidence of the potential efficacy of small molecule MKIs in ES and support the future efforts of *in vivo* models evaluating efficacy and safety of these agents.

#3007 The epigenetic regulators KDM5C and KAT6A influence AKT inhibitor response in ER positive breast cancer.

Valentina Cutano[1], Shanade Dunn[1], Lorna Hopcroft[1], Eleanor M. Wigmore[1], Lambert Montava Garriga[1], Sungmi Park-Chouinard[2], Wu Qing[2], Lee Hyung Joo[2], Cath Eberlein[1], Michele Chirichella[1], Daniel Barrell[1], Toby Gurran[1], Omid Tavana[2], Neeraj Aryal[2], Jerome T. Mettetal[2], Huayang Liu[2], Ho Man Chan[2], Susan E. Critchlow[1], Ultan McDermott[1], Simon T. Barry[1]

[1]Astrazeneca, Cambridge, United Kingdom,[2]Astrazeneca, Boston, MA

Breast cancer is one of the most common cancers worldwide, and around 80% of breast cancers are oestrogen receptor positive (ER+ BC). For patients with ER+ advanced BC with one or more *PIK3CA/AKT1/PTEN* tumor alterations, capivasertib (AKT inhibitor) in combination with fulvestrant (selective oestrogen receptor (ER) degrader) is a recommended treatment. An innate PI3K/AKT pathway inhibitor resistance can occur in patients with ER+ BC, limiting their efficacy. Therefore, novel therapeutic strategies are needed to increase sensitivity to treatments in patients with ER+ BC. With this aim, from CRISPR-based sensitization screens in ER+ BC cells, we have found that the effectiveness of the AKT inhibitor capivasertib is improved by targeting the epigenetic regulators, KDM5C (lysine demethylase 5C) or KAT6A (lysine acetyltransferase 6A). Knockout (KO) of KDM5C or KAT6A strongly enhances the response to capivasertib monotherapy and its treatment in combination with fulvestrant in *PIK3CA*-mut and *PTEN*-null ER+ BC cells, as well as re-sensitizes capivasertib-resistant ER+ BC cells. Importantly, the effects of the genetic KO were recapitulated with a pan-KDM5 inhibitor and a selective KAT6A/B inhibitor in combination with capivasertib in ER+BC cells, suggesting that combination therapies, consisting of capivasertib with KDM5 or KAT6A inhibitors, could be beneficial in patients. Moreover, transcriptomic analysis and chromatin profiling techniques show that both KDM5C and KAT6A KO downregulate expression and alter chromatic accessibility of a subset of ER-target genes and this phenotype is enhanced in combination with capivasertib, suggesting that targeting KDM5C or KAT6A sensitizes cells to AKTi through a novel epigenetic regulation of ER-signaling. Also, this study reports for the first time a landscape of epigenetic differences upon capivasertib monotherapy treatment and in combination with fulvestrant in ER+BC cells, revealing changes in chromatin accessibility as a consequence of treatment with AKTi and the ER degrader. This suggests that epigenetic remodelling can lead to resistance to capivasertib and fulvestrant therapy in cancer cells. In summary, this findings identified and validated KDM5C and KAT6A as novel epigenetic targets, the inhibition of which enhances efficacy of AKTi in PI3K pathway mutated ER+ breast cancer. Inhibitors of KDM5C and KAT6A may be potential combination partners for capivasertib in ER+ breast cancer.

#3008 The interplay between FOXO3 and FOXM1 influences sensitivity to AKT inhibition in PIK3CA and PIK3CA/PTEN altered estrogen receptor positive breast cancer.

Valentina Cutano[1], Ming Li Chia[2], Eleanor M. Wigmore[1], Stuart C. Williamson[1], Amanda L. Christie[3], Brandon Willis[3], James Kerr[1], Sophie D'Arcy[1], Lauren Bradshaw[1], Cath Eberlein[1], Lambert Montava Garriga[1], Elza de Bruin[1], Susan E. Critchlow[1], Kevin M. Brindle[2], Simon T Barry[1], Susana Ros[1]

[1]Astrazeneca, Cambridge, United Kingdom,[2]Cancer Research UK, Cambridge, United Kingdom,[3]Astrazeneca, Boston, MA

Combining fulvestrant (a selective estrogen receptor (ER) degrader) with the PI3K-AKT signalling inhibitors such as alpelisib (PI3Kα inhibitor) or capivasertib (AKT inhibitor) gives benefit to patients with ER+ breast cancer (ER+ BC) harboring *PIK3CA* mutations (alpelisib) and *PIK3CA*, *PTEN* and *AKT-1* altered tumors (capivasertib). While *PIK3CA* mutations are common, PI3K-AKT signalling activation can also occur due to other alterations, including in *PTEN* or *AKT-1*, which alter pathway function and dependency. Deletion of *PTEN,* leading to ablation of PTEN protein, attenuates the effectiveness of PI3Kα inhibition in *PIK3CA* altered tumors. Our study demonstrates that in ER+ BC tumors with *PIK3CA* activating mutations, co-occurring *PTEN* homozygous or hemizygous loss is common. This study evaluates the impact of reduced PTEN protein expression on the efficacy of AKT inhibition with capivasertib in the presence of *PIK3CA* mutations. In *PIK3CA* altered and intact PTEN protein, *in vivo* tumor and *in vitro* cell line models, PI3Kα and AKT inhibitors are equally effective. However, in *in vivo* and *in vitro PIK3CA* altered models, reduction in PTEN protein expression reduces the effectiveness of PI3Kα inhibition alone and in combination with fulvestrant, while AKT inhibition remains effective. The anti-tumor activity of both monotherapy and combination treatment with PI3Kα or AKT inhibitors is associated with a decrease in FOXM1 protein and FOXM1-mediated gene expression. The regulation of FOXM1 expression is FOXO3-dependent and is directly related to the ability of the PI3Kαi or AKTi to reduce AKT dependent downstream signalling. When FOXO3a is deleted from PTEN deleted - T47D and MCF7 cells, treatment with capivasertib did not reduce FOXM1 expression. Indeed, FOXO3a loss leads to an increase in FOXM1 expression, resulting in no impact on cell viability despite the presence of capivasertib. These findings indicate that inhibiting AKT signalling is a more effective strategy than targeting PI3Kα to address this crucial effector node across a heterogeneous array of PI3K-AKT tumor drivers. Furthermore, the study highlights the pivotal role of the AKT-FOXO3-FOXM1 axis in mediating responses to AKT inhibitors in ER+ breast cancer with *PIK3CA* mutations regardless of *PTEN* expression. In addition, loss of FOXO3a expression can mediate resistance, and FOXM1 downregulation serves as a crucial biomarker of response to the combination treatment.

#3009 STX-478, a *PIK3CA* mutant-selective inhibitor, alone and in combination with romidepsin for *PIK3CA* mutant CRC.

Addison T. Zick, Alexa E. Schmitz, Alec B. Cornelio, Cheri A. Pasch, Dustin A. Deming

University of Wisconsin-Madison, Madison, WI

Background: Hyperactivation of PI3K has been linked to enhanced tumor cell growth and survival, highlighting its importance as a therapeutic target in colorectal cancer (CRC). In this study, we aim to explore the effects of STX-478, a mutant-selective, allosteric *PIK3CA* inhibitor, to assess its impact on *PIK3CA* mutant CRC. Additionally, this study aims to investigate a potential therapy in combination with STX-478 that may amplify its efficacy. A histone deacetylase inhibitor, romidepsin, was chosen as a therapy of interest due to previous work that has shown enhanced activity in CRC lines in combination with PI3K inhibitors.

Methods: CRC cell lines SW48 and SW48PK (Horizon Discovery, SW48 with a $PIK3CA^{H1047R}$ mutation) were utilized in a WST assay to determine the impact of STX-478 treatment. Immunoblotting was performed on SW48 and SW48PK with STX-478 single agent or in combination with romidepsin. ImageJ was used to quantify these blots to evaluate PI3K protein expression. Patient derived cancer organoids (PDCOs) were utilized to determine how growth was affected by STX-478 treatment. PDCO lines were derived from biopsies and surgical procedures, after approved Institutional Review Board protocols and with patient consent. Their response was determined by measuring the longest diameter of any given PDCO at Day 0 versus Day 2. Glass's Delta was determined to quantify effect size and assess any significant growth reduction. Romidepsin was also tested as a secondary agent in both western blots and diameter analysis.

Results: SW48 did not have a significant change in cell viability at high concentrations of STX-478 compared to controls. In contrast, SW48PK showed a significant response to STX-478 treatment at even 500 nM ($p<0.001$). Immunoblotting showed little difference in phosphorylation of AKT in both SW48 and SW48PK, however, in SW48PK, at low concentrations of STX-478, a decrease of phosphorylated ribosomal S6 was seen. In a $PIK3CA^{H1047R}$ mutant PDCO line, a significant response was seen at 750 nM, (Glass's delta = 1.16) 1,000 nM (1.29), 1500 nM (1.51), and 2000 nM (1.62). When treated with the combination of STX-478 and romidepsin, PDCOs had a significant response compared to control and single agents (median percent relative change 12%; control: 39.1% $p<0.001$, STX-478: 27.8%, $p<0.001$, Romidepsin: 19.4%, $p = 0.013$).

Conclusion: This study demonstrates that STX-478, a mutant-selective, allosteric *PIK3CA* inhibitor, exhibits varying effects on CRC cell lines in both 2D and 3D culture models. The combination of STX-478 and romidepsin is promising and deserves further *validation in vivo.*

#3011 Novel CDK12 inhibitors with preclinical anti-tumor activity and best-in-class profile on HER2 low breast cancer patient samples.

C. Seth Nanda, M. New, A. Velentza-Almpani, J. Martinez-Torres, N. K. Bah, N. A. Leonard, F. A. B. Sangkolah, K. K. Nan, E. Peerani, D. Ranatunga;
Pear Bio, London, United Kingdom

CDK12 is an oncogenic ATP-dependent kinase that participates in transcriptional regulation by directly phosphorylating RNApol-II when in complex with cyclin K. Overexpression or amplification of CDK12 is associated with hyper-transcription including upregulation of DNA damage repair enzymes (e.g., RAD51) which then interact with BRCA1, BRCA2 and modulate genomic instability (CDK12 directly phosphorylates cycE1 in the pre-replication complex) and induce uncontrolled cellular proliferation. Immunohistochemistry (IHC) experiments have shown high expression of CDK12 in multiple solid tumors and is associated with poor prognosis. Genomic or chemical inhibition of CDK12 reduces cancer cell proliferation in vitro and in vivo.

A series of novel CDK12 inhibitors were designed, synthesized and screened in a panel of efficacy, selectivity, safety/toxicity, target engagement and functional assays. PB301, PB316, PB325 and PB338 were identified as lead reversible inhibitors exhibiting high on-target potency and low off-target inhibition (non-transcriptional CDKs e.g., CDK2, CDK4, CDK6). For instance, PB325 and PB301 were, respectively, ~800x and 16x more potent than SY-143 (a selective CDK12/13 inhibitor) in 2D cell proliferation assays on a panel of cancer cell lines (e.g., IC50 of 0.1nM for PB325, 5nM for PB301 and 81nM for SY-143 on CAL51 cell line). Moreover, in efficacy assays, the median IC50 for PB316 was 42.99nM (n=7 cell lines), 66.4nM (n=10 patient-derived organoids) and 51.25nM (N=10 primary breast microtumors). Based on this, 50nM was chosen as the CDK12i dose to be tested as an exploratory drug (monotherapy and combo therapy) using fresh ex vivo tissue samples from patients enrolled in the observational clinical trial PEAR-TNBC (NCT05435352) to identify potential combination drug partners and compare drug efficacy to standard-of-care neoadjuvant therapies. Using in vivo models, good bioavailability, plasma and tissue distribution was observed in PK/PD studies upon oral dosing for all the lead compounds in Balb/c mice and key biomarkers like RNApol-II pSer2 and RAD51 showed significant decrease upon successful inhibition of CDK12 in vitro and in vivo. Moreover, our novel compounds demonstrated efficacy in reducing tumor burden in xenografted Balb/c mice (SUM149PT cell line) with once/twice-daily oral dosing.

In summary, we identified a novel series of CDK12 inhibitors which have drug-likeness and high therapeutic potential in solid tumors. Our lead compounds have been assessed and carefully selected using our precision medicine platform to highlight drug molecules that can treat fresh tumor samples as a monotherapy and in combination with standard of care therapeutics. These molecules will be investigated further to nominate a development candidate and commence IND-enabling studies.

#3012 A highly potent selective CDK9 inhibitor OBP-004 reduces metastatic tumor burden in bone, brain, lung and lymph nodes and decreases growth of triple-negative breast cancer cells in bone.

Tiina E. Kahkonen[1], Gergana Galabova[2], Ru Yang[3], Jie Wen[3], MIchael Thormann[2], Jussi M. Halleen[1]

[1]OncoBone Therapeutics Ltd, London, United Kingdom,[2]Origenis GmbH, Planegg, Germany,[3]PharmaLegacy LLC, Shanghai, China

CDK9 is a promising target in many cancers. Development of first generation CDK9 inhibitors has been stopped due to severe adverse effects, but next generation selective CDK9 inhibitors are considered safer and more effective. OBP-004 is a highly potent selective small-molecule inhibitor of CDK9 with favorable physicochemical properties, 17-20 h in vivo half-life and high tissue biodistribution in brain, lung, spleen and kidneys. Triple-negative breast cancer (TNBC) patients have limited treatment options together with high incidence of metastatic relapse. TNBC typically forms multi-organ metastases and has a high incidence of bone metastases. In this study, we demonstrate preclinical efficacy of OBP-004 on metastatic tumor burden, and more specifically on bone metastatic TNBC.
For studying efficacy on metastatic disease, NMRI nude mice were inoculated intravenously with luciferase-labelled MV4-11 human acute monocytic leukemia cells. OBP-004 was given orally at a dose of 1.0 mg/kg three times a week (3-day on, 4-day off). The mice were randomized to groups based on body weight and bioluminescence imaging (BLI) signal at day 15, and tumor growth was monitored by BLI during the study. Treatment was started after the randomization at day 15 and continued until day 32. For studying efficacy on tumor growth in bone metastatic microenvironment in more detail, BALB/c mice were inoculated intratibially with aggressive luciferase-labelled 4T1 mouse TNBC cell line. OBP-004 was given orally at a dose of 0.8 mg/kg three times a week (Mon/Wed/Fri). The mice were randomized to groups based on body weight and BLI signal at day 4. Treatment was started after the randomization at day 4 and continued until day 21. During the study, tumor growth was monitored by BLI, cancer-induced bone changes by X-ray radiography, and bone pain by mechanical allodynia using Von Frey filaments.
The 1.0 mg/kg dosing (3-day on, 4-day off) of OBP-004 in the MV4-11 study resulted in slight decrease of body weight without any clinical signs. The optimized dosing with 0.8 mg/kg (Mon/Wed/Fri) in the 4T1 study was well tolerated. In the MV4-11 model, OBP-004 showed strong decrease of bone, brain, lung and lymph node metastases. In the intratibial 4T1 model, OBP-004 decreased tumor growth in bone from day 10 forward, bone pain at day 14, and cancer-induced bone loss at day 21.
We conclude that the highly potent selective CDK9 inhibitor OBP-004 reduces metastatic tumor growth in bone, brain, lung and lymph nodes and decreases metastatic growth of TNBC cells in bone microenvironment, bone pain and cancer-induced bone loss in an aggressive preclinical TNBC model.

#3013 GSC000829, a novel selective FGFR2/3 inhibitor, displays superior antitumor activity in preclinical FGFR-driven neoplasms models.

Tian Han, Donglin Fu, Tao Cheng, **Yuanfeng Xia**, Zhilong Hu, Fanglong Yang

Changchun GeneScience Pharmaceutical Co., Ltd., Shanghai, China

Fibroblast growth factors (FGF) and their receptors (FGFRs) are pivotal in a myriad of cellular functions. Tumorigenesis onset due to FGFR genomic alterations is commonly observed across diverse solid tumors. Although several FGFR inhibitors targeting FGFR1-3 or FGFR1-4 have gained approval for treating various solid tumors, their widespread application is hindered by the development of resistant gatekeeper mutations in FGFR proteins and toxicities linked to FGFR1 and/or FGFR4, necessitating precise dosing or even drug withdrawal. Here, we report the discovery of a novel pre-clinical candidate compound GSC000829 with a strong inhibition towards FGFR2/3 and a significantly improved selectivity over FGFR1 and FGFR4. Furthermore, GSC000829 shows excellent efficacy in various biochemical and cellular assays corresponding to different FGFR fusions or mutations. It also demonstrates enhanced antitumor activity at lower dosage in FGFR3-driven CDX models compared to the pan-FGFR inhibitor Erdafitinib, as well as other FGFR3-selective inhibitors such as TYRA300 and LOXO-435. GSC000829 exhibits favorable physicochemical and pharmacokinetic properties along with an excellent preclinical toxicity profile with no obvious phosphate increase at quite high exposure level in rats. Taken together, these findings bolster the rationale for advancing GSC000829 into clinical trials as a potential best-in-class FGFR isoform-selective inhibitors, offering an approach for treating advanced solid tumors harboring FGFR2/3 aberrations.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Antibody-Based Cancer Therapeutics 2

#3014 The mechanism of action of ADCs are dependent on Rab GTPases.

Astrid Medhus[1], Kay Oliver Schink[2], Ane Sager Longva[1], Olav Engebraaten[1], Kristian Berg[1], Anette Weyergang[1]

[1]Oslo University Hospital, Institute for Cancer Research, Oslo, Norway,[2]University of Oslo, Institute of Basic Medical Science, Oslo, Norway

Antibody-drug conjugates (ADCs) are therapeutic compounds designed to exert targeted toxicity as compared to conventional chemotherapy. The conjugation of a cytotoxic payload to an antibody trough a chemical linker serves to lower the systemic toxicity and thereby increase the therapeutic window. However, an enhanced understanding of the mechanism of action of ADCs is needed, as little is known about how these drugs are trafficked and processed within the cell.
The tumor-targeted activity of ADCs depend on the presence of target molecules on the tumor cell surfaces, and the overall response of ADCs is generally dependent on the expression level of these surface receptors. However, ADCs are dependent on cellular uptake and intracellular trafficking for the cytotoxic payload to be released and reach its target within the cell. This process of endocytosis and subsequent intracellular trafficking is regulated by a group of small molecular switches called Rab GTPases. These proteins acts as key regulators of the endo/lysosomal machinery, and we hypothesized them to impact ADC efficacy.
We used cell lines from breast and lung cancer origin to study the mechanism of action of different ADCs dependent on RAB5 and RAB4 expression. We have found that the makeup of the ADC - comprising the antibody moiety, linker design, and choice of payload - dictates how it is taken up and processed, and thereby determines which Rab GTPases are critical for its therapeutic effect. Our results demonstrate how ADC design influences intracellular trafficking and processing, and points towards linker design as a major regulator of the intracellular fate of an ADC.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Kinase and Phosphatase Inhibitors 2

#3014 ASN-7350, a highly selective FGFR2/3 dual inhibitor, for FGFR2/FGFR3 driven solid tumors.

Qiaoling Sun[1], Jingmin Guan[1], Haifeng Song[1], Jing Lv[1], Peng Zeng[1], Mengyuan Wang[1], Yonghui Yu[1], Shuai Luo[1], Jinna Yu[1], Liang Wu[1], Tielin Wang[1], Alice Chen[2]

[1]Asieris Pharmaceuticals (Shanghai) Co,Ltd, Shanghai, China,[2]Asieris Pharmaceuticals, Palo Alto, CA

Alterations in fibroblast growth factor receptors (FGFRs) are recognized as oncogenic drivers in numerous human cancers. Several FGFR inhibitors, with similar potencies against FGFR1-3 or FGFR1-4, have been approved and demonstrated modest clinical benefits in FGFR-altered urothelial carcinoma and bile duct cancer. The clinical benefit was limited partly due to FGFR1- and FGFR4-mediated side effects. In addition, FGFR2/3 acquired resistance mutations after initial response to pan-FGFR inhibitor limit the long-term clinical efficacy as well. 60% of patients develop these secondary FGFR2 kinase domain mutations in FGFR2-altered cholangiocarcinoma, and 13-25% of patients develop FGFR3 resistance mutations in urothelial carcinoma. ASN-8639 and ASN-7350 were designed to address these challenges in treating multiple solid tumors harboring FGFR2/3 alterations. ASN-7350 is a novel, highly selective, and potent non-covalent FGFR2/3 inhibitor (IC50 < 5 nM in kinase assays). It showed greater than 200-fold selectivity for FGFR3 over FGFR1/4 in cellular assays. The prodrug ASN-8639 is in preclinical developed to improve the pharmacokinetic profile of ASN-7350. ASN-8639 was efficiently converted to ASN-7350 and showed dose-proportional increases in exposure and clinically acceptable oral bioavailability across four different species. ASN-7350 was more potent in inhibiting FGFR3 wt/mut signaling than competitor compounds. Its cell killing potency was 10× stronger compared to a reference compound currently in clinical development in cell lines harboring FGFR3-TACC3 fusion or erdafitinib-resistant FGFR3-V555M mutation, and meanwhile with a better the cellular selectivity of FGFR3 over FGFR1 and FGFR4. ASN-8639 demonstrated significant anti-tumor efficacy in cancer model of RT112 with FGFR3-TACC3 fusion and erdafitinib-resistant mutations of FGFR3-V555M. ASN-7350 also exhibited high potency against FGFR2. It produced comparable activity to a reference FGFR2 inhibitor in clinical development in multiple FGFR2-altered cell lines. Notably, ASN-8639 was more efficacious than reference FGFR2 inhibitor in the endometrial tumor model with erdafitinib-resistant FGFR2-N549K mutation at the same dose. These findings support the further clinical development of ASN-8639 as a potential best-in-class FGFR2/3 dual inhibitor for the treatment of bladder, endometrial, and other solid tumors with FGFR2/3 aberrations.

#3015 EGFR x MET tsAb: Differentiated MET biparatopic design with optimal MET inhibitory activity to pursue best-in-class opportunity.

Yanzhou Zhang[1], Ming Jiang[2], Hongyu Chen[2], Mengran Qian[1], Renke Li[1], Huang Yan[1], Huan Li[1], Xiaona Sun[2], Sujuan Huang[2], Xuechun Zhang[2], Ming Fang[2], Yue Wu[2], Fan Wang[2], Mingchao Kang[2], Xiaomin Song[2], Xi Wu[2]

[1]BeiGene (Shanghai) Biotechnology Co., Ltd., Shanghai, China,[2]BeiGene (Beijing) Co., Ltd., Beijing, China

Acquired resistant mutation after small molecule inhibitor treatment in non-small cell lung cancer (NSCLC) develops invariably through mutations in EGFR or through activation of compensatory pathways such as MET. BG-T187 is a tri-specific antibody (TsAb) targeting EGFR and MET with a differentiated MET biparatopic designation designed to treat tumors driven by activated EGFR and/or MET signaling. Stronger antiproliferative effects and MET signaling inhibition by BG-T187 compared to traditional EGFR/MET bi-specific antibody were observed in vitro. Additionally, potent in vivo anti-tumor activity was observed upon BG-T187 treatment of human tumor xenograft models driven by EGFR activation mutation and/or MET amplification. Interestingly, stronger anti-tumor activity of BG-T187 than that of traditional EGFR/MET bi-specific antibody was observed in xenograft models with MET amplification. Through a comprehensive assessment of EGFR on-target toxicity risk, we demonstrated that BG-T187 show better HEKn selectivity than EGFR/MET bi-specific antibody, indicating potential lower on-target toxicity risk of BG-T187. Collectively, our findings represent a novel EGFR/MET tri-specific antibody with differentiated MET biparatopic and pursue best-in-class potential.

#3016 Therapeutic efficacy of a novel combination of ck2 inhibitor cx-4945 with cytotoxic therapy in neuroblastoma preclinical models.

Marudhu Pandiyan Shanmugam, Muhammed Danial, Rajesh Rajaiah, Koby Duke, Katie Mercer, Yasin Uzun, Sinisa Dovat, Giselle Saulnier Sholler, Chandrika Gowda Behura

Pediatrics, Penn State University College of Medicine, Hershey, PA

Introduction: Neuroblastoma is a pediatric cancer of the sympathetic nervous system, which is often diagnosed at a clinically advanced stage with primary or acquired resistance to conventional chemotherapy. Protein Kinase CSNK2A1 (CK2) is an intrinsically active, ubiquitously present serine-threonine kinase overactive in various solid cancers, including neuroblastoma (NBL). Recurrent genetic alteration in CK2 is not detected in NBL. CX-4945 (Silmitasertib) is an ATP-competitive CK2 selective small-molecule irreversible inhibitor of CK2 with inhibition constant (Ki) values in the low nanomolar range and high selectivity (49 of 250 kinases) versus other kinases. CX-4945 has shown *in vivo* anti-tumor activity in solid tumors and leukemia has favorable pharmacokinetic properties and is well-tolerated in human subject studies. Here, we report the therapeutic efficacy of CX-4945 in combination with temozolomide and irinotecan NBL preclinical models.

Methods: The susceptibility of NBL cell lines with and without MYCN amplification was tested against CX-4945. We measured CK2 mRNA expression, protein level, and CK2 kinase activity in NBL cell lines and NBL PDX samples (n=18). CK2 knockdown was achieved in SMS-KCNR and SK-N-BE2 cell line using shRNA against CK2α and phenotype was assessed using cell viability assay, apoptosis, spheroid formation, migration, invasion assay. Cells were also injected into the flank of athymic mice to assess engraftment potential. We performed gene expression analysis using RNA sequencing of CX-4945 treated and gene knockdown NBL cells. MYCN-NBL cell line-derived subcutaneous model was developed in athymic mice. Mice were treated with a combination of Irinotecan (IRN) and temozolomide (TMZ) with and without CX-4945 for up to 28 days. Cohorts were followed for tumor growth and survival.

Results: CK2α shRNA silencing in NBL cell lines resulted in significantly reduced proliferation, increased apoptosis, reduced spheroid formation, and reduced migratory potential. The IC_{50} of CX-4945 (3-6uM) in NBL cell lines also showed synergy with the other standard chemo drugs, Temozolomide and Irinotecan. Gene expression analysis showed a decrease in the expression of several known MYC target proteins. The cohort receiving IRN + TMZ with CX-4945 showed significant tumor inhibition (50-60%) and prolonged survival time compared to the TMZ+IRN group.

Conclusion: Protein kinase CK2 is intrinsically active and negatively impacts survival in HR-NBL patients. In MYCN-NBL xenograft models, CX-4945 is well tolerated and shows superior therapeutic efficacy when combined with cytotoxic drugs Irinotecan and temozolomide. The ongoing Phase 1/II study is evaluating the safety, tolerability, and efficacy of combining CX-4945 with TMZ+IRN in relapsed refractory NBL patients ((NCT06541262).

#3017 Profiling patient response to TTK/PLK1 dual antagonist BAL0891 using 3D patient-derived organoid model in a microphysiological system.

Junfeng Wang[1], MinKyung Kang[2], Delaney Donnelly[1], Jihye Baek[1], Bushra Rajput[1], Byungjun Lee[1], Hyeon-geun Park[1], Yunha Shin[1], Tsung-Li Liu[1], Aneesh Sathe[1], Yangji Kim[1], Kyusuk Baek[1], Sanghee Yoo[1], Salman Ahmed[3], Jae Jung Lee[2], Seunghyun Ma[3]

[1]Qureator, Inc., San Diego, CA,[2]SillaJen, Inc., Seoul, Korea, Republic of,[3]Medical Affair, SillaJen Bio, San Francisco, CA

Introduction: Dysregulation of cell cycle checkpoints in cancer cells drives uncontrolled proliferation and tumor progression. Threonine Tyrosine Kinase (TTK) and Polo-like Kinase 1 (PLK1) are key regulators of the spindle assembly checkpoint (SAC) during mitotic division. Their overexpression is linked to tumor aggressiveness and poor prognosis in multiple malignancies. BAL0891, a first-in-class dual TTK/PLK1 inhibitor disrupts SAC integrity, increases cytoplasmic DNA, activates the cGAS/STING pathway, induces senescence-associated secretory phenotypes (SASP), and elevates PD-L1 expression, suggesting potential for synergy with immune checkpoint inhibitors. To explore patient-specific responses and identify predictive biomarkers of sensitivity to BAL0891, we utilized 3D patient-derived organoid (PDO) models within a microphysiological system (MPS), offering physiologically relevant insights beyond traditional models.

Methods: PDOs from renal cell carcinoma, triple-negative breast cancer, gastric cancer, and colorectal cancer were established in collaboration with Qureator. These PDOs were cultured in Qureator's CurioChips, which incorporate hydrogel-based extracellular matrix (ECM) to mimic the tumor tissue. Following organoid stabilization, BAL0891 was administered and cytotoxicity was assessed through live/dead dye staining and organoid volume measurements. PD-L1 expression was analyzed via flow cytometry to evaluate the potential for combination therapy with anti-PD-L1/PD-1 inhibitors. Cytokine profiling was conducted using multiplex secretome analysis to assess changes in the co-cultures. Additionally, RNA sequencing was performed to identify gene expression signatures associated with sensitivity and resistance to BAL0891.

Results: BAL0891 exhibited variable cytotoxicity across PDOs, with a subset demonstrating resistance. Responding PDOs showed SASP, confirmed by β-Galactosidase staining, increased PD-L1 expression, and distinct pro-inflammatory cytokine profiles compared to non-responders. Preliminary cytokine analyses indicates that BAL0891 reshapes the immune landscape in sensitive PDOs. Ongoing RNA sequencing analysis aims to identify gene clusters associated with sensitivity to BAL0891, offering potential biomarkers or therapeutic targets.

Conclusion: This study highlights the value of PDO-based 3D MPS in evaluating patient-specific responses to BAL0891 and identifying predictive biomarkers. These findings establish a foundation for patient stratification and personalized treatment strategies in clinical trials combining BAL0891 with immune checkpoint inhibitors. Further analysis of gene signatures may provide insights into potential therapeutic targets and improve our understanding on the mechanism driving TTK/PLK1 inhibition and its combination with immunotherapy.

#3018 Discovery of SIGX1094R, a novel FAK inhibitor simultaneously blocking FAK and SRC signaling.

Haisheng Zhang, Shu Zhuo, Lei Zhang, Lin Li, Wanfen Peng, Fengtao Jiang, Yufang Chen, Lin Lin

Signet Therapeutics, Shenzhen, China

Diffuse gastric cancer (DGC) is a highly lethal malignancy with only minimally effective systemic therapies. Our previous studies identified the Focal Adhesion Kinase (FAK) as a novel and promising target for DGC. To enhance the efficacy of FAK inhibition in cancer therapy, we developed a potent small-molecule inhibitor, SIGX1094R. This inhibitor targets both FAK and the related kinase SRC, which complexes with FAK, whereas current FAK inhibitors in clinical trials only inhibit p-FAK.In DGC cell line models and mouse organoid models, SIGX1094R significantly inhibited cell growth and demonstrated much greater potency than current FAK inhibitors in clinical trials, with similar results observed in DGC patient-derived organoids. To further evaluate efficacy, we found that SIGX1094R significantly blocked tumor growth in several DGC patient-derived xenografts, whereas current first-line drugs demonstrated limited efficacy. This aligns with clinical results, highlighting SIGX1094R's strong potential to replace the existing standard of care. Additionally, SIGX1094R demonstrated significantly greater efficacy in ascites models (both in vitro and in vivo) compared to the current standard treatments. In addition to treating DGC, SIGX1094R shows promise in preclinical studies for treating ovarian, triple-negative breast, and pancreatic cancers. It also has high potential for use in combination therapies with targeted treatments for KRAS and EGFR mutations. GLP tox studies demonstrated that most of the lesions in high dose of SIGX1094R animals at the end of the recovery period were fully recovered.The drug received investigational New Drug (IND) clearance both from the U.S. Food and Drug Administration (FDA) and the National Medical Products Administration (NMPA) in China. SIGX1094R, poised to be the world’s first targeted therapy for DGC, is the inaugural project in a pipeline discovered by AI and validated using organoid disease models.

#3019 Targeting transcriptional regulation using CDK7 and CDK9 inhibition as a novel combination therapy in fibrolamellar carcinoma.

Austin Stram, Manabu Nukaya, Patrick Carney, Eleanor Riedl, Jeremy D. Kratz, Sean Ronnekleiv-Kelly

University of Wisconsin-Madison, Madison, WI

Background: Fibrolamellar carcinoma (FLC) is a rare liver cancer with a 5-year survival rate between 35-40%. FLC typically affects a younger patient population, the majority receiving a diagnosis between the ages of 10-35. There are currently no curative systemic therapies and an unmet need for novel and effective therapeutics to improve survival. A unique molecular hallmark of FLC is a fusion event between heat shock protein 40 (*DNAJB1*) and the catalytic subunit alpha of protein kinase A (*PRKACA*). This event creates the FLC specific oncoprotein (DNAJ-PKAc) which has been shown to promote FLC tumor formation. Downstream signaling of DNAJ-PKAc remains unknown, however, this fusion protein has been shown to cause enhancer remodeling to upregulate FLC specific drivers of proliferation.

Methods: Western blot analysis was performed on patient tumors, normal tissue, and patient derived organoids (PDOs) for active RPB1, including phosphorylation of serine 2, serine 5, and serine 7 (pRBP1-s2, s5, s7). Single agent activity of SY5609 was assessed at 144 hours in PDOs. Synergy was assessed at 144 hours using a dose titration grid. SynergyFinder 3.0 was used to produce Highest Single Agent (HSA) synergy scores. Viability was determined using CellTiterGlo (CTG, 50% v/v). RNA was extracted from PDOs for qPCR to measure relative FLC specific driver gene expression, including *SLC16A14* and *LINC00473*. SY5609 was treated continuously while VIP152 was removed after 24 hours to mimic *in vivo* pharmacokinetics.

Results: Relative to normal tissue, FLC tumors had an increase in pRPB1-s5 (6.38, $p<0.05$) and pRPB1-s7 (5.82, $p<0.05$) compared to cholangiocarcinoma (CCA) (2.42, n.s.; 1.10, n.s.) and hepatocellular carcinoma (HCC) (2.61, n.s.; 0.95, n.s.). CDK7 inhibition with SY5609 in FLC PDOs had a 9x greater selectivity than normal liver PDOs and 216x greater than CCA PDOs with IC_{50}=0.39nM, 3.14nM, and 84.22nM, respectively. FLC PDOs treated with physiologic concentrations of SY5609 showed downregulation of FLC specific enhancer driven gene *SLC16A14* but not *LINC00473* with fold changes of 0.51 and 0.84. SY5609 did not regulate *SLC16A14* in CCA PDOs (fold change=2.78) and *LINC00473* was undetectable in all samples. The addition of CDK9 inhibition with VIP152 was synergistic in FLC PDOs (HSA=8.79) which was not seen in CCA PDOs (HSA=-1.82). Combination treatment synergistically downregulated FLC specific driver gene *LINC00473* (fold change=0.41), and decreased pRBP1-s2, 5, and 7 shown via western blot.

Conclusion: Here, we show FLC has an increase in phosphorylated RPB1 specifically at s5 and s7, and a unique sensitivity to CDK7 inhibition with SY5609. The addition of CDK9 inhibition using VIP152 is synergistic at downregulating FLC specific driver genes and decreasing activated RPB1 and viability. Ongoing work is validating this combination in animal models to assess toxicity and *in vivo* efficacy.

#3021 Discovery of a novel and selective CDK2 inhibitor for targeted cancer therapy.

Douglas D. Fang, Yueqin Liu, Yang Liu, Wei Sha, Charles Z. Ding

Shenzhen Yangli Pharma. Tech. Co., Ltd., Shanghai, China

Targeted inhibition of CDK2 presents a promising therapeutic strategy for breast cancer patients who experience disease progression following CDK4/6-based therapies. In addition, CDK2 hyperactivity or CCNE1 amplification drives the progression of many cancer types, making it an attractive target. However, developing CDK inhibitors is often complicated by toxicities resulting from off-target inhibition of other CDK family members, particularly CDK1 and CDK9, which are essential for normal cell proliferation and survival. Achieving selectivity for CDK2 is therefore crucial to maximize therapeutic efficacy while minimizing adverse effects, enabling a broader therapeutic window in clinical applications. Here, we present VB18214 as a novel and selective CDK2 inhibitor. In biochemical assays, VB18214 demonstrated potent inhibition of the CDK2/cyclin E1 complex (IC_{50} = 0.6 nM) and exhibited 200-fold selectivity over CDK1/cyclin B1. Intracellular NanoBRET assays confirmed its high affinity for CDK2/cyclin E1 (IC_{50} = 3.8 nM), along with exceptional selectivity—124-fold over CDK1/cyclin B1, 12-fold over CDK4/cyclin D1, 94-fold over CDK6/cyclin D3, 334-fold over CDK7/cyclin H, and 1348-fold over CDK9/cyclin T1. In CCNE1-amplified OVCAR3 ovarian cancer cells, VB18214 effectively inhibited cell proliferation (IC_{50} = 18.5 nM). Compared to the clinically advanced CDK2 inhibitor PF-07104091, VB18214 demonstrated 5-fold greater potency in inhibiting CDK2 kinase activity, 16-fold higher affinity for CDK2 in NanoBRET assays, 2-fold greater selectivity over CDK1 in both biochemical and intracellular assays, and 9-fold higher antiproliferative activity in OVCAR3 cells.These findings position VB18214 as a potent and selective CDK2 inhibitor with significant potential for clinical development in cancers driven by CDK2/cyclin E dysregulation, as well as CDK4/6 treatment progressed mBC. More characterization data for VB18214 will be updated at the meeting.

#3022 ODY-CDK, a brain-penetrant, selective CDK2 inhibitor that demonstrates antitumor activity in an intracranial *CCNE1*-amplified breast tumor model.

Joe Gozgit[1], Gerald Lelais[1], Ellen Vieux[1], Sam Zelman[1], Laura Stransky[2], Hyeseok Shim[1], Kim Aardalen[1], Casey Landry[1], Arun Thottumkara[1], Jin Choi[1], Chip Lesburg[1], Sebastian Schneider[2], Chaya Stern[1], Elizabeth McMillan[1], Hanbin Lu[1], Caroline Ho[1], Nigel Waters[1], John Shen[1], Natalie Dales[1], Shifeng Pan[2], Bob Abraham[2], Gary D. Glick[1], Elaine M. Pinheiro[1]

[1]Odyssey Therapeutics, Inc., Boston, MA,[2]Odyssey Therapeutics, Inc. (former employee), Boston, MA

Cyclin-dependent kinase 2 (CDK2) is a member of the serine/threonine family of protein kinases that acts in complex with cyclins E1/E2 and A1/A2 to drive entry into and progression through S/G2-phases of the cell cycle. Amplification of *CCNE1* or overexpression of cyclin E1 protein leads to persistent CDK2-cyclin E1 activation and phosphorylation of the retinoblastoma protein (pRb), thereby promoting uncontrolled cell cycle progression. In addition, cancer cells with loss-of-function (LoF) mutations in the retinoblastoma gene (*RB1*) exhibit variable levels of dependence on CDK2-cyclin A2 activity for progression through S/G2 phases of the cell cycle and have shown vulnerability to CDK2 inhibition. Brain metastases are frequently observed in cancers that harbor *CCNE1* or *RB1* alterations, such as small cell lung cancer (SCLC), non-small cell lung cancer (NSCLC), and triple-negative breast cancer (TNBC). Clinical-stage CDK2 inhibitors are not brain penetrant, and a brain-penetrant CDK2 inhibitor could provide a targeted therapeutic option for these high need patients. Here, we report on a brain-penetrant, selective CDK2 inhibitor, ODY-CDK, for the treatment of cancers with *CCNE1* or *RB1* genetic alterations with brain metastases or at high risk of developing them. ODY-CDK potently inhibits CDK2 (Ki = 3.1 nM) and demonstrates 40 to 180-fold selectivity over CDK1/5/6/7/9 as measured by cellular NanoBRET assays. ODY-CDK inhibits pRb in *CCNE1*-amplified ovarian and breast cancer cells and demonstrates antiproliferative activity in *CCNE1*-amplified and *RB1*-null ovarian, lung and breast cancer cells. In a clinically relevant human bone marrow assay, ODY-CDK is predicted to have a low risk of neutropenia that enables safe combinations with other agents. In vivo, once daily oral administration of ODY-CDK to mice with subcutaneous *CCNE1*-amplified HCC1569 breast or *RB1* LoF NCI-H526 SCLC xenografts was well tolerated and demonstrated antitumor activity comparable to the clinical-stage CDK2 inhibitor PF-07104091. ODY-CDK treatment provoked sustained pRb inhibition in HCC1569 tumors. Pharmacokinetic evaluation of ODY-CDK demonstrated brain penetration across species with equivalent free exposure observed between cerebrospinal fluid (CSF) and plasma in dog (CSF Kp_{uu} 0.9). To evaluate the intracranial efficacy, *CCNE1*-amplified HCC1569 cells were implanted into the cranium of NOG mice and tumor growth was measured by MRI. Daily oral dosing of ODY-CDK resulted in tumor regression in 8 out of 11 mice, while PF-07104091 showed modest activity with regression in only a single mouse. These data demonstrate that ODY-CDK is a selective brain-penetrant CDK2 inhibitor with differentiating intracranial antitumor activity to existing clinical-stage CDK2 inhibitors and support the evaluation of ODY-CDK in patients with brain metastases that have a high unmet medical need.

#3023 Preclinical study of TR-412, a novel and highly selective CLK inhibitor for acute myeloid leukemia.

Wentao Zhang, **He Tian**, Mengyang Yan, Qian Shao

Tarapeutics Pharmaceutical Science Inc, Bengbu, China

Alternative splicing (AS) is a major mechanism for diversifying mRNA transcripts and regulating protein expression. Most tumors exhibit widespread splicing abnormalities relative to peritumoral healthy tissues, including frequent retention of normally excised introns, inappropriate expression of isoforms normally restricted to other cell types or developmental stages, and splicing errors that disable tumor suppressors or promote oncogene expression. The CDC2-like kinases (CLKs) and dual-specificity tyrosine-regulated kinases (DYRKs) are thought to govern the efficiency and specificity of AS by directly phosphorylating serine/arginine-rich splicing factors (SRSFs) and thereby influencing pre-mRNA splice junction selection. TR-412 is a novel inhibitor of CLK2/3 and DYRK1A/B, which was evaluated its anti-leukemic activities both in vitro and in vivo. TR-412 showed strong inhibitory effects in an exon-skipping luciferase reporter assay, achieving an IC50 of 120 nM. Furthermore, it significantly suppressed the proliferation of hematological malignancies, with a median IC50 of 350 nM. To understand the mechanism of anti-cancer cell growth, the effect of TR-412 on AS and protein expression of key tumor related biomarkers were examined. The experimental results showed that TR-412 effectively inhibited pSRSF (IC50 <100 nM in AML cells). In addition, RNA-seq analysis revealed that TR-412 induced global splicing changes, which typically resulted in exon exclusion (exon skipping) of cassette exon. To further investigate the effect of TR-412 on tumor growth in vivo, we established multiple AML-derived subcutaneous xenograft models (CDX), which were treated with varying doses of TR-412. In particular, complete tumor regression was achieved in the MV4-11 tumor model. Overall, the preclinical findings strongly support that this novel CLK inhibitor TR-412 is worthy of further exploration in hematologic malignancies.

#3024 The novel selective CDK9 Inhibitor ORI-15412 reduces PD-L1 expression and drives the efficacy in combination therapies for melanoma and triple-negative breast cancer.

Gergana Galabova, Michael Almstetter, Nicole Brusis, Christiane Gilch, Roland Koestler, Julie Kondrotas, Jan Kubitzki, Henrik Kuhn, Hendrik Liebers, Federico Medda, Patricia Perez-Galan, Jean Tassel, Nadine Traube, Andreas Treml, David Wifling, Nasser Yehia, Peter Zegar, Michael Thormann

Origenis GmbH, Planegg, Germany

Aggressive cancers like melanoma and triple-negative breast cancer (TNBC) are challenging to treat due to limited therapeutic options and high relapse rates. Advances in combination therapies offer promise by targeting multiple cancer progression and resistance pathways. This study explores ORI-15412, Origenis' novel, oral CDK9 inhibitor, as monotherapy and in combination therapies in syngeneic melanoma (B16F10) and TNBC (4T1) murine models. ORI-15412, developed with Origenis' proprietary MOREsystem®, MolMind®, BRAINstorm™, and Cippix® technologies, shows unhindered brain penetration, high selectivity, and potency. Its CDK9 inhibition effectively targets the pTEFb complex and downstream pathways, including phospho-RNA Pol II, MCL-1, and c-MYC, inducing apoptosis and inhibiting osteoclast differentiation in cancer cell models (L363, MV4-11, and huPBMCs). ORI-15412 also dose-dependently reduces PD-L1 expression, highlighting its potential to modulate immune responses. In vivo, ORI-15412 monotherapy showed significant tumor growth inhibition (TGI) in B16F10 melanoma and 4T1 TNBC models. Combined with anti-PD-1 antibody, Vemurafenib, or Trametinib, it enhanced anti-tumor activity, achieving 72-84% TGI in the B16F10 model. In the 4T1 TNBC model, combining ORI-15412 with anti-PD-1 antibody achieved a 63% TGI, outperforming monotherapies or controls. ORI-15412 was non-toxic at effective doses in mono and combination therapies. These findings highlight ORI-15412 as a pivotal component in combination therapy for hard-to-treat cancers. Its effects on tumor growth inhibition and immune checkpoint modulation support its selection as a clinical candidate for melanoma, TNBC, and other malignancies.

#3025 Optimization of therapeutic index of SGR-3515, a first-in-class Wee1/Myt1 inhibitor through intermittent dosing for monotherapy and combination with chemotherapy in xenograft tumor models.

Shaoxian Sun, Felicia Gray, Sarah Silvergleid, Robert Pelletier, Lin Tang, Andrew Placzek, Jiashi Wang, Pieter Bos, Jennifer Knight, Anthony Clark, Zhijian Liu, Naveen Thakral, Aleksey Gerasyuto

Schrodinger, New York, NY

Background: Cancer cells often have deregulated G1-S phase in cell cycle and rely on the G2-M checkpoint to delay mitosis allowing for completed DNA damage repair. Wee1 and Myt1 kinases regulate G2 to M phase transition by inhibitory phosphorylation of cyclin dependent kinase (CDK1) to prevent premature entry to mitosis. Small molecule inhibitors targeting either Wee1 or Myt1 have shown promising clinical benefit in solid tumors as a monotherapy and/or combination therapy. Emerging evidence suggests that Wee1 and Myt1 have a synthetic lethal relationship in tumor cells, and Myt1 upregulation contributes to acquired resistance to Wee1 inhibitors. Here we describe the superior anti-tumor activity of SGR-3515, a first-in-class Wee1/Myt1 inhibitor, compared to single inhibition of Wee1 or Myt1 as a monotherapy, synergistic combination with chemotherapy and optimization of dosing schedule to achieve improved therapeutic index in xenograft tumor models.

Methods: SGR-3515 was identified internally using Schrödinger's computational platform. Its binding affinity to Wee1 or Myt1 and inhibition potency of kinase activity was measured by surface plasmon resonance (SPR) assay and ADP-Glo kinase activity assay, respectively. SGR-3515 effects on DNA damage and cell cycles were investigated in tumor cell lines using gH2Ax and DNA staining high content imaging assays, respectively. The cellular target engagement was measured by pCDK1 Y15 for Wee1 inhibition and pCDK1 T14 for Myt1 inhibition in tumor cell lines. The in vivo anti-tumor activity was evaluated in cell line derived xenograft models.

Results: SGR-3515 is a novel and potent small molecule inhibitor of Wee1/Myt1. The co-inhibition of Wee1 and Myt1 induces rapid DNA damage and causes significant tumor cell apoptosis. SGR-3515 demonstrates superior anti-tumor activity in vivo in xenograft models compared to single inhibition of Wee1 or Myt1 alone, consistent with the Wee1 and Myt1 synthetic lethal relationship. Furthermore it suppresses the acquired resistance associated with a Wee1 inhibitor (ZNc3). Optimization of intermittent dosing schedule of SGR-3515 allows sufficient recovery of Wee1 inhibition mediated myelosuppression while maintaining similar anti-tumor activity as the continuous dosing in xenograft tumor models. Intermittent dosing of SGR-3515 in combination with carboplatin achieved synergistic anti-tumor activity without significantly worsening hematological effects.

Conclusions: The robust anti-tumor activity of SGR-3515, a first-in-class Wee1/Myt1 inhibitor confirms the synergy of Wee1 and Myt1 co-inhibition. SGR-3515 dosing schedule optimization improves therapeutic index as a monotherapy and in combination with Carboplatin. The preclinical data supported the progression of SGR-3515 to clinical study (NCT06463340).

#3026 ARTS-023: a potent and selective CDK4 Inhibitor demonstrating anti-tumor activity in preclinical ER+ breast cancer models.

yali guo[1], jinhong chen[1], nathan schomer[2], jiaqi liang[1], tingru zhou[1], xipan liu[1], wenheng liang[1], wei pang[1], jia fu[1], xiaobin zhang[2], dai cheng[1], john campbell[2], tao ji[2], fang li[2], yaoyu chen[2], **qing sheng**[2]

[1]Allorion Therapeutics, Guangzhou, China,[2]Allorion Therapeutics, Natick, MA

Cell cycle deregulation is a hallmark of cancer, and cyclin-dependent kinases (CDKs) play a pivotal role in driving tumor proliferation by regulating cell cycle progression. Among these, CDK4 and CDK6 are critical in promoting cell G1 to S transition. While three CDK4/6 inhibitors have been approved for treating estrogen receptor-positive (ER+), human epidermal growth factor receptor 2-negative (HER2-) breast cancers, eventual relapse and severe hematological toxicities, particularly neutropenia, remain major clinical challenges. Preclinical data suggest that CDK6 dependence is predominantly associated with hematopoietic and lymphoid cell lines, whereas CDK4 dependence is enriched in breast cancer cell lines. This distinction highlights the potential of developing a next-generation CDK4-selective inhibitor to minimize hematological toxicity, allow for higher CDK4 inhibition, combination with other CDK inhibitors and improve therapeutic efficacy in ER+ breast cancer. Here we report the development and preclinical characterization of ARTS-023, an orally bioavailable CDK4 inhibitor with high selectivity over CDK6. In enzymatic assay, ARTS-023 potently inhibits the activity of CDK4/CyclinD1 complex with 50% inhibitory concentration (IC50) in the sub-nanomolar range, displaying near 60-fold selectivity against CDK6 and over 130-fold selectivity against other CDKs assessed. A very low hit rate (S (10) = 0.017, at 1uM) is observed when ARTS-023 is assessed in whole Kinome profiling, further revealing the selectivity of this compound. ARTS-023 also demonstrates potent CDK4 inhibition and selectivity against CDK6 in NanoBRET and other cellular assays. ARTS-023, at low nanomolar concentrations, inhibits Rb phosphorylation and blocks the G1/S transition, resulting in growth arrest in ER+ breast cancer cell lines. Compared to palbociclib, ARTS-023 is 32-fold more selective in inhibiting the proliferation of ER+ breast cancer cell lines over human hematopoietic stem cells, suggesting that a CDK4-selective inhibitor may have reduced cytotoxicity on hematopoietic lineages. In vivo, ARTS-023 exhibited strong anti-tumor activity as a single agent across various ER+ breast cancer xenograft models. Additionally, it demonstrated robust synergistic effects when combined with the CDK2 inhibitor AVZO-021 in both palbociclib-sensitive cell line-derived xenograft models and palbociclib-resistant patient-derived xenograft models. Taken together, these findings establish ARTS-023 as a promising next-generation CDK4-selective inhibitor, offering improved efficacy and reduced toxicity for patients with ER+ breast cancer. Furthermore, the favorable toxicity profile of ARTS-023 supports the potential combination with CDK2 inhibitors to enhance therapeutic outcomes.

#3027 Killing two birds with one stone: veratridine functions as a dual inhibitor of both hyperactive mTORC2 and mitochondria in colon cancer cells.

Morgan Eikanger, Khosrow Rezvani

University of South Dakota, Vermillion, SD

Despite considerable advances to improve colorectal cancer (CRC) survival over the last decade, therapeutic challenges remain due to the rapid metastatic dissemination of primary tumors. There has been an increase in early-onset CRC (patients under age 50) incidences in all ethnicities. Early-onset CRC introduces another major health challenge as these patients are commonly diagnosed with advanced, metastatic forms of CRC, resulting in higher mortality rates, showing the clear need to develop safer and more effective therapies. There has been significant progress in understanding the tumorigenic pathways responsible for the invasion and metastasis of human CRC. Current evidence indicates that overactive mitochondria and hyperactivation of the Rictor-mTORC2-AKT signaling pathway drive key metastatic players and support the formation and progression of metastatic cells in diverse malignant tumors, including early-onset CRC. Small molecule inhibitors that selectively interfere with these key metastatic pathways have become a primary focus of targeted therapy as they control proteins involved in tumor dissemination without affecting normal cells. Selective mTORC2 inhibitors are becoming a potential optimal treatment strategy for patients with CRC because they eliminate therapeutic limitations and drug resistance reported for mTORC1 and mTORC1/mTORC2 inhibitors. Veratridine (VTD), a lipid-soluble alkaloid extracted from Liliaceae plants, can transcriptionally increase UBXN2A, a ubiquitin-like protein. UBXN2A's E3 ubiquitin ligase partners enable UBXN2A to target dually and selectively induce 26S proteasomal degradation of the following substrates: mitochondrial HSP70 (mortalin) proteins and Rictor in the mTORC2 signaling pathway. This study explains the dual-action molecular mechanisms of the VTD-UBXN2A axis in patient-derived xenograft (PDX) cell lines. Longitudinal analysis of cells after completing real-time cell analysis using xCELLigence technology and generating a 3D spheroid CRC model using PDX cells indicate that VTD can effectively restrict cell migration. Additionally, Seahorse bioenergetic assays showed that VTD reduces mitochondria respiration and glycolysis. These results indicate the dual-targeting efficiency of VTD on metastatic cancer cells. This study opened a new platform for repurposing VTD, a supplemental anti-hypertension molecule, into an effective targeted therapy in CRC tumors.

#3028 Tumor suppressor activation: unlocking a novel path to overcome CDK4/6 inhibitor resistance in HR-positive breast cancer.

Hee-Sung Park, Kyu-Kwang Cho, Martin Pettersson, Chakrapani Subramanyam

Promedigen, Daejeon, Korea, Republic of

Clinically approved CDK4/6 inhibitor drugs, though initially effective, often generate acquired resistance in HR-positive breast cancer, leading to 25-35% of patients becoming nonresponsive. A number of drivers for this resistance have been identified, including cyclin D1 upregulation. Herein, we present an innovative strategy to tackle this pressing challenge. We have developed a novel small molecule, PMG-A7, that activates a key tumor suppressor critical to maintaining cellular homeostasis and regulating the cell cycle. PMG-A7 induces a robust, dose-dependent reduction in resistance drivers, demonstrating efficacy at single-digit nanomolar concentrations. Further, PMG-A7 upregulates cell cycle inhibitors such as p27, effectively countering CDK4/6 inhibitor resistance. When used in combination with a CDK4/6 inhibitor, PMG-A7 significantly suppresses resistance mechanisms. These findings highlight tumor suppressor activation as a promising combination therapeutic strategy to help overcome drug resistance to CDK 4/6 inhibitors in the clinic.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Novel Antitumor Agents 2
Poster Session

#3032 Selective pharmacological activation of the mitochondrial protease OMA1 inhibits tumor growth and induces regression in tumors expressing low levels of FAM210B.

Matthew Kostura, Michael Luther, Michael Stocum, Todd Hembrough, Zahid Bashir

Bantam Pharmaceutical, Durham, NC

1-Thiazol-2-yl-N—3-methyl-1H-pyrozole-5-carboxylic acids have been described as anti-tumor agents. Two members of this family, BTM-3528 and BTM-3566, exhibit robust, single agent *in vivo* activity in models of Diffuse Large B-Cell Lymphoma (DLBCL). Drug activity is correlated with activation of the OMA1-ATF4 ISR axis. *In vitro*, response to drug is associated with G1/S growth arrest and , in DLBCL, apoptosis.

We evaluated the tumor response activity profile of BTM-3528 and BTM-3566 *in vitro* in panels of solid and hematopoietic tumor lines. Cell growth inhibition was determined using Cell Titre Glo (Crown Bio OmniScreen). Both compounds demonstrated growth inhibitory activity in a broad range of solid and hematopoietic tumor lines. Biomarker analysis did not reveal correlations between drug activity and mutation or copy number changes associated with tumor oncogenes. Analysis of RNAseq data identified a panel of 9 genes whose expression predicted response to drug. Amongst these is a mitochondrial protein, FAM210B, where response to drug is inversely correlated to RNA expression. We demonstrate that ectopic expression of FAM210B specifically regulates the activity of BTM-3566 but no other compounds that also activate OMA1.

BTM-3566 was evaluated *in vivo* using 16 PDX models of diverse origin including uterine, esophageal and biliary tract (Crown Bio HuBase) . Tumors were prospectively selected based on FAM210B RNA expression (quintile binning). Seven tumors were in the first, lowest quintile, whereas the remaining nine were distributed in the 2nd through 5th quintiles. Response to BTM-3566 occurred exclusively in 5 tumors (uterine, esophageal and biliary tract) within the first quintile of FAM210B expression. Two of the tumors exhibited signs of regression.

Selective activation of OMA1 leads to changes in mitochondria including alterations in cristae structure, morphology and expression of BH3 proteins such as MCL1. The outcome is cell growth inhibition and in DLBCL, Bax-dependent apoptosis. Such changes in mitochondrial structure and function may prime tumor cells to apoptosis in the presence of a BH3 mimetic. Combinations of BTM-3566 with the BH3 mimetic navitoclax results in synergistic cell killing activity in select solid tumor lines *in vitro*. BTM-3566 increased the potency of navitoclax by approximately 7-fold, increasing both cell killing and caspase activation.

Conclusions: BTM-3566 targets an pathway important in mitochondrial quality control leading to tumor cell growth and regression. In vivo, drug activity correlated with low expression of RNA for the mitochondrial protein FAM210B. BTM-3566 demonstrated robust activity in vivo in solid tumors of diverse origin with low FAM210B RNA expression. Rational combinations with BH3 mimetics will extend the therapeutic utility of BTM-3566 in otherwise difficult to treat tumors.

#3033 Increased mitochondrial protein import necessitates greater reliance on the mitochondrial unfolded protein response (UPR^{mt}) and the protease LONP1 to maintain mitochondrial protein solubility and cell viability in acute myeloid leukemia (AML).

Matthew Tcheng, Veronique Voisin, Marcela Gronda, Rose Hurren, Lan Xin Zhang, Yue Feng, Zaynab Mamai, Brady Stock, Yulia Jitkova, Andrea Arruda, Steven M. Kornblau, Mark D. Minden, Aaron D. Schimmer

University Health Network Princess Margaret Cancer Centre, Toronto, ON, Canada

Almost all mitochondrial proteins are encoded by nuclear DNA, translated in the cytosol, and imported into the mitochondria. Once inside the mitochondria, these unfolded, aggregation prone precursors are processed and folded into mature forms. Failure to properly process and fold these newly imported proteins results in the formation of toxic aggregates. To counter the mitochondrial stress from newly imported proteins, cells developed the mitochondrial unfolded protein response (UPR^{mt}), a conserved pathway which activates the transcription of mitochondrial proteases and chaperones to fold newly imported precursors and degrade protein aggregates. There are no UPR^{mt} gene sets in the KEGG, Gene Ontology or Reactome databases, so we compiled a 39-gene signature of the known components of the human UPR^{mt}. In primary AML cells, expression of this UPR^{mt} signature was increased compared to normal hematopoietic cells. UPR^{mt} expression was strongly correlated with mitochondrial protein import expression, highlighting the protective role of the UPR^{mt} in countering the stress of increased protein import. Leading edge analysis identified the protease LONP1 as a top driver of the UPR^{mt} signature and analysis of AML cells' dependency on UPR^{mt} genes (Depmap) also identified LONP1 as a top essential gene. We focused additional studies on LONP1 and its role in protecting AML cells from mitochondrial stress. LONP1 mRNA expression was increased in AML compared to normal hematopoietic cells. LONP1 protein was increased >2-fold in 26/39 primary AML samples, compared to bulk (n=14) and CD34+ (n=3) hematopoietic cells. In AML, LONP1 expression positively correlated with expression of protein import and UPR^{mt} genes as well as decreased overall survival. LONP1 folds newly imported precursors and degrades aggregated mitochondrial proteins. To assess the role of LONP1 in mitochondrial proteostasis, we developed a novel assay to measure mitochondrial protein aggregation. LONP1 genetic depletion and chemical inhibition with Omaveloxolone and bardoxolone methyl increased mitochondrial protein aggregation and cell death in AML lines and primary AML with high LONP1 but not hematopoietic cells or primary AML with low LONP1. In primary AML, sensitivity to LONP1 chemical inhibition or genetic depletion positively correlated with LONP1 expression (Omaveloxolone (n=16, R^2=0.64); Bardoxolone methyl (n=30, R^2=0.65); LONP1 shRNA (n=9, R^2=71)). In summary, AML cells have increased mitochondrial protein import, necessitating a heightened dependence on the UPR^{mt} to maintain mitochondrial proteostasis. Targeting the UPR^{mt} at the level of LONP1 selectively induces mitochondrial protein aggregation and eliminates AML cells while sparing normal hematopoietic cells.

#3034 SY-12696, a novel and potent MALT1 protease inhibitor, for the treatment of B-cell lymphomas.

Xintao Cao[1], Jijun Li[2], Yongliang Sun[1], Chang Lu[1], Yuan Ji[1], Miao Zhang[1], Zhifeng Chen[2], Shenyu Zhao[3], Yan Zhu[2], Hong Luo[3], **Yinghui Sun**[1]

[1]Department of Discovery Biology, Shouyao Holdings (Beijing) Co., Ltd, Beijing, China,[2]Department of Medicinal Chemistry, Shouyao Holdings (Beijing) Co., Ltd, Beijing, China,[3]Department of DMPK, Shouyao Holdings (Beijing) Co., Ltd, Beijing, China

Background: MALT1 (Mucosa-associated lymphoid tissue lymphoma translocation protein 1) is a key component of the CBM complex (CARD9/10/11/14-BCL10-MALT1) downstream of Bruton's tyrosine kinase (BTK) in the B-cell receptor signaling pathway. Through its unique scaffolding and proteolytic functions, MALT1 precisely modulates the NF-κB pathway and regulates cell proliferation, differentiation and immunity. MALT1 is major driver of a subset of B-cell lymphomas, making it an attractive target for therapeutic intervention. Inhibition of MALT1 is considered a promising therapeutic approach for the treatment of several B-cell lymphomas, including tumors with acquired BTK inhibitor (BTKi) resistance.

Methods: Based on structure-activity relationship analysis, series of MALT1 inhibitors were synthesized and screened. The potency and downstream effects of compounds were evaluated using biochemical enzyme assay, cellular phenotype and functional studies and *in vivo* xenograft models. Furthermore, the potential for enhanced efficacy through combination with BTKi was investigated in TMD8 cells overexpressing the BTK C481S mutation.

Results: SY-12696 was identified as a novel, potent and small molecular MALT1 inhibitor, it showed excellent potency on MALT1 protease activity both in biochemical and in cellular assays with nanomolar IC_{50}s. SY-12696 suppressed cleavage of MALT1's substrate (e.g. Rel B) in the activated B-cell subtype of diffuse large B cell lymphoma (ABC-DLBCL) cell lines, highlighting its capability to disrupt the NF-κB pathway. In cellular proliferation assays, SY-12696 effectively inhibited the growth of ABC-DLBCL cell lines, including the BTKi-resistant cell line OCI-Ly3 (carrying CARD11 L224P, MYD88 L265P mutations) and the BTKi-sensitive cell line OCI-Ly10 (carrying CD79A Δ191-208, MYD88 L265P mutations). In the OCI-Ly3 xenograft model, oral administration of SY-12696 at 10 mg/kg twice daily (bid) resulted in >90% tumor growth inhibition (TGI). Additionally, a synergistic effect of SY-12696 with the BTKi was observed on cell viability in TMD8-BTK ^{C481S} cells. The compound also exhibited desirable drug-like properties, including favorable pharmacokinetic properties and safety profile.

Conclusion: Based on current studies, SY-12696 has demonstrated significant inhibitory potency on ABC-DLBCL cancer cells *in vitro* and *in vivo*, which makes SY-12696 a promising candidate for further development as a monotherapy or in combination with BTKi to treat relapsed/refractory B-cell lymphoma, particularly those resistance to BTKi.

#3035 Effects of novel isoform selective HSP90 beta inhibitors alone and in combinations against experimental esophageal adenocarcinoma.

Md Sazzad Hassan[1], Erin Garzella[1], Annie Ritter[2], Elizabeth Heffernan[2], Aktar Ali[2], Brian Blagg[2], Urs von Holzen[1]

[1]Indiana University School of Medicine (South Bend, IN), South Bend, IN,[2]University of Notre Dame, South Bend, IN

Background: Inhibition of the heat shock protein 90 (HSP90) chaperone activity with small molecules is an attractive therapeutic approach for cancer treatment because more than 300 client proteins are involved in aggressive cancer growth and metastasis. To date, ~20 inhibitors have undergone clinical trials, however, all have failed due to pan-inhibitory activities and insufficient isoform selectivity. In this study, we have investigated isoform selective HSP90β inhibitors, NDNB21, NDNB25 and NDNB11.82 on esophageal adenocarcinoma (EAC), which is one of the most aggressive human cancers with increasing incidence in the United States. A major target for EAC therapies is the human epidermal growth factor receptor 2 (HER2), which is a well-known client protein of HSP90. In this research, we tested the effect of NDNB21 and NDNB25 on HER2 overexpressing EAC cell lines, including one cell line that acquired lapatinib resistance either alone or in combination with HER2/MET targeting by lapatinib/capmatinib.

Methods: We first evaluated HER2/pHER2 and MET/pMET expression status by Western blot analysis in a panel of EAC cell lines (Flo-1, ESO26, OE19, OE33, SK-GT-2, ESO51, OACM5.1C, and LPR-OE19). Lapatinib-resistant OE19 (LPR-OE19) cell line was established from OE19 cells by intermittent exposure to increasing concentrations of lapatinib for a period over six months. Lapatinib is a potent EGFR/HER2 inhibitor and capmatinib is a potent c-MET inhibitor. Antiproliferative activities were measured by WST-1 assay and Western blot analyses were performed to evaluate apoptosis.

Results: NDNB21 and NDNB25 dose-dependently inhibited *in-vitro* cell proliferation of HER2 overexpressing EAC cell lines with NDNB11.82 maintaining much lower potency. All three HER2 overexpressing EAC cell lines showed significant sensitivity to NDNB21 and NDNB25 mediated inhibition of cell proliferation with IC_{50} values between 16 nM to 2 μM and degree of sensitivities are OE19>LPR-OE19>OE33. NDNB21 and NDNB25 dose-dependently induced apoptosis as measured by the expression of cleavage of poly ADP-ribose polymerase (cleaved PARP). Treatment with increasing doses of NDNB21/NDNB25 resulted in a dose-dependent decrease in HER2, p-HER2, AKT, and p-AKT. Coadministration of NDNB21 or NDNB25 with lapatinib effectively inhibited HER2 phosphorylation and significantly enhanced inhibition of cell proliferation in OE19/LPR-OE19 but not in OE33. The OE33 cells with the strongest expression of phosphorylated MET showed reduced sensitivity to HER2 targeted NDNB21/NDNB25/lapatinib induced cell death compared to that of OE19/LPR-OE19. OE33 showed enhanced cell death when HER2 targeted NDNB25 were combined with MET inhibitor capmatinib.

Conclusions: In conclusion, our data shows that NDNB21/NDNB25 exhibited potent apoptotic activity against HER2-positive EAC cells either alone or in combination.

#3036 Direct co-targeting of Bcl-xL and Mcl-1 exhibits synergistic anti-cancer effects in AR-V7-expressing mCRPC preclinical models.

Benjamin C. Brim[1], Andres F. Leon[1], Erica L. Beatson[1], Jessica D. Kindrick[1], Kinjal Bhadresha[1], Xiaohu Zhang[2], Giulia C. Napoli[1], Emily N. Risdon[1], Keith T. Schmidt[1], Erin Beck[2], Carleen Klumpp-Thomas[2], Michele Cerebelli[2], Douglas K. Price[1], Cindy H. Chau[1], Craig J. Thomas[2], William D. Figg[1]

[1]Genitourinary Malignancies Branch, National Cancer Institute, Bethesda, MD,[2]Division of Preclinical Innovation, National Center for Advancing Translational Sciences, Rockville, MD

There is an unmet need to develop novel treatment options for patients with metastatic castration-resistant prostate cancer (mCRPC). Patients often develop resistance to hormonal therapies that target the AR-axis (e.g., abiraterone, enzalutamide). A splice variant of AR, AR-V7, is associated with resistance to these inhibitors as well as mCRPC progression and poor prognoses. We embarked upon a high-throughput screen to identify synergistic combinations of targeted therapies using two CRPC cell lines, LNCaP95 and VCaP-CR. The goal of the drug screen is to identify rational targeted combination therapies for mCRPC, where efficacy can be achieved at lower, equally effective doses in order to minimize toxicity. Extensive bioinformatic analysis identified several synergistic combinations, including dual targeting of Bcl-2 family proteins using BH_3 mimetics. Combinations targeting Bcl-xL (A-1331852 and Navitoclax) and Mcl-1 (S63845) synergistically decreased cell viability and induced apoptotic activity via cleavage of PARP, caspase 3, and caspase 7 across AR-V7 expressing CRPC cell lines (LNCaP95, VCaP-CR, 22Rv1) as early as two hours post-treatment. The effect of the treatment combination on downstream targets was assessed via western blot analysis. We demonstrated synergistic anti-tumor effects with Mcl-1/Bcl-xL co-targeting in three-dimensional (3D) spheroid CRPC models and in the patient-derived LuCaP-167CR organoid model, which represents a more physiologically relevant model for evaluating drug response and efficacy. We also explored the use of a Bcl-xL-specific PROTAC to minimize platelet toxicity associated with Bcl-xL inhibitors in the clinic. We showed similar synergistic efficacy with the S63845/Bcl-xL targeting PROTAC combination in the 3D spheroid models compared to the small-molecule Bcl-xL inhibitors while also inducing apoptosis. Our findings provide unique insight into the dependence on Bcl-2 family proteins in mCRPC. Our findings also support further preclinical development of Bcl-xL and Mcl-1 inhibitors for mCRPC.

#3037 Targeting pro-survival MYC oncogene expression in small cell lung cancer and large cell neuroendocrine carcinoma of the lung with a novel small molecule PIM2 inhibitor.

Katherine G. Minton, Anthony H. Cuadros, Olivia C. Terry, Phu D. Pham, Mateusz Opyrchal, Kelvin P. Lee, Misty D. Shields

Indiana University Melvin and Bren Simon Cancer Center, Indianapolis, IN

Introduction: Small cell lung cancer (SCLC) and large cell neuroendocrine carcinoma of the lung (LCNEC) are aggressive neuroendocrine carcinomas (NECs) that exhibit frequent chemoresistance and lack effective treatments for relapsed disease. *MYC* paralogs are frequently amplified on extrachromosomal DNA in lung NECs. Recent interrogation into the evolution of SCLC has identified *c-MYC* amplification as a major driver of tumor plasticity across the neuroendocrine spectrum. As such, targeting molecular underpinnings related to *MYC* amplification provides a therapeutic vulnerability for lung NECs. JP11646, a potent non-ATP competitive inhibitor of PIM family members that function to phosphorylate Ser329 on c-MYC, has preclinical efficacy in a number of cancers including triple negative breast cancer and multiple myeloma. Here, we investigate the efficacy and functional effects of JP11646 in lung NECs.

Methods: JP11646 sensitivity was evaluated in triplicate with eight serial dilutions for 72 h (hours). The transient effects of JP11646 after 24 h were evaluated in H1155, H524, H209, and H1417, which represent the spectrum of MYC paralog amplification in lung NECs, through RNAseq. Protein expression was evaluated via western blot analysis (PIM2 1:1000). *PIM2* RNA interference (50 nM) was performed to investigate effects on JP11646 sensitivity and interactions between *PIM-* and *MYC-* paralogs after 72 h.

Results: A panel of MYC paralog amplified cell lines differentially express PIM2 and exhibit nanomolar potency for JP11646 (IC_{50}: mean 87 nM, range 7 - 117 nM). Transient knockdown of PIM2 results in reductions in *PIM3* and *l-MYC* in H209. Following 24 h JP11646 treatment, we find that cells exhibit reduction of PIM2 and MYC paralogs and extensive downregulation of oncogenes including amplified *MYC* paralogs and *AURKA*. Interestingly, a pattern of upregulation of reciprocal *MYC* paralogs is observed in H1155, H209, and H1417. Insignificant changes are observed in *PIM* family expression with 24 h JP11646 treatment. After 72 h, we find that *PIM2* knockdown further enhances JP11646 sensitivity in H1155, reducing IC_{50} two-fold.

Conclusion: Given the observed reduction of PIM2 protein levels following treatment, we hypothesize that JP11646 functions through a feedback mechanism, disrupting PIM2:MYC interactions to reduce MYC paralog RNA/protein expression in lung NECs and exert its anticancer effects. Future studies are underway to further examine the mechanism and preclinical effects of JP11646, including xenograft studies, proteasome inhibitor studies, and CRISPR knockout of *PIM2*.

#3038 Preclinical evaluation of combination therapy of HJ-037 with anti-PD-1 antibody treating KRAS^{G12C} mutated tumors.

Na Guo, Xiangyu Yang, Longjun Yang, Fengtian Du, Huiqiao Ling, Ke Xue, Lina Zhang, **Jianxin Ji**, Zhigang Wu

Chengdu Huajian Science Co., Ltd., Chengdu, China

Background: The development and clinical application of KRAS^{G12C} inhibitors have made significant progress in recent years and some groundbreaking clinical results have been reported. However, overcoming resistance of KRAS^{G12C}-OFF covalent blockade remains a key focus in the fight against KRAS^{G12C} mutated cancers. Combination therapy may be one of the best treatment strategies to overcome the resistance.

Methods and Results: HJ-037 is an orally available, potent, and highly selective covalent KRAS^{G12C} inhibitor, which showed significantly superior inhibitory activities against NCI-H358 and Mia PaCa-2 cells to current marketed KRAS^{G12C} inhibitors, and favorable safety profile was observed in pre-clinical study, providing a good safety foundation for its combination with PD-1 inhibitor. In a Colon Cancer CT26-mKRAS^{G12C} cell line subcutaneous syngeneic model, animals treated with HJ-037 plus anti-PD-1 antibody showed complete tumor regression without recurrence. A proof-of-concept clinical trial combining HJ-037 with PD-1 inhibitor is currently ongoing, and preliminary data shows a positive trend in efficacy and safety profile.

Conclusions: Preclinical study results indicate that the combination therapy of HJ-037 with PD-1 inhibitor could enhance the intensity and duration of antitumor activity compared to monotherapy, with satisfactory safety, therefore possessing a better potential for the treatment of cancer patients harboring KRAS^{G12C} mutation.

#3039 Elucidating hsa_circ_0001038 and circRNA_400029 circular RNAs mechanisms in response to splicing factor 3 inhibitor in cervical cancer cells.

Amahle Nyalambisa, Zodwa Dlamini, **Rahaba Makgotso Marima**

University of Pretoria, Pretoria, South Africa

Cervical cancer (CCa) is the fourth leading cause of cancer-related death among women worldwide. Around 90% of CCa cases are reported in low- and middle-income countries (LMICs), with Sub-Saharan Africa (SSA) bearing over 80% of the global burden. CircRNAs hsa_circ_0001038 and circRNA_400029 have been implicated in cervical cancer. Splicing factor 3 key a key factor in circRNA generation. However, mechanisms of these ceRNAs in CCa is poorly understood. This study aimed at elucidating hsa_circ_0001038 and circRNA_400029 mechanisms in response to splicing factor 3 inhibitor, theophylline in CCa. Using bioinformatics, CircAtlas, the study identified miRNA binding sites for hsa_circ_0001038, selecting miR-205-5p for further analysis due to its tumor-suppressive role. Similarly, miRTarBase predicted miR-16-5p as a key interacting miRNA for circRNA_400029. The downstream gene targets of these miRNAs were explored, focusing on those associated with CCa. Cell cycle FACS analysis and apoptosis assay were used to study cell biological response of theophylline to CCa cells SiHa and C33A. Furthermore, gene specific primers of hsa_circ_0001038, circRNA_400029 and SRSF3 were used to study gene expression in drug treated and control groups. Interestingly, ceRNA network was constructed, showing that one gene can be targeted by more than one miRNA. Additionally, pathway analysis using KEGG, STRING, and Reactome highlighted key signaling pathways, such as the HPV E5-EGFR-RAS-ERK and HPV E6-Notch pathways, which are implicated in cell proliferation, survival, and oncogenesis in CCa. Cell cycle analysis revealed G2/M arrest in response to theophylline treatment, while there was no significant cytotoxic effects of the drug, as revealed by apoptosis FACS analysis. hsa_circ_0001038, circRNA_400029 and SRSF3 were downregulated by theophylline treatment. Understanding circular RNAs and their interaction with splicing factors holds potential translational and clinical applications.

#3040 Memantine, (a dual α7-nAChR/NMDAR antagonist) displays anti-tumor activity in human squamous cell lung cancer.

J. C. Christian[1], K. L. Denning[1], K. J. Modi[1], R. S. Light[1], S. L. Miles[1], Y. Chen[2], P. Dasgupta[1];
[1]Marshall University School of Medicine, Huntington, WV, [2]Bluefield State University, Bluefield, WV

Purpose of the study: Squamous cell lung carcinoma (LUSC), also called epidermoid carcinoma, is a type of non-small cell lung cancer (NSCLC) that typically develops in one of the air passages, or bronchi, of the lungs. It is the second most common type of NSCLC and accounts for roughly 30 percent of all lung cancer cases. The development of LUSC bears an 85% correlation with smoking habits. Nicotine, the addictive component of cigarettes, promotes the growth and progression of lung cancers via the α7-nicotinic acetylcholine receptor (α7-nAChR) subunit in human lung cancer cells. Published reports show that the α7-nAChR is over expressed on LUSCs relative to normal lung epithelial cells. Therefore, agents which block the function of α7-nAChR should inhibit the growth of human LUSC cells. The drug memantine is a dual α7-nAChR/NMDAR antagonist which is used clinically to combat dementia associated with mild -to-moderate Alzheimer's disease in patients. Receptor binding assays have shown that the affinity of memantine for α7-nAChR receptors is greater than that of NMDARs. The primary objective of our study was to determine the anti-cancer activity of memantine in human LUSC.

Experimental procedures. The expression of α7-nAChR on human LUSC cells was analyzed by ELISA. The effect of memantine of nicotine-induced proliferation of LUSC cells was measured by Proliferating Cell Nuclear Antigen (PCNA) ELISA assays. The growth-inhibitory activity of memantine was confirmed in chicken chorioallantoic membrane (CAM) model systems of LUSC. Next, the anti-tumor activity of memantine was measured in two independent mice models, namely the cell derived xenograft (CDX) mouse model and the patient derived xenograft (PDX) mouse model. Finally, siRNA methodology was used to delineate the signaling pathways underlying the anti-proliferative activity of memantine.

Results: Memantine displayed robust anti-proliferative activity in a panel of human LUSC cell lines. The anti-proliferative activity of memantine was also observed in chicken CAM models of LUSC. The treatment of LUSC cells with memantine induced cell cycle arrest at G1/S phase. Finally, the administration of memantine via dietary methods decreased nicotine-induced growth of LUSC tumors in both CDX and PDX tumors in immunodeficient mice models.

Conclusions: The drug memantine could be repurposed for the treatment of LUSC in patients.

Support or Funding Information:
Funding for our study was supported by an NIH R15-AREA Grant (2R15CA161491-02), Edwards Cancer Center Pilot grant, Cabell Huntington Hospital, Marshall University. This work was supported in part by the West Virginia IDeA Network of Biomedical Research Excellence (WV-INBRE) grant GM103434 (PI: Dr. G. Rankin).

#3041 Arsenoplatin-5: A small molecule that delivers arsenous acid.

D. Miodragovic[1], W. Qiang[2], B. Hong[3], T. O'Halloran[3];
[1]Northeastern Illinois University, Chicago, IL, [2]Northwestern University, Evanston, IL, [3]Michigan State University, East Lansing, MI

Arsenic trioxide (ATO), an FDA-approved drug for treating Acute Promyelocytic Leukemia (APL), increased the survival of newly diagnosed and relapsed APL patients. Despite its success in treating blood cancer, this success did not translate in clinical trials treating solid tumors due to low bioavailability, rapid renal clearance, and cardiotoxicity when higher doses are applied. The search for agents that deliver ATO to solid tumors has been ongoing for almost two decades. While a number of nanoformulations have been evaluated, none have been approved for clinical use. Our solution to this problem is developing small molecules that release arsenous acid, the aqueous and active form of ATO. Inspired by the synergy between cisplatin and ATO, we designed arsenoplatins, dual pharmacophore agents in which an aqueous form of arsenic(III) is covalently bound to the platinum(II) center. Given superior arsenoplatin-5 (AP-5) activity against TNBC (triple-negative breast cancer) cell lines relative to cisplatin or ATO used as single drugs, its potency was evaluated in a five-dose NCI-60 screen using the Sulforhodamine B (SRB) assay by Developmental Therapeutics Program at the National Cancer Institute (DTP-NCI). The COMPARE algorithm was used to compare GI_{50}, TGI, and LC_{50} values, thereby allowing evaluation of the inhibitory and cytotoxic activity of AP-5 to all other agents in the NCI database. A very high Pearson correlation coefficient (PCC) of 0.84 is obtained when AP-5's GI_{50} values were compared to GI_{50} values of ATO, indicating a similar mechanism of action. The uptake of AP-5 was evaluated in TNBC MDA-MB-231 cells using ICP-MS (inductively coupled plasma mass spectrometry). Significantly more arsenic atoms than platinum atoms in cells were taken up upon incubation of MDA-MB-231 cells with 10 μM AP-5. These results are consistent with a model in which the Pt-As bond in AP-5 breaks inside the cell and releases arsenous acid moiety, with arsenic being more retained in cells than platinum, in correlation with high PCC revealed. Interestingly, when comparing LC_{50} values of AP-5 with all other agents in the NCI database using a COMPARE algorithm, the highest PCC was obtained for alkylating agents, pipobroman and cisplatin (0.47 and 0.46, respectively). These results support a dual mechanism for arsenoplatins wherein the inhibitory activity of AP-5 is due to arsenic pharmacophore and cytotoxic activity due to platinum pharmacophore. Remarkably, although bearing both platinum and arsenic pharmacophores, AP-5 is significantly less toxic than cisplatin, based on single maximum tolerated dose (MTD) studies in vivo in female C57BL/6 mice. These results demonstrate that AP-5 is a potent, well-tolerated dual pharmacophore agent in vivo and represents the first small molecule capable of delivering an aqueous form of arsenic(III).

#3042 Non-covalent thioredoxin reductase inhibitors for TNBC.

B. Flowers[1], A. Rullo[1], P. Petukhov[2], I. Kastrati[1];
[1]Loyola University Chicago, Maywood, IL, [2]University of Illinois Chicago, Chicago, IL

Triple negative breast cancer (TNBC) has the lowest 5-year mortality and lacks targeted therapeutics. Therefore, there is a need to explore more therapeutic targets and strategies. Previous research has indicated that TXNRD1 may be a relevant target in other cancers and is elevated in TNBC and high levels of TXNRD1 and TXNRD2 correlate to lower recurrence free survival and lower overall survival (TXNRD1) and has emerged as a possible therapeutic target.The thioredoxin system includes thioredoxin reductase (TXNRD) and thioredoxin (Trx). TXNRD takes electrons from NADPH to reduce the disulfide bond in thioredoxin. Reduced thioredoxin then goes on to reduce reactive oxygen species (ROS), other oxidized species, and proteins within the cell. This system is critical in maintaining intracellular redox homeostasis, especially in breast cancer, where tumor cells heavily rely on these detoxifying systems to balance ROS produced by the dysregulated metabolism in cancer.Previous research has shown that targeting the thioredoxin reductase system using FDA approved auranofin has anticancer activity. However, auranofin is a covalent inhibitor of thioredoxin reductases, inhibits isoforms indiscriminately, and has significant side effects.Here, we show that new non-covalent inhibitors developed to target thioredoxin glutathione reductase in *Schistosoma mansoni*, also inhibit human TXNRD as demonstrated through fluorescent biochemical assays and qPCR of TXNRD related genes. Additionally, these non-covalent TXNRD inhibitors (TXNRD(i)s) show anti-cancer activity in both *in vitro* and *in vivo* TNBC models. Treatment with these TXNRD(i)s reduces viability and collagen invasion in TNBC cell lines. Similarly, knocking down TXNRD1 reduces TNBC cell invasion through collagen. Indicating TXNRD1 may be the primary target. In a TNBC xenograft, these TXNRD(i)s inhibit primary tumor growth, alter gene expression levels of multiple epithelial-mesenchymal transition (EMT) associated genes within the tumor and inflammatory markers within the host animal. These data also indicate there is a potential use of these inhibitors in a metastatic model that remains to be explored.Overall, we have shown that these TXNRD(i)s inhibit human TXNRD, have anti-cancer effects in TNBC *in vitro* and *in vivo*, inhibit collagen invasion, and alter EMT and inflammatory gene expression levels. Further research on the downstream mechanisms and optimization of these TXNRD(i)s is needed.

#3043 Preclinical efficacy assessment of brincidofovir against glioblastoma.

K. Seo[1], T. Ozawa[1], D. R. Raleigh[1], S. Nagatani[2], **M. Hazama**[2];

[1]UCSF Brain Tumor Center, San Francisco, CA, [2]SymBio Pharmaceuticals Limited, Minato-Ku, Tokyo, Japan

Introduction: Clinical use of the cytidine-analogue antiviral, cidofovir (CDV), is limited by nephrotoxicity. The lipid-conjugated CDV, brincidofovir (BCV), is characterized by a lack of nephrotoxicity, as well as superior activity compared to CDV. The objectives of this study were to examine the preclinical efficacy of BCV against glioblastoma (GBM), a malignant tumor with an extremely poor prognosis, and to identify biomarkers predicting the efficacy of BCV against GBM.

Methods: BCV cytotoxicity was tested *in vitro* in 11 human GBM cell lines, using the CellTiter-Glo® (CTG) assay. Those cell lines were then analyzed by whole-transcriptome sequencing, and differential gene expression analysis between BCV-sensitive and non-BCV sensitive cell lines was performed using DESeq2 software. To examine the influence of O^6-methylguanine-DNA methyltransferase (MGMT) expression on BCV sensitivity, monoclonal MGMT-overexpressing cell lines were established using lentiviral vector-based gene transfer in U87MG cells. MGMT gene and protein expression were confirmed using qPCR and western blot, respectively, and the BCV IC_{50} values were compared among these cell lines using the CTG assay. Finally, the *in vivo* anti-tumor efficacy of BCV was evaluated in nude mice that were orthotopically implanted with firefly luciferase-transfected U87MG cells. Mice were i.p. administered vehicle or BCV (10, 20, or 40 mg/kg) twice weekly, and bioluminescence imaging (BLI) was performed twice weekly after i.p. D-Luciferin injection to evaluate intracerebral tumor growth. Survival was evaluated using the Kaplan-Meyer method.

Results: The CTG assay revealed a median BCV IC_{50} value of 2.2 μM. Sub-micromolar BCV IC_{50} values were obtained in KALS-1, T98G, and LN-18 cells. In these highly sensitive cell lines, differential gene expression analysis identified glypican 6 (GPC6) as the gene showing the most significantly decreased expression, and neuronal tyrosine-phosphorylated phosphoinositide-3-kinase adaptor 2 (NYAP2) as the gene with the most significantly increased expression. Compared to the parent MGMT-negative U87MG cells, two MGMT-overexpressing cell lines exhibited BCV IC_{50} values that were lower by 16.3-fold and 2.5-fold. *In vivo* experiments demonstrated that BCV significantly decreased intracranial tumor growth, determined as BLI, in a dose-dependent manner during the treatment period compared with the vehicle group. With the exception of weight loss in the BCV 40 mg/kg group, no apparent systemic toxicity was observed in the other BCV dose groups. Compared with the vehicle group, the BCV 20 mg/kg group exhibited significantly increased survival.

Conclusion: BCV exerted antitumor effects on GBM *in vitro* and *in vivo*, regardless of MGMT status, and improved survival *in vivo*. Low GPC6 expression and high NYAP2 expression could serve as clinical pharmacologically significant biomarkers that predict high sensitivity to BCV.

#3044 Butyrate modulates key oncogenic pathways in triple-negative breast cancer: insights from transcriptomic profiling.

Gabriel Borges Velez[1], Diego N. Bracero-Sanchez[2], Liah M. Roman-Calderon[1], Ariana S. Garcia-Lopez[1], Angel J. Amaral-Maisonet[3], Jeannette L. Salgado-Montilla[1], Esther A. Peterson-Peguero[4], Josue Perez-Santiago[1]

[1]Division of Clinical & Translational Cancer Research, UPR - Comprehensive Cancer Center, San Juan, Puerto Rico,[2]Division of Clinical & Translational Cancer Research, University of Maryland, College Park, MD,[3]Science-Interdisciplinary Studies, UPR - Rio Piedras, San Juan, Puerto Rico,[4]Department of Biology, UPR - Rio Piedras, San Juan, Puerto Rico

Introduction: Triple-negative breast cancer (TNBC) is a highly aggressive subtype with a poor prognosis, affecting approximately 5% of breast cancer patients and lacking targeted therapies. Recent studies highlight the potential of short-chain fatty acids (SCFAs), metabolic byproducts of the microbiome, as anticancer agents. Among these, butyrate exhibits anti-inflammatory, immunomodulatory, and antineoplastic effects in several cancer types. Our preliminary data shows that butyrate exerts cytotoxic, anti-migratory, and antiproliferative effects on TNBC cells. However, to understand molecular mechanisms related to butyrate treatment and investigate its therapeutic potential in TNBC, this study measured transcriptomic changes after butyrate treatment of TNBC. **Methods:** MDA-MB-231 cells (TNCB cell model) were treated with 5 mM butyrate for 24 hours. RNA was extracted, quantified, and assessed for integrity before sequencing on the Illumina NextSeq 550. Bioinformatics workflows included quality control (FastQC), trimming (Trimmomatic), and alignment to the GRCh38 human genome using STAR. Read quantification was performed with RSEM, and differential gene expression was analyzed using R statistical software (tximport and DESeq2 packages). Functional annotation, pathway enrichment, and protein interaction analyses of significantly differentially expressed genes were conducted using Metascape and STRING (adj. p-value<0.05). **Results:** Butyrate treatment significantly altered the expression of 4,352 transcripts in MDA-MB-231 cells. The most upregulated transcript, DHRS2, a cell cycle regulator with tumor suppressor properties, exhibited an 8.8-fold increase. Conversely, ZNF709, a zinc finger protein frequently overexpressed in cancers, showed a 7.8-fold decrease. Pathway analysis revealed that affected transcripts are involved in critical oncogenic processes, including cell adhesion, cytokine signaling, wound healing, regulation of cell migration, and MAPK signaling. STRING analysis identified clusters of proteins significantly associated with protein phosphorylation regulation, along with binding-related molecular functions and phosphoprotein. **Conclusions:** Our results demonstrate that butyrate modulates the transcriptome of MDA-MB-231 cells, targeting pathways involved in oncogenic processes such as cell adhesion, migration, and signaling, which is consistent with our cellular results. Key transcripts, such as DHRS2 and ZNF709, are novel prognostic markers for prostate and gastric cancer respectively, highlighting butyrate's capacity to regulate tumor suppressor and oncogenic pathways. These findings support butyrate's potential as a microbiome-derived therapeutic for TNBC.

#3045 Development of a first-in-class PDIA6/IRE1 modulator for selectively sensitizing cancer cells to ER stress and regulated cell death.

Wei Jia[1], Xiaobing Zhang[1], Bo Kang[2], Zhao Xu[1], Chencong Bo[1], Mingxing Yin[1], Shujian Ren[1], Zhengshu Chen[1], Amar Al-Ansi[1], Hongban Zhong[1], **Ying-Jie Wang**[1]

[1]Nain Biotech Co., Ltd., Hangzhou, China,[2]Zhejiang University, Hangzhou, China

Background: A high proliferation rate of cancer cells requires increased protein synthesis leading to ER stress, a condition characterized by accumulation of unfolded or misfolded proteins in the ER lumen. Three interconnected Unfolded Protein Response (UPR) pathways, IRE1, PERK, and ATF6 pathways, are activated to relieve ER stress or to initiate apoptosis if prolonged strong ER stress remains unsolved. Thus, the chronically elevated ER stress levels in cancer cells constitute an Achilles' heel and provide a window of opportunity for development of therapeutic regimens. Despite multiple ongoing preclinical and clinical studies using various agents and regimens to overactivate ER stress and UPR, agents that can specifically induce UPR in cancer cells but not in normal cells are still lacking.

Methods: Metabolic activity-based phenotypic assay was employed to identify NAI003 as the most potent anticancer compound during lead optimization where over three hundred small-molecule NCEs were derived from the hit compounds. HuProt™ Human Proteome Microarray and chemoproteomics approaches were used to identify target proteins to which NAI003 can directly bind. The top ranked target proteins were each validated by specific siRNAs, followed by Biacore analysis to quantify target binding affinity. Subsequently, multiple approaches were used to further understand the MoA of NAI003 and to assess its developability.

Results: Our preclinical candidate compound NAI003 directly binds with high affinity (Kd=1.8 nM) and selectivity to PDIA6 protein that is known to catalyze protein folding and thiol-disulfide interchange reactions in the ER. NAI003 blocks the PDIA6/IRE1 protein-protein interaction in ER-stressed cancer cells and thereby inducing constitutively activated IRE1 signaling that ultimately leads to regulated cell death (RCD). NAI003 series compounds have subnanomolar to low micromolar IC50s against selected cervical, lung, ovarian, liver, pancreatic, skin and brain cancer cells *in vitro*, and potently inhibit their *in vivo* propagation in multiple CDX and PDX models. Remarkably, they completely spare normal cells that usually have much lower levels of ER stress. Furthermore, in rodent models, NAI003 compounds exhibit low acute toxicity, desirable pharmacokinetics profile and reasonable oral bioavailability. Importantly, NAI003 compounds exhibit synergism with PARP inhibitors (e.g. Talazoparib), proteasome inhibitors (e.g. Ixazomib) and metabolic stressors (e.g. glucose deficiency) that are all known to induce ER stress in cancer cells.

Conclusion: NAI003 is a potential first-in-class small-molecule PDIA6/IRE1 modulator that sensitizes cancer cells to ER stress and RCD by selectively overactivating IRE1 signaling. It holds great promise in treating selected cancers either as a single agent or as a combination therapy with marketed anticancer drugs.

#3046 Combination therapy targeting genomic and signal transduction vulnerabilities in epithelioid hemangioendothelioma.

Gillian DeWane, Nicholas Scalora, Yuliia Drebot, Ali Khan, Souradip Sinha, Krishnendu Ghosh, Nicole Merritt, Colleen Fullenkamp, Munir Tanas

Pathology, University of Iowa, Iowa City, IA

Background: Epithelioid hemangioendothelioma (EHE) is a vascular sarcoma that frequently presents with early onset metastasis and lacks an effective medical therapy. EHE sarcomas are defined by the presence of gene fusions, where 85-90% of all EHE tumors contain TAZ-CAMTA1 and 10-15% contain YAP-TFE3. These fusion proteins bypass regulation by the Hippo pathway and act as important transcriptional coactivators by activating a TEAD-based transcriptional program, which is responsible for activating genes in several downstream pathways, including the PI3K pathway. Topoisomerase II, a chromatin modifier, was found to act as a key cofactor for the TAZ-CAMTA1 and YAP-TFE3 transcriptional programs. Herein, we propose utilizing inhibitors as a combination therapy targeting the PI3K-Akt axis, topoisomerase II, and TEAD binding of the TAZ-CAMTA1 and YAP-TFE3 transcription factors.
Methods: Experiments were completed utilizing NIH 3T3 cells or a human liposarcoma cell line, SW872, that have been engineered to express the TAZ-CAMTA1 or YAP-TFE3 fusion proteins, or human EHE extended primary cell cultures. Several *in vitro* hallmarks of cancer assays were performed including 3D soft agar or poly-HEMA assays to measure anchorage independent growth and 2D clonogenic assays to measure cell survival. In each assay, cells were treated with various concentrations of vehicle control, everolimus, an mTORC1 inhibitor, IK930/VT-107, TEAD inhibitors, teniposide, a topoisomerase II inhibitor, or a combination of two or all three.
Results: In the cells mentioned above, treatment with everolimus, IK930, teniposide and the combination of everolimus and IK930 and teniposide and IK930 showed a dose dependent decrease in anchorage independent growth when compared to the vehicle control. In soft agar and poly-HEMA, synergy was found with the combination of everolimus and IK930 and teniposide and IK930. To examine the cytotoxicity of the drugs, a clonogenic assay was performed on cells treated with everolimus and IK930 and observed no apparent cytotoxicity in cells treated with these inhibitors, however we did see cytotoxicity when EHE cells were treated with VT-107.
Discussion/Conclusion: Because most EHE cells contain either the TAZ-CAMTA1 or YAP-TFE3 fusion proteins that activate a transcriptome that promotes several hallmarks of cancer, targeting the main way the fusions interact with DNA could mitigate these effects. Previous studies investigating the use of monotherapies to target cells expressing the fusion proteins show limited effectiveness. However, targeting both the interaction of the fusion proteins' ability to interact with DNA as well as an important pathway for EHE cells, such as the PI3K pathway, could lead to a greater effectiveness in decreasing EHE tumor progression. These studies here show everolimus, teniposide and IK930/VT-107 as a potential combination therapy for EHE.

#3047 Glycan-targeted therapy for effective treatment of pancreatic cancer.

Erica J. Peterson[1], Vignesh Vudatha[2], Vashti Bandy[2], Praveen Bhoopathi[2], Arunima Punjala[2], Thomas M. Clausen[3], Jennifer E. Koblinski[4], Chunqing Guo[5], Larisa Litovchick[1], Jose G. Trevino[2], Nicholas P. Farrell[6]

[1]Internal Medicine, Virginia Commonwealth University, Richmond, VA,[2]Surgery, Virginia Commonwealth University, Richmond, VA,[3]University of Hawaii at Manoa, Oahu, HI,[4]Pathology, Virginia Commonwealth University, Richmond, VA,[5]Immunology, Virginia Commonwealth University, Richmond, VA,[6]Chemistry, Virginia Commonwealth University, Richmond, VA

Patients with the most common pancreatic malignancy, pancreatic ductal adenocarcinomas (PDAC), typically present with advanced disease and their cancer progresses 6-12 months after treatment with the front-line regimen, FOLFIRINOX (5-fluorouracil, oxaliplatin, irinotecan and leucovorin). Therefore, there is a critical need for new and effective treatment regimens for PDAC patients. The novel polynuclear platinum agent, Triplatin (BBR3464), showed objective responses in a subset of patients, including a pancreatic cancer patient with liver metastasis in clinical trials. Although Triplatin did not advance beyond Phase II, our new understanding of its mechanism of action supports the rationale for its re-examination against tumors expressing high levels of glycosaminoglycans (GAGs), specifically chondroitin-4-sulfate (C4S). C4S is a tumor-specific GAG attached to proteoglycans such as CD44, glypicans and syndecans, expressed on the cell surface and in tumor stroma. The positive charge of Triplatin increases its binding affinity to negatively charged GAGs, which facilitates drug accumulation into the tumor cells and increases the level of platinum-DNA adducts. Recent studies suggest that overexpression of GAGs, particularly CS, contributes to the dense fibrotic stroma associated with PDAC, and resistance to chemotherapeutics and new immunotherapeutic agents. Our preliminary data indicates that alterations in the expression of GAG levels in PDAC cell lines affect the cytotoxicity and cellular uptake of Triplatin. First, we show Triplatin is generally more active than oxaliplatin against human and mouse PDAC cell lines. Secondly, a GAG-deficient CHX1990 cell line (CRISPR KO of β-1,4-galactosyltransferase 7 (B4GalT7), verified by reduction in binding of CS-binding peptide, rVAR2-V5, shows a correlative loss in cytotoxicity. Interestingly, the reduction in Triplatin Pt-DNA adduct formation observed in the CHX1990 B4GalT7 KO (HS and CS deficient), CSGalNAcT1/2 KO (CS deficient) and CHST 11/12 KO (chondroitin-4-sulfate (C4S) deficient) is at similar levels, suggesting DNA platination by Triplatin is dependent specifically on C4S. Third, we show significant activity of Triplatin against high GAG-expressing PDAC PDX and mouse CHX1990 models *in vivo*. Finally, we show high GAG expression in PDAC patient samples vs normal tissues, highlighting the potential of GAG-targeted platinum therapy. Together, our results show that GAGs may provide a viable biomarker for Triplatin in PDAC patients, producing a significant clinical advantage over oxaliplatin in this setting. A more active platinum would not only increase response rates and durations of response, but also avoid the toxicity of relatively inactive therapy.

#3048 *In vitro* and i*n vivo* anti-cancer properties of novel synthetic inhibitor targeting human NAD(P) dependent steroid dehydrogenase-like.

H. Kim[1], S.-H. Yoon[2], S. Lee[2], S. Ryu[2], H.-B. Lee[3], B.-J. Lee[4], W. Han[3];

[1]Seoul National University Hospital, Seoul, Korea, Republic of, [2]Seoul National University Graduate School, Seoul, Korea, Republic of, [3]Seoul National University College of Medicine, Seoul, Korea, Republic of, [4]Ajou University College of Pharmacy, Suwon-si, Korea, Republic of

Background: NAD(P)-Dependent Steroid Dehydrogenase-Like (NSDHL), which is involved in cholesterol synthesis, has been found to play a role in breast cancer stemness, growth, and metastasis. NSDHL is emerging as a potential new therapeutic target for breast cancer. This aim is to evaluate molecular mechanisms underlying the anti-cancer properties of a novel NSDHL inhibitor in breast cancer models *in vitro* and *in vivo*.

Methods: A structure-based inhibitor of NSDHL (Compound 9) was developed by Dr. Lee Bong-Jin. Compound 9 (1-250 μM) was treated in diverse human breast cancer cell lines (MCF-7, ZR75-1, BT474, BT-20, MDA-MB-231) for 2-7 days and administered by oral gavage (2.5 mg/kg/day) for 30 days in an orthotropic breast tumor model of BALB/c Nude mouse. Anti-cancer activities and molecular mechanisms of Compound 9 were evaluated by cell cycle analysis using DNA staining with PI, apoptosis analysis using annexin V/PI-labeling, cell proliferation analysis using crystal violet assay, cell migration analysis using transwell migration assay, western blot, immunohistochemistry, and TEM image.

Result: Rhodamine B-conjugated Compound-9 was easily internalized into breast cancer cells within an hour. Compound 9 exerted anti-proliferative and anti-migratory activity, G0/G1 phase arrest, and apoptotic and autophagic death along with the downregulation of XIAP and BCL2, the upregulation of P62 and LC3II, and modulation of the Akt/mTOR/MAPK signaling pathway. A combination of Compound 9 and paclitaxel enhanced the anticancer activity of paclitaxel in cultured breast cancer cells. Compound-9, when given orally to mice, inhibited the breast tumor growth without affecting their body weight.

Conclusions: We suggest that Compound 9 can be employed as a potential therapeutic drug to target NSDHL in cancer as well as cholesterol-related diseases.

#3049 Synergistic growth-inhibitory efficacy of LSD1 and BCL-XL inhibitors in JAK2+ AML/MPN cells.

Mark A. Forsberg[1], Zhe Wang[2], Sovira Chaudhry[1], Anna Skwarska[1], Raajit Rampal[3], Alexandra Schurer[1], Kira Gritsman[1], Guangrong Zheng[4], Daohong Zhou[5], Marina Konopleva[1]

[1]Montefiore Einstein Comprehensive Cancer Center, Bronx, NY,[2]Division of Immunobiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH,[3]Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, NY,[4]Department of Medicinal Chemistry, UF College of Pharmacy, Gainesville, FL,[5]Department of Biochemistry and Structural Biology and Center for Innovative Drug Discovery,, The University of Texas Health Science Center at San Antonio, San Antonio, TX

This study explores a potential synergy between Lysine-specific demethylase 1 inhibitors (LSD1i) and BCL-XL inhibitors for acute myeloid leukemias (AML) arising from myeloproliferative neoplasms (MPN). LSD1i prolongs the survival of post-MPN AML murine models (Rampal et al. Blood 2020) and induce apoptosis in AML cell lines via upregulating BAX (Wang et al. Blood, 2019). Our analysis of the RNA-seq and data from the Beat 1.0 AML cohort, CRISPR screen data from Cancer Cell Line Encyclopedia, Public Avana 21Q2 dataset, and multi-omics from post-MPN sAML patients (Rodriguez-Meira et al., Nat Genet. 2023) showed that post-MPN AML exhibited high expression of *BCL2L1*/BCL-XL (p=0.0026), compared to de novo AML (Wang, ASH 2024, #2749). We explored the synergy between the LSD1i Iadademstat (Selleckchem), and BCL-2/BCL-XL inhibitor, Navitoclax, or the platelet-sparing BCL-XL degrader, DT2216 (Dialectic Therapeutics). JAK2 mutated cell lines, Hel and Set2, and Ruxolitinib-resistant (RR) lines derived from them were utilized. The activities of LSD1i, navitoclax, and DT2216, alone and in combination, were tested using Cell Titer Glo assays of 20,000 cells at 72 hours. LSD1i as a single agent (0.6-50 nM) reduced viability plateauing at 50-68% in all tested cell lines. Navitoclax and DT2216 effectively reduced cell viability; when combined with 10 nM of LSD1i, IC_{50} values were significantly lower (Table 1). These findings were next verified using the Annexin 5 flow cytometry at 24 hours co-treatment. All combinations showed a significant increase in apoptosis over either compound alone (Table 1). Synergy was confirmed with SynergyFinder+ software (mean: 18.86-72.47 zip model). In summary, $JAK2^{+}$-mutant post-MPN AML cell lines and isogenic Ruxolitinib-resistant lines showed sensitivity to BCL-XL inhibitors and a synergistic increased sensitivity to these compounds when combined with low dose LSD1 inhibitor, Iadademstat. Mechanisms behind the synergy are being studied and will be reported.

Summary of Glo Titer Assays and Annexin 5 Flow Cytometry Data with mean Synergy Scores

			Glo Titer Assay

#3050 Targeting SREBP-driven transcriptional programs in metastatic prostate cancer.

Prashanth Parupathi, Lakshmi Sirisha Devarakonda, Enkiel Francois, Bhaskar C Das, Avinash Kumar

Long Island University, Brooklyn, NY

Prostate cancer (PCa) is the most commonly diagnosed cancer and the second leading cause of cancer-related deaths among men in the United States. Metastasis is the major cause of mortality associated with prostate cancer, and despite the availability of targeted therapeutic agents, metastatic prostate cancer remains a lethal disease. Therefore, there is a significant unmet need to identify new drug targets and develop novel targeted therapeutic agents. Sterol regulatory element binding proteins (SREBPs) are a family of transcription factors, comprising SREBP-1 and SREBP-2, that govern lipid homeostasis by regulating the expression of numerous enzymes involved in fatty acid and cholesterol synthesis (lipogenesis). The role of SREBPs in regulating non-lipogenic transcriptional programs is beginning to be elucidated. Published findings associate perturbation of SREBP-dependent transcriptional programs in the development, progression, and metastasis of various cancers, including PCa. Our analysis of publicly available patient datasets revealed increased gene expression for SREBPs in prostate tumors compared to normal prostate. Further, we discovered significantly higher gene expression for SREBPs in metastatic samples compared to primary prostate tumors. Moreover, we found significantly elevated levels of SREBPs in more invasive PC3M and C4-2B compared to the less invasive PC3 and LNCaP prostate cancer cell lines. Hence, we hypothesized that pharmacological inhibition of SREBPs might be an effective therapeutic strategy against metastatic prostate cancer. We have developed a novel boron-containing compound, BF175, which inhibits the expression and transcriptional activity of SREBPs, but the information on the anticancer action of BF175 in various cancers, including prostate cancer, is very limited. In this study, we investigated the SREBP-mediated anticancer activity of BF175 in prostate cancer. We found that BF175 inhibited the viability, proliferation, and metastatic potential as well as induced apoptosis in all prostate cancer cell lines tested. We also confirmed that BF175 inhibited the expression of SREBPs in the tested prostate cancer cell lines. Of note, BF175 exhibited significantly higher potency as an anticancer agent in more invasive prostate cancer cell lines compared to their less invasive counterparts. Taken together, our results demonstrate that BF175 shows promise as a novel anticancer agent that may improve outcomes in lethal metastatic prostate cancer.

#3051 DiaXCIP3M: A new small drug molecules conjugate displaying a strong antiproliferative in vitro and in vivo activity against human small cell lung cancer.

Gregoire Pierre Prevost[1], Gwenael Forcher[2], Anne-Caroline Chany[2], Laurent Fontaine[2]

[1]CIPREVO, Antony, France,[2]Institut des Molecules et Materiaux du Mans - UMR 6283 CNRS -, Le Mans, France

The high medical need for new, original therapeutic molecules remains clear for all those fighting small cell lung cancer (SCLC). DiaXCIP3M based on patented technology belongs to a new class of small drug molecules conjugates (SDMCs). Traditional chemotherapy mostly relies on the use of a cocktail of several anticancer drugs. However, two different drugs display two different pharmacokinetics and two different tissue biodistributions meaning that it is very challenging to anticipate the ratio of these two drugs in the tumor or normal cells. Small molecule drug conjugates (SMDCs) are a promising strategy to reduce these limits by coupling two distinct cytotoxic molecules in one new drug therefore inducing only one pharmacokinetic and one biodistribution. The inter-variability of the drug exposure between patients is thus expected to be reduced compared to the cocktail approach. Reduction of the variability allows a better definition of the recommended dose to actively and safely treat the cancer patients. Preclinical studies performed today indicate that DiaXCIP3M has a strong product profile for further development with 1/ a patented chemical structure, 2/ an original mechanism of action that involves simultaneously inhibition of two validated anticancer targets, resulting in activity in a large range of cancer subtypes, 3/ a powerful in vitro antitumor activity at low nM against human SCLCs, 4/ a suitable in vivo plasma stability assessed by iv route in mouse superior to 2 hrs, and 5/ an induction of in vivo tumor reduction at safe dose in human SCLC xenografted model in mice.DiaXCIP3M has the potential to become an integral part of the therapeutic landscape for ES-SCLC, particularly as a second-line alternative to the currently validated chemotherapy, topotecan, or as a third-line treatment after topotecan failure.

#3052 Butyrate reduces NLRP3 RNA expression in oral squamous cell carcinoma.

Oscar Antonio Loperena Gonzalez, Angel J. Amaral Maisonet, Jurelis Torres Reyes, Jeannette L. Salgado Montilla, Gabriel Borges Velez, Josue Perez Santiago

University of Puerto Rico Comprehensive Cancer Center, San Juan, PR

Background: Oral squamous cell carcinoma (OSCC) is a type of oropharyngeal cancer associated with elevated levels of IL-1β, which can be secreted with the activation of the inflammasome NLRP3 and caspase 1 signaling pathway. High levels of IL-1β in OSCC leads to cancer progression, invasiveness, autocrine signaling which promotes metastasis, and prolonged inflammation that contributes to tumorigenesis. Inflammasomes are proteins essential for rapid responses in the innate immunity and they work with caspases to promote inflammation signaling, but persistent signaling can induce malignant transformation of cells. Additionally, OSCC is exposed to microbial products, short chain fatty acids (SCFA) which can influence transcription of inflammasomes and caspases; yet it has not been evaluated in OSCC. We have observed that butyrate treatment reduces cell viability, migration, and proliferation in OSCC cell model (OECM-1). Therefore, we aimed to investigate the SCFAs effect in regulating genes *NLRP3*, *NLRP6*, *Caspase 1* and *Caspase 4* in OECM-1.

Methods: We extracted RNA from OECM-1 untreated and treated either with butyrate, acetate, or propionate at 5mM for 24 hours. We quantified RNA expression NLRP3, NLRP6, caspase 1, and caspase 4 by probe-based qRT-PCR using the gene RPP30 as the endogenous control. We calculated the fold change using comparative Ct method (ΔΔCt) and t-test to determine significance difference in the levels of inflammasome and caspase after SCFA treatment vs untreated cells.

Results: Levels of NLRP3 significantly decreased (fold change: -2.43, $p=0.022$) and levels of caspase 1 significantly increased (fold change: 1.51, $p<0.001$) after 24 hours exposure of butyrate. There were no significant changes in gene expression levels of NLRP6 or caspase 4. Treatment with propionate resulted in the increase of NLRP3 (fold change: 1.94, $p=0.086$), NLRP6 (fold change: 2.22, $p=0.058$), caspase 1 (fold change: 2.84, $p=0.026$), caspase 4 (fold change: 1.87, $p=0.057$). No significant changes in levels of the inflammasomes or caspases were observed with acetate treatment.

Conclusion: This study demonstrates that butyrate reduces NLRP3 inflammasome expression on OSCC, promotes caspase 1 expression and does not alter NLRP6 and caspase 4 expression. Conversely, our data shows that propionate increases NLRP3 and caspase 1 transcription, which increases IL-1β levels; and increments NLRP6 and caspase 4 transcription, both associated with inflammation. This proposes butyrate's ability to reduce IL-1β levels in OSCC and potentially be promoting alternate pathways with caspase 1. Modifying the microbiome to induce greater butyrate secretion or direct inhibition of NLRP3 inflammasome through medications, can represent a novel treatment strategy for OSCC.

#3053 SHP2 inhibition with RMC4630 demonstrates antitumor efficacy and potentiates nanoparticle-paclitaxel response in pancreatic cancer.

Nicola Grimaldi, Lily Darman, Mitchel Ramos, Margaret Schwarz, Niranjan Awasthi

Indiana University School of Medicine, South Bend, IN

Objective: Pancreatic ductal adenocarcinoma (PDAC) is a highly lethal malignancy with a grim prognosis. The combination of nab-paclitaxel and gemcitabine (NPT-GEM) remains the standard treatment for advanced and metastatic PDAC, achieving a median survival of approximately 8.5 months. An activating mutation in the KRAS gene is central to PDAC pathogenesis, driving cancer cell proliferation, survival, and tumor progression through downstream pathways, including PI3K/AKT/mTOR and RAS-RAF-MEK-ERK. Despite being a critical target, KRAS has long been considered "undruggable" due to its small size and the lack of accessible binding sites. The SHP2 inhibitor RMC4630, targeting a key coactivator of KRAS signaling, represents a promising therapeutic approach for PDAC.

Methods: In vitro cell proliferation assays were performed using the colorimetric WST-1 method. Protein expression levels were assessed by immunoblotting. In vivo tumor growth studies were conducted in 4-6-week-old female NOD/SCID mice bearing AsPC-1 subcutaneous xenografts.

Results: In vitro assays demonstrated dose-dependent inhibition of proliferation in PDAC-associated cell lines treated with RMC4630 and NPT-GEM. A synergistic effect was observed with the combination therapy. In $KRAS^{G12D}$AsPC-1 cells, NPT-GEM, RMC4630, and their combination inhibited proliferation by 33%, 13%, and 74%, respectively. Similarly, in $KRAS^{G12C}$ MIA PaCa-2 cells, inhibition rates were 46%, 20%, and 78%, while in $KRAS^{wt}$ BxPC-3 cells, inhibition was 63%, 26%, and 73%. PDAC Stromal cell proliferation was inhibited by 48%, 25%, and 60% with NPT-GEM, RMC4630, and their combination, respectively. Immunoblot analysis of KRAS ^{G12D}-mutant cells revealed that RMC4630 treatment decreased phosphorylation of PI3K/AKT and RAS-RAF-MEK-ERK pathway proteins, while increasing apoptosis marker proteins cleaved-PARP-1 and cleaved-caspase-3. In vivo, RMC4630 and NPT-GEM significantly delayed tumor growth, with the combination demonstrating synergistic effects. Tumor weights were reduced from 0.22g in controls to 0.09g with NPT-GEM, 0.077g with RMC4630, and 0.06g with the combination. No significant body weight changes were observed, indicating minimal toxicity.

Conclusion: These findings underscore the therapeutic potential of RMC4630, especially in combination with standard chemotherapy, as a promising approach for managing KRAS-mutant PDAC.

#3054 A potent triterpene combination treatment for eliminating castration resistant prostate cancers.

Kunj Bihari Gupta[1], Kanza Mamouni[1], Georgios Kallifatidis[2], Truett Taylor[1], Bal. L. Lokeshwar[1]

[1]Georgia Cancer Center, Augusta University, Augusta, GA,[2]Biology, Augusta University, Augusta, GA

Patients with advanced prostate cancer (PCa) with castration resistance and neuroendocrine phenotype (CRPC) respond poorly to most existing therapies (median survival, <2y). The studies of antitumor activities of the bioactive pentacyclic triterpenes (PTTs), such as Oleanolic Acid (OA) and Ursolic Acid (UA), have been reported in multiple tumor models. Here, we tested the efficacy of OA and UA, individually and in combination, against PCa cells in both in-vitro and in-vivo systems. We found ~ 50% ($p<0.05$) reduction in tumor growth and terminal tumor weight in the CRPC line 22Rv1 tumors that were implanted subcutaneously in athymic nude mice following oral gavage at 50 mg/kg with OA and UA alone and in 1:1 combination three times a week. There was no detectable systemic toxicity to the host mice. Further, *in-vitro* mechanistic investigation of the effect of OA and UA unveiled that at higher concentrations, a 1:1 combination ratio of OA and UA shows synergistic activity against PCa cells (e.g. 22Rv1, PC3, LNCaP, and C4-2), in contrast, this combination showed insignificant toxicity on a non-tumorigenic human prostate epithelial cell line (NHPrE1). To investigate the molecular mechanism of tumor cell-specific cell death, we explored the effect of these PTTs on ROS production, glucose metabolism, extracellular oxygen consumption rate, and ATP production in both 22Rv1 and PC3 cells. The combination treatment of OA and UA significantly increased the ROS level up to 80% ($p<0.05$) and considerably decreased the mitochondrial Oxygen Consumption Rate (OCR). The levels of intermediates of glycolysis were significantly increased, but tricarboxylic acid (Krebs cycle) metabolites decreased significantly. Immunocytochemical and Immunoblotting analyses of tumor tissues from xenografts showed excessive cytotoxic autophagy as the leading cause of cell death. An increased autophagy-associated membrane-bound LC3B corroborated and higher expression of other markers of autophagy (e.g., Beclin-1, P62/SQSTM1, ATGs, and pULK-1) were seen in cells treated with OA, UA, and their combination. In contrast to increased autophagy markers, markers associated with apoptosis (e.g., cleaved PARP-1, Caspase-3, etc.) were either undetectable or insignificant. Overall, ongoing studies showed that OA and UA in a 1:1 combination induce cancer-cell-specific toxicity mainly via autophagy. This study demonstrated that the triterpenes (OA, UA, and OA+UA) have compelling potential to inhibit CRPC in patients, and because they exhibit little systemic toxicity, yet show significant antitumor activity, they could be used as a neo- or adjuvant therapeutics with current FDA-approved cytotoxic chemotherapy drugs.

#3055 Developing the cyclic peptide AD05 as a novel Hsp90 inhibitor for triple-negative breast cancer therapy.

Ilham Zarguan[1], Sumin Lu[2], vamsi Krishna Kommalapati[2], Alisha Hussain[2], Dhruvi Paladiya[2], Wayne Fang[2], Lamiae Belayachi[1], Abdelaziz Benjouad[1], Abdessamad Debbab[3], Ahmed Chadli[2]

[1]CReSS, Health Sciences Research Center, International Faculty of Medicine, International University of Rabat, Rabat, Morocco,[2]Georgia Cancer Center, Augusta University, Augusta, GA,[3]Institut fur Pharmazeutische Biologie und Biotechnologie, Dusseldorf, Germany

The Heat-shock protein 90 (Hsp90), emerged as an exciting molecular target in the late 90s after being recognized as the driving force behind the Ansamycin antibiotic geldanamycin's antitumoral activity. Since then, extensive research has been conducted to develop Hsp90 inhibitors for clinical applications in cancer therapy. Specifically in triple-negative breast cancer (TNBC), studies have shown that using Hsp90 inhibitors as single agents, or in combination with immunotherapy can offer new leads to better therapeutic efficacy. However, traditional inhibitors targeting the N-terminal domain of Hsp90 often trigger a heat shock response (HSR) or are pan-inhibitors which results in detrimental side effects in clinical trials. Considering this, this study aims to identify and characterize small molecules that can inhibit Hsp90 and degrade its oncogenic client proteins, without inducing the HSR. Using a high-throughput progesterone reconstitution screening assay, a cyclic peptide, AD05, was identified from medicinal plant extracts and their symbiotic microorganisms. This compound is intriguing because it inhibits Hsp90 in a distinct manner from the classical N-terminal Hsp90 inhibitor tested in Phase III clinical trials; 17-N-allylamino-demethoxygeldanamycin (17-AAG) and does not induce the HSR. The binding of AD05 to Hsp90 was further characterized in purified and cell-based systems using IP linked to LC-MS, molecular docking analysis, cellular thermal shift assay (CETSA), and Western blot that showed an efficient degradation of oncogenic client proteins. AD05 exhibited significant cytotoxicity against cancer cells evaluated in MTT assays compared to normal cells, immunohistochemistry (IHC), immunofluorescence, electron microscopy, and Seahorse metabolic analyses. Our findings suggest that bioactive natural products are effective and promising inhibitors against the Hsp90 machine for cancer research and therapy.

#3056 Structural optimization of lapatinib analogs for overcoming CNS metastases in breast cancer.

Mostafa Mohammed Ahmed Aref, Eneye D. Ajayi, Md A. Emran Hossain, Rokaia S. Abdullah, Hamed I. Ali

Pharmaceutical Sciences, Texas A&M University, College Station, TX

Due to its role in aggressive disease progression and poor clinical outcomes, HER-2 kinase was considered a vital target in breast cancer (BC). Central nervous system (CNS) metastases represent a significant challenge in HER2+ BC, as they are often refractory to existing therapies such as lapatinib. Our previous work focused on the structural optimization of lapatinib analogs to enhance potency, selectivity, and pharmacokinetics. The HER2-selective derivatives were synthesized and characterized, with nanomolar IC_{50} values range of [5.4-12 nM], more the reference drug lapatinib (IC_{50}: 95.5 nM). Compound 17d demonstrated outstanding HER2 selectivity and minimal off-target kinase activation. Broad-spectrum activity was observed (GI_{50}: 1.43-2.09 μM), with a strong preference for HER2+ BC cells over HER2– cells, achieving up to 20-fold selectivity in antiproliferative assays. Compound 17d emerges as a promising candidate with the potential to overcome the limitations of current HER2 therapies. Its potent HER2-selective inhibition, robust *in vivo* efficacy, and favorable pharmacokinetic profile highlight its therapeutic potential for HER2+ breast cancer. Our current study mainly focuses on the structural optimization of our lead compound to be more BBB penetrable to overcome the HER-2 CNS Metastatic cancers by applying *in-silico, in-vitro*, and *in-vivo* models.

#3057 Telomerase and G-quadruplex dual-targeting chimera inhibits melanoma via telomere disruption.

Yutong Sui[1], qi xu[1], mingsheng liu[1], jinyu liu[1], geng qin[2]

[1]Jilin University, Changchun City, China,[2]Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun City, China

Interference with telomerase and telomere maintenance have historically been viewed as a highly attractive target for anticancer therapies by restraining proliferative capacity via telomere length. A range of screens have identified many small molecule inhibitors of telomerase, but these inhibitors have all encountered obstacles in the early stages of preclinical studies primarily due to their limited potency and delayed onset of cytotoxic effects. Ligand-induced stabilization of telomeric G-quadruplexes (G4s) formation have been thought to be negative regulators of telomerase activity. However, given that G4-forming sequences are pervasive in human genome, G4 ligands display quite limited intra-G4 selectivity, resulting in a risk of side effects in therapeutic use. Here, we introduce an innovative telomere targeting strategy leveraging telomerase and G4 dual-targeting chimera. We design and synthesize such chimera by connecting telomerase inhibitor BIBR1532 to G4 ligands pyridostatin via a linker. On one hand, pyridostatin can enhance the anticancer potency of BIBR1532 by targeting telomere G4 structures. On the other hand, BIBR1532 can recruit pyridostatin to the telomere region by directly interacting with telomerase, thereby mitigating its off-target effects. As expected, the chimeric compound is capable of telomerase inhibition and suppress melanoma progression in vitro and in patient-derived xenograft (PDX) model with no observable toxicity. Notably, the anti-melanoma effects of the chimeric compound outperform that of BIBR1532 or pyridostatin alone. Our study provides a more effective strategy for telomerase inhibition, and the telomerase and G4 dual-targeting chimera is a promising candidate for anticancer therapy.

#3058 AR-dependent anticancer action of BF175 in hormone sensitive prostate cancer.

Lakshmi Sirisha Devarakonda, Prashanth Parupathi, Ekniel Francois, Bhasker C. Das, Avinash Kumar

Long Island University, Brooklyn, NY

Androgen receptor (AR) is a well established key biological contributor to prostate cancer progression. Despite significant efforts which have resulted in the therapeutic agents that target the AR signaling being the therapy of choice, prostate cancer remains one of the topmost causes of cancer-related deaths among men in the United States. Hence, development of novel targeted therapeutics that augment or supplant AR-based therapy remains a top priority. Sterol regulatory element binding proteins (SREBPs)are a family of transcription factors, consisting of SREBP-1 and SREBP-2, that control lipid synthesis. Available literature provides evidence for the cooperation between SREBPs and AR signaling in promoting prostate cancer progression. We observed that the SREBP expression is higher in LNCaP, C4,and C4-2 AR-positive/androgen-dependent compared to DU145, and PC3 AR-negative/androgen-independent prostate cancer cell lines. Therefore, we hypothesized that pharmacological targeting of SREBPs might be a promising therapeutic approach in hormone sensitive prostate cancer. We developed a novel boron-containing small molecule inhibitor of SREBPs, BF175, whose anticancer activity against prostate cancer has not been elucidated. In our study, we investigated the AR-dependent anticancer activity of BF175 in prostate cancer. We observed inhibition of viability, proliferation, and metastatic potential as well as induction of apoptosis in all prostate cancer cell lines treated with BF175. We also observed reduction in the levels of SREBPs in all prostate cancer cell lines treated with BF175. Notably, the anticancer action of BF175 was dependent on the AR status and BF175 demonstrated significantly more potent anticancer action in AR-positive/androgen-dependent compared to AR-negative/androgen-independent prostate cancer cell lines. Altogether, our data shows that BF175 may be a potential novel therapeutic agent for hormone sensitive prostate cancer.

#3059 Targeting tumor progression: The impact of SMR peptide and miRNA on exosome-inflammasome-EMT axis in breast cancer.

M. Huang[1], E. L. Johnson[1], L. Yang[2], J. Stiles[1], A. Uren[3], F. Yan[1], V. C. Bond[1];

[1]Morehouse School of Medicine, Atlanta, GA, [2]Emory University School of Medicine, Atlanta, GA, [3]Georgetown University, Washington, DC, WA

Background: In breast cancer, the interplay between exosomes, the inflammasome, and epithelial-mesenchymal transition (EMT) significantly influences tumor progression and metastasis. Exosomes carry molecules that affect cellular processes like inflammation and EMT. The inflammasome produces pro-inflammatory cytokines, promoting tumor-associated inflammation and stimulating EMT, which enhances cancer cell invasiveness. Exosomes also deliver miRNAs that modulate gene expression and promote EMT.
Objective: This study investigates the role of the secretion modification region (SMR) peptide in regulating interactions between exosomes, the inflammasome, and EMT in breast cancer, focusing on miRNA influence on gene expression.
Methods: MDA-MB-231 breast cancer cells were treated with tumor exosomes or exSMRwt. Exosomes were isolated and characterized using nanoparticle tracking analysis. Inflammasome activation was assessed by measuring caspase-1 and pro-inflammatory cytokines (IL-1β, IL-18). miRNA expression was evaluated using the nCounter Human miRNA assay.
Results: The SMR peptide suppressed MDA-MB-231 cell activity and inhibited exosome release, crucial for cancer progression. exSMRwt-treated cells showed reduced inflammasome activity and altered miRNA expression, with significant upregulation and downregulation of specific miRNAs. Nine miRNAs were identified as closely related to breast cancer progression, inhibiting cell proliferation, EMT, migration, invasion, and metastasis.
Conclusion: The SMR peptide is a promising therapeutic agent in breast cancer, targeting multiple pathways involved in tumor progression. It inhibits inflammasome activation, reduces pro-inflammatory cytokine production, and modulates exosome-mediated signaling. The peptide also influences miRNA regulation, suppressing inflammation and inhibiting tumor growth and metastasis. This study highlights the therapeutic potential of the SMR peptide and provides direction for further miRNA research in breast cancer.

#3060 The cyclopeptide enniatin a inhibits the chaperone hsp90 and induces mitophagy in breast cancer cells.

Vamsi Krishna Kommalapati[1], Asif Elahi[2], Nada M. Eisa[3], Michael A. Serwetnyk[4], Abdessamad Debbab[5], siva panda[6], Daniela Marasco[7], Brain Blagg[4], Ahmed Chadli[1]

[1]Biochemistry and Molecular Biology, Augusta University, Augusta, GA,[2]University of Alabama at Birmingham, Birmingham, AL,[3]Department of Biochemistry, Mansoura University, Mansoura, Egypt,[4]Department of Chemistry and Biochemistry, The University of Notre Dame, Notre Dame, IN,[5]Institute of Pharmaceutical Biology and Biotechnology, Heinrich-Heine-University Dusseldorf, Dusseldorf, Germany,[6]Chemistry and Biochemistry, Augusta University, Augusta, GA,[7]Department of Pharmacy, University of Naples Federico II, Naples, Italy

Heat shock protein 90 (Hsp90) is a molecular chaperone that plays a key role in protecting the proteome. In cancer cells, this Hsp90 function is hijacked to promote cancer cell proliferation. Except for the Pimitespib (TAS-116), approved for clinical use in Japan in 2022, no Hsp90 inhibitors have yet been approved by the FDA. One of the main side effects of the current Hsp90 inhibitors tested in the clinic is their induction of the heat shock response (HSR). Therefore, identifying new inhibitors that destabilize the oncoproteins clients of Hsp90 without inducing HSR is an attractive strategy to harness the clinical potential. We previously reported that the natural product Enniatin A (EnnA) is a novel Hsp90 inhibitor satisfying this criterion. Here, we report that EnnA potently induces mitophagy in breast cancer cells. The cytoplasmic form of Hsp90 has been shown to be more abundant in the mitochondria of tumor cells compared to mitochondria of normal tissues. We show that EnnA can enter multiple compartments of cancer cells, including the mitochondria, and inhibits Hsp90. Furthermore, we show that EnnA induces mitochondrial dynamics impairment as reflected by loss of mitochondrial membrane potential, reduced oxygen consumption rate, and loss of ATP production. We also show that targeting Hsp90 by EnnA reduced the level of cox4, a component of the electron transport chain, leading to parkin-mediated mitophagy. Our data indicate that EnnA represents a member of a new class of Hsp90 inhibitors that impair mitochondrial function in cancer cells and is a promising compound to treat breast cancer.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Novel Drug Resistance Mechanisms
Poster Session

#3064 The interaction of calcium-sensing receptor with KIF11 enhances cisplatin resistance in lung adenocarcinoma.

Fuhao Wang, Ming Chang, Xiao Zhang, Xiaoyi Li, Zhiying Chen, Wei Zhang, **Jian Zhang**

Southern University of Science and Technology (SUSTech Shenzhen), Shenzhen, China

Lung cancer remains the deadliest form of cancer globally, and non-small cell lung cancer (NSCLC) accounts for 80%-85%. Chemotherapy remains the foundational treatment for NSCLC, with platinum-based regimens serving as the primary first-line therapy for advanced stages of the disease. Cisplatin is a widely used platinum drug with strong broad-spectrum anticancer activity. However, the development of chemotherapy resistance frequently results in treatment failure. Consequently, further research into the mechanisms underlying tumor chemoresistance is crucial for enhancing our understanding of tumor cell biology. This research will aid in identifying new resistance-related genes and molecules, facilitate the development of novel chemotherapeutic agents, and improve treatment regimens. In this study, we first established two cisplatin-resistant lung adenocarcinoma cell lines, A549-DDP and H1299-DDP, by exposing them to escalating concentrations of cisplatin. Through transcriptome analysis and examination of the correlation between gene expression and the prognosis of lung adenocarcinoma patients treated with chemotherapy, we discovered that CaSR was significantly upregulated in cisplatin-resistant LUAD cells. Additionally, high expressions of CaSR were closely associated with poor prognosis in LUAD patients receiving chemotherapy. As a member of the Gprotein-coupled receptor (GPCR) family, the role of CaSR in tumor chemoresistance has been infrequently reported. To further investigate this, we generated LUAD cell lines with stable overexpression of CaSR and confirmed its essential role in cisplatin resistance. Meanwhile, we observed that CaSR knockdown significantly enhanced the sensitivity of cisplatin-resistant LUAD cells. Importantly, a combination of cisplatin with the CaSR inhibitor NPS-2143 significantly inhibited the growth of cisplatin-resistant LUAD cells *in vitro* and *in vivo*. Furthermore, CaSR was found to be involved in the cell cycle of cisplatin-resistant LUAD cells and affected the protein levels of BRCA1 and cyclin B1. Moreover, we have observed an interaction between CaSR and KIF11. In LUADcells, KIF11 was identified as a crucial hub within the CaSR signaling pathway, regulating the expression of cyclin B1 and BRCA1 and promoting cisplatin resistance. Our study highlighted the therapeutic potential of targeting CaSR to mitigate the chemotherapy resistance of LUAD. Furthermore, it explores a novel mechanism underlying chemoresistance in LUAD and provides essential experimental evidence, presenting the case as a promising therapeutic target for overcoming cisplatin resistance in clinical settings. This work was supported by the NSFC Project (82173336, 81972766,81972420), The Science and Technology Project of Shenzhen(JCYJ20210324104214040), the Medical Research Innovation Project (G030410001).

#3065 Tribbles 2 drives lineage maintenance and survival in neuroendocrine prostate cancer by regulating N-Myc stability.

Jitender Monga[1], Rohith Guddeti[1], Craig Rogers[1], Shirish Gadgeel[2], Dhananjay Chitale[3], Jagadananda Ghosh[1]

[1]Urology, Henry Ford Health, Detroit, MI,[2]Hematology & Oncology, Henry Ford Health, Detroit, MI,[3]Pathology, Henry Ford Health, Detroit, MI

Neuroendocrine prostate cancer (NEPC) is a highly aggressive and treatment-resistant subtype of prostate cancer, characterized by an increased propensity for visceral metastasis. As prostate cancer develops resistance to second-generation androgen receptor inhibitors, such as enzalutamide, many patients exhibit tumors with highly proliferative, metastatic cells that adopt neuroendocrine features. This form of treatment-emergent NEPC (t-NEPC) occurs in over 20% of cases, contrasting with the much rarer de novo NEPC, where neuroendocrine (NE) cells (~1%) within the prostate transform into malignant entities. The clinical management of NEPC is challenging due to a limited understanding of molecular targets that can selectively combat these rapidly growing and invasive cells. One intriguing target is the pseudokinase Tribbles 2 (TRIB2), which has been found to be overexpressed in both t-NEPC and de novo NEPC. Elevated TRIB2 expression is implicated in promoting neuroendocrine differentiation in prostate adenocarcinoma cells, facilitating their escape from androgen-dependence and contributing to resistance against AR inhibitors. Functionally, TRIB2 enhances tumor cell survival and proliferation by fostering the adoption of neuroendocrine traits, thereby accelerating disease progression. Inhibition of TRIB2, however, reverses neuroendocrine traits and restores sensitivity to anti-androgen therapies, indicating that TRIB2 plays a critical role in therapeutic resistance by driving cellular trans-differentiation. Despite this, the precise mechanisms by which TRIB2 contributes to the onset and maintenance of neuroendocrine features in prostate cancer remain unclear. Our studies using well-characterized NEPC tumors, and established NEPC cell lines have consistently shown that TRIB2 is closely associated with neuroendocrine phenotypes both *in vitro* and *in vivo*. Notably, TRIB2 appears to regulate these features by promoting the upregulation and stabilization of N-Myc, a key oncogene in neuroendocrine differentiation, through inhibition of its ubiquitination mediated proteasomal degradation. CRISPR-Cas9 mediated modulation of TRIB2 expression levels in NEPC cells and tumors results in corresponding changes in their neuroendocrine characteristics, reinforcing the notion that TRIB2 is a critical driver of NE trans-differentiation. These findings highlight TRIB2 as a novel regulator in the progression and maintenance of NEPC, with its effects likely mediated through downstream modulation of N-Myc activity.

#3066 Fumarylacetoacetate hydrolase (FAH) stimulates resistance to CDK4/6 inhibitors in hormone receptor-positive breast cancer via a novel non-canonical function.

Jenny Hogstrom[1], Boryana Petrova[2], Hanna Doh[1], Camila Perea[1], Su Min Hong[1], Nina Kozlova[1], Kayla Cruz[1], Conor L. Evans[3], Jonah Lee[1], John Clohessy[1], Gerburg Wulf[1], Laura Collins[1], Naama Kanarek[2], Taru Muranen[1]

[1]Beth Israel Deaconess Medical Center, Boston, MA,[2]Boston Children's Hospital, Boston, MA,[3]Massachusetts General Hospital, Boston, MA

Breast cancer is the most prevalent cancer among women worldwide with hormone receptor-positive (HR+) cancer constituting 70% of all breast cancers. HR+ breast cancer patients are usually treated with targeted therapies, which include hormone therapy, as well as CDK4/6- and PI3K-inhibitors. Unfortunately, the tumors usually become resistant over time. In addition to genetic drivers of resistance, metabolic perturbations and enhanced activity of metabolic enzymes can also contribute to tumor growth, resistance and poor survival. We have discovered that Fumarylacetoacetate hydrolase (FAH), the last enzyme in tyrosine catabolism pathway, is enriched in HR+ breast tumors and correlates with poor survival. By using HR+ patient-derived organoid cultures (PDOs), we show that FAH stimulates resistance to multiple standard-of-care therapies. Despite its canonical function in tyrosine catabolism, FAH overexpressing cells do not preferentially utilize the tyrosine catabolism pathway. Instead, we surprisingly observe increased nuclear localization of FAH in patients treated with endocrine therapy and/or CDK4/6-inhibitors. Similarly, ER degraders and CDK4/6-inhibitors increase the ratio of nuclear FAH in patient-derived organoids, suggesting that the nuclear localization could drive resistance. To investigate this, we cloned a nuclear localization signal (NLS) to FAH and observed that FAH-NLS expressing PDOs were more resistant to CDK4/6-inhibitors. In contrast, blocking the nuclear translocation reversed the FAH-mediated resistance, showing that the nuclear localization is essential for the resistance phenotype. Collectively this suggests a yet uncharacterized moonlighting function of FAH in the nucleus and links this metabolic enzyme to treatment resistance in HR+ breast cancer.

#3067 The long non-coding RNA CDH3-AS1 facilitates gemcitabine resistance and lung metastasis via TGFβ activation in pancreatic ductal adenocarcinoma.

M. Yang[1], R. Wang[1], H. Sun[1], M. Dong[2], **Q. Chen**[1];

[1]University of Macau, Taipa, Macao, [2]Guangzhou Laboratory, Guangzhou, China

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal malignancies, with chemotherapy serving as the primary treatment for PDAC when surgery is not feasible. Gemcitabine is commonly used as the first-line chemotherapeutic agent in PDAC treatment, yet resistance to gemcitabine frequently emerges, necessitating the development of novel strategies to improve its efficacy. In our study, we established a gemcitabine resistant PDAC cell model through an evolutionary process involving gradually increasing gemcitabine concentrations. RNA-Seq analysis revealed significant upregulation of extracellular matrix (ECM) signaling in resistant cells. ECM dysregulation impeded gemcitabine uptake, leading to resistance. In addition, resistant cells showed reduced proliferation compared to parental cells, further exacerbating resistance. Mechanically, we found enhanced activation of the transforming growth factor β (TGFβ) pathway in resistant cells, resulting in increased expression of ECM-related genes and cyclin kinase Inhibitor p57. Moreover, we found that the long non-coding RNA (LncRNA) CDH3-AS1, the antisense of CDH3, was significantly upregulated in resistant cells and exhibited a positive correlation with ECM signaling in SMAD4 mutant PDAC, suggesting its role as a regulator of TGFβ signaling. Disrupting CDH3-AS1 impaired TGFβ activation in resistant cells by inhibiting TGFBR1 and SMAD4, thereby reversing gemcitabine resistance. Interestingly, CDH3-AS1 also regulated the expression of CDH3 in resistant cells, promoting lung metastasis through mediating epithelial-to-mesenchymal transition (EMT). The study reveals CDH3-AS1 as a novel regulator of TGFβ activation that contributes to PDAC progression, providing a new potential therapeutic target for the treatment of this aggressive cancer.

#3068 The clonal nature of FGFR3-TACC3 in glioma: Mechanism discovery and preclinical study.

Y. Li[1], T. Li[1], X. Ren[1], J. Liang[2], J. Fan[1], X. Wang[2], S. Yu[1], W. Zhang[3], X. Yang[2];

[1]Tianjin Medical University General Hospital, Tianjin, China, [2]Beijing Tsinghua Changgung Hospital, Beijing, China, [3]Wake Forest School of Medicine, Winston-Salem, NC

During the course of treatment, tumor cells can undergo a Darwinian process of clonal evolution, where resistant cell clones emerge, proliferate and replace more vulnerable ones, ultimately leading to increased treatment resistance. Numerous oncogenic fusion genes have recently been identified in gliomas, promoting malignant transformation and serving as potential therapeutic targets. Among these, the FGFR3-TACC3 (F3-T3) fusion gene was initially detected in glioblastoma multiforme (GBM), with its fusion protein comprising primarily FGFR3 structural domains and a smaller portion of TACC3. F3-T3 fusions are consistently expressed in both untreated and recurrent tumors, confirming the clonal persistence of these fusion events. Our previous study implicated F3-T3 in chemotherapy resistance in GBM, though the underlying mechanism remained unclear. In this study, we further investigate the clonal nature and functional role of F3-T3 in GBM cells. Through bioinformatics data mining, we discovered that F3-T3 functionally enriches DNA repair pathways, as shown by Gene Set Enrichment Analysis (GSEA). Experimental results demonstrated that GBM cells harboring F3-T3 maintain their proliferation, invasion and migration capabilities under temozolomide (TMZ) treatment. Subsequent RNA sequencing revealed activation of the PI3K-AKT signaling pathway in F3-T3 GBM cells under TMZ conditions. Further analysis identified PKM2 as a downstream substrate of the F3-T3 protein, linking it to the DNA damage response. Experimental evidence highlights the critical role of the F3-T3/PI3K-AKT/PKM2 axis in mediating chemoresistance in F3-T3 GBM. Importantly, our preclinical models demonstrated synergistic efficacy when combining TMZ with either FGFR or PI3K inhibitors in F3-T3 GBM. In summary, our findings underscore the significance of the F3-T3/PI3K-AKT/PKM2 axis in driving chemotherapy resistance in F3-T3 GBM and present a potential therapeutic strategy for gliomas with F3-T3 fusions, providing empirical support for future fusion gene-targeted investigations.

#3069 Inhibition of PGE2 signaling by an EP2/4 dual antagonist OCT-598 prevents acquisition of therapy-resistance and tumor relapse.

Y. Lee[1], H. Choi[1], J.-W. Lim[1], S. Lee[2], Y. Kim[2], C. Choi[2], T. Yoon[1];

[1]OSCOTEC Inc., Seongnam, Korea, Republic of, [2]Samsung Medical Center, Seoul, Korea, Republic of

Conventional antitumor drug discovery focuses primarily on selective killing of cancer cells. However, more often than not, cancer cells become resistant to the therapy and tumors eventually relapse in a more malignant form, potentially even accelerating disease progression afterwards. Therefore, it is of paramount importance to curtail the process by which cancer cells adapt to the therapeutic pressure to re-invent themselves and regenerate. Prostaglandin E2 (PGE2) is widely recognized as an important mediator of wound healing and tissue regeneration after injury by orchestrating reparative immune responses and mobilizing tissue stem cells. Likewise, in cancer, the PGE2 pathway has been shown to promote tumor growth, immune evasion, angiogenesis, and cancer stem cell (CSC) survival. Thus, upon cytotoxic insults, the apoptotic signal in dying cells induces PGE2 production, which enables, in a paracrine manner, the surviving cells to persist and eventually repopulate. Therefore, blockade of the PGE2 signals concurrently with cell-killing is anticipated to prevent tumors from acquiring therapy resistance. Of the known PGE2 receptors EP1-4, EP2 and EP4 are best known to convey its pro-tumor and immune-evasive signals. OCT-598 is a potent and selective dual antagonist of EP2 and EP4 with Ki values of 23 nM and 0.2 nM vs EP2 and EP4, respectively. OCT-598 has been shown previously to elicit complete regression in a mouse syngeneic TC-1 tumor model when used in conjunction with the standard of care chemo-immunotherapy regimen (Abstract 3234, AACR 2023). In this study, we present “anti-resistance” activities of OCT-598. In vitro, chemotherapy-induced cell deaths are followed by a dormant period, where the ‘un-dead’ cells show enlarged morphology and hyperploidy, and subsequently by repopulation of smaller, proliferative para-diploid cells. Addition of OCT-598 along with the chemotherapeutic agent decreased the number of the transient, enlarged cells and inhibited eventual repopulation in a dose-dependent manner. In vivo, OCT-598 abrogated tumor relapse after irradiation in CT26 mouse syngeneic tumor model, leading to complete remissions. Based on these observations, a clinical trial is set to be initiated to test the “anti-resistance” activity of OCT-598 as an adjuvant to the standard-of-care treatment in patients with advanced solid tumors.

#3070 Cytomegalovirus infection enhances spheroid formation and drives aggressive phenotype in glioblastoma via upregulation of SOX2 pRB pAKT and STAT3/IL-6 signaling.

Vida Tajiknia[1], Noe Mercado[1], Jacquelin Real[1], Eain Murphy[2], Sean Lawler[1]

[1]Legorreta Cancer Center at Brown University, Providence, RI,[2]Upstate Medical University, Syracuse, NY

Background: Cytomegalovirus (CMV) infection has been implicated in glioblastoma (GBM) progression, with effects on stemness, immune evasion, and angiogenesis. Our work investigates the impact of CMV infection on spheroid formation, oncogenic pathways including SOX2, retinoblastoma protein (pRB), phospho-AKT (pAKT), and STAT3/IL-6 signaling, as well as cytokine modulation. Additionally, we evaluate the therapeutic potential of ganciclovir in reversing CMV-induced effects.
Methods: GBM cell lines LN229, U251, U87, U138, and T98G were infected with the GFP-expressing CMV TB40 strain at a multiplicity of infection (MOI) of 0.5. Infection was confirmed via fluorescence microscopy and Western blotting for CMV pp65 protein. The stable cell line with infection was confirmed after multiple passage and presence of CMV protein. Spheroid formation assays assessed morphological changes and aggressiveness in vitro. Western blotting analyzed the expression of SOX2, pRB, pAKT, and phospho-STAT3 (pSTAT3), while cytokine profiles, including PD-L1, VEGF, angiopoietin-2, and IL-6, were measured in non-infected, infected, and ganciclovir-treated cells using Luminex panel.
Results: CMV infection was confirmed in all GBM cell lines, with infection rates ranging from 60% to 90%. CMV-infected cells exhibited accelerated and more aggressive spheroid formation compared to non-infected cells. Infection led to upregulation of SOX2, pRB, pAKT, and pSTAT3, accompanied by elevated IL-6, indicating enhanced stemness, proliferation, and pro-inflammatory signaling. Cytokine profiling revealed significant increases in PD-L1and angiopoietin-2 with decrease in soluble VEGF levels following infection and treatment with Gancylovir, reflecting immune suppression and angiogenesis. Ganciclovir treatment modulate pro-tumorigenic cytokines, creating a more favorable tumor microenvironment.
Conclusions: CMV infection accelerates spheroid formation and enhances the aggressive phenotype in GBM via upregulation of SOX2, pRB, pAKT, and STAT3/IL-6 signaling, alongside immune evasion and angiogenic cytokine shifts. Our data suggest the therapeutic potential of targeting CMV and its downstream pathways in GBM. These findings highlight the critical role of CMV in GBM pathogenesis and its promise as a therapeutic target.

#3071 Improving the docetaxel-based chemotherapy in therapy resistance prostate cancer.

Md Rakibul Alam, Amos Olalekan Akinyemi, Jianlin Wang, Mithu Howlader, Lixiang Gu, Zhiguo Li

Toxicology and Cancer Biology, University of Kentucky, Lexington, KY

Prostate cancer is known to have a relatively good prognosis, but long-term hormone therapy can lead to castration-resistant prostate cancer (CRPC). Docetaxel, a third-generation chemotherapy drug based on inhibiting depolymerization of microtubules, provide excellent initial response in patients for the CRPC treatment. Despite the improved survival duration and reduction of tumor size observed in some patients, many have no response to the drugs or develop resistance over time. In this study, to elucidate the molecular basis of docetaxel resistance, we established docetaxel resistance prostate cancer PC3-TR, C4-2-TR and DU-145-TR cell lines, which exhibited higher LD_{50} and lower drug uptake against docetaxel than parental PC3, C4-2 and DU-145 cell lines. We employed quantitative high throughput screen with a collection of 2500 FDA approved drugs to identify drugs that can enhance the docetaxel sensitivity of docetaxel resistance cell lines. ML385 has been identified as a potent NF-E2 related factor-2 (Nrf2) synthetic inhibitor, and its treatment of docetaxel resistance cells significantly suppressed the Nrf2 signaling by decreasing the cytosolic and nuclear Nrf2 levels. In addition, docetaxel resistance cell lines showed marked increases in nuclear accumulation of Nrf2 compared to parental cell lines, suggesting that Nrf2 signaling is homeostatically activated in docetaxel resistance cell lines. Here we identified that silencing of Nrf2, docetaxel sensitivity of resistance cell lines was increased, and that of parental cell lines were reduced by activation of Nrf2. Combination treatment of ML385 with docetaxel induced cell death in docetaxel resistance cell lines. Together, these results provide new insight in the understanding of docetaxel resistance and direct a therapeutic approach to overcome docetaxel resistance in CRPC treatment.

#3072 Novel approach to target trastuzumab resistant, HER2+ breast cancer: Activation of PKCdelta.

Maria Mejia[1], Debra Wyatt[2], Mitchell F. Denning[2], Kelvin Billingsley[3], **Clodia Osipo**[2]

[1]Biochemistry and Molecular Program, Loyola University Chicago, Maywood, IL,[2]Cancer Biology, Cardinal Bernardin Cancer Center, Loyola University Chicago, Maywood, IL,[3]Chemistry and Biochemistry, Loyola University Chicago, Maywood, IL

The ERBB2/HER2 oncogene is amplified in 15% of breast cancers leading to overexpression of the HER2 protein. Trastuzumab based therapy has improved survival outcomes for patients with localized and regional HER2+ tumors. However, the prognosis for patients with HER2+ metastatic breast cancer remains poor, with survival rates as low as 30%. Resistance to anti-HER2 targeted therapy is a key factor contributing to disease progression. Previously, we showed that Notch1 is a driver of trastuzumab resistance and PKCα attenuates Notch signaling to prevent resistance. There are many isoforms of PKC in breast cancer cells. This study investigated the contributions of at least 6 PKC isoforms in the context of trastuzumab sensitive and resistant breast cancer cell lines (isogenic BT474 sensitive and resistant and de novo resistant HCC1954). PKCδ mRNA and protein were expressed higher than any other PKC isoform and further increased in resistant compared to sensitive cells. The activity of PKCs overall was less in resistant compared to sensitive cells. Exogeneous addition of TPA activated PKC and potently inhibited proliferation, cell cycle progression, and mammosphere formation only in resistant cells and not in isogenic sensitive cells. Knockdown of PKCδ rescued these growth phenotypes, suggesting that TPA-mediated activation of PKCδ was sufficient to inhibit growth of trastuzumab resistant cells lines. Based on these encouraging findings, we tested other PKC modulators to identify potentially safer alternatives to TPA. Among the seven compounds (TPPB, Prostratin, iPr-ILV, Ac-ILV, 1,2-dioctanoyl-sn-glycerol, 1-oleoyl-2-acetyl-sn-glycerol and Bryostatin) screened for growth phenotypes of HCC1954 and BT474 resistant cell lines, TPPB was as potent as TPA (IC50=14nM TPPB vs. 0.45nM TPA). TPPB-mediated growth inhibition was dependent on PKCδ as knocked down of PKCδ using an RNAi approach almost completely rescued the inhibition of growth. An RNA sequencing approach was used to determine the mechanism by which TPA-mediated activation of PKCδ inhibits proliferation and cancer stem cell survival of trastuzumab resistant breast cancer cell lines. The most significant pathway activated by TPA was the TNFα- NFKβ pathway, suggesting that the mechanism by which activated PKCδ inhibits growth of trastuzumab resistant breast cancer could be through activation of a pro-inflammatory signaling cascade. In particular, the S100 family of cytokines were significantly upregulated by TPA, and their expression was reversed by PKCδ knockdown. These results suggest that even though TPA has been shown to be an effective agent to activate PKCδ, TPPB could possibly be a safer alternative. Future studies will determine mechanisms by which activating PKCδ selectively inhibits growth of trastuzumab resistant breast cancer *in vivo* and if PKCδ is a novel vulnerability for trastuzumab resistant disease.

#3073 Metabolic dependency on de novo pyrimidine synthesis in platinum resistant ovarian cancer.

H. Cardenas, G. Zhao, A. M. Isac, **D. E. Matei**;
Northwestern University - Chicago, Chicago, IL

Background: High grade serous ovarian cancer (OC) is lethal due to near universal development of resistance to platinum-based chemotherapy.
Materials and Methods: We used cisplatin resistant (Cis-R) cells generated by repeated cisplatin treatment of sensitive (Cis-S) OC cell lines, transcriptomic and metabolomic analyses to identify key metabolic pathways associated with platinum resistance. In vivo experiments used intraperitoneal (ip) OC xenografts and patient derived xenografts (PDX).
Results: Pathway analysis of differentially abundant metabolites in Cis-R vs. Cis-S OVCAR5 and COV362 cells identified enrichment of pyrimidine metabolism (FDR<0.05) related to increased de novo pyrimidine synthesis. 15N-glutamine flux analysis confirmed increased de novo pyrimidine synthesis in Cis-R cells. Inhibition of this pathway using the DHODH inhibitor brequinar (BRQ) decreased cell viability and induced expression changes in genes of the mitochondrial electron transport in Cis-R compared with Cis-S cells. Oxygen consumption rate (OCR) measured with a Seahorse assay indicated lower (P<0.05) OCR (baseline, ATP-related, and maximal) and spare respiratory capacity (SRC) in Cis-R vs. Cis-S OVCAR5 cells. BRQ induced dose-related inhibition of OCR in both Cis-R and Cis-S cells. SRC was inhibited by BRQ only in Cis-R cells. In vivo, BRQ attenuated growth of ip Cis-R OC xenografts but did not alter Cis-S tumors. Tumor growth was also inhibited (p<0.01) by BRQ in a Cis-R PDX model. BRQ plus carboplatin enhanced (p<0.05) the inhibitory effects of carboplatin alone in ip Cis-R OC xenografts.
Conclusions: Our results support that Cis-R cells acquire dependency on the de novo pyrimidine synthesis and maintain relatively low levels of mitochondrial oxidation, rendering Cis-R cells and tumors vulnerable to inhibitors of this pathway.

#3074 Sorafenib resistance and cholesterol metabolism in hepatocellular carcinoma.

Veerababu Nagati, Dennis Kwabiah, Yamile Abuchard Anaya, Manish K. Tripathi

Medicine and Oncology ISU, University of Texas Rio Grande Valley, McAllen, TX

Hepatocellular carcinoma (HCC) is among the most prevalent cancers and a leading cause of cancer-related deaths worldwide. Sorafenib, a multikinase inhibitor, serves as a key first-line treatment for HCC when surgical intervention is not an option. However, primary and acquired resistance to sorafenib has significantly limited its effectiveness, reducing the disease control rate. Dysregulation of numerous genes that influence cancer cell proliferation, survival, and drug resistance contributes to this challenge. Identifying the molecular drivers of sorafenib resistance remains critical to improving treatment outcomes. Several factors, including activation of oncogenic pathways (e.g., Akt/mTOR), hypoxia, cholesterol metabolism, multidrug resistance, and autophagy, play pivotal roles in driving resistance. RNA/DNA binding proteins, such as Y-box binding protein 1 (YBX1), are central to cancer progression, metastasis, and drug resistance. Elevated YBX1 expression correlates with poor prognosis in HCC. Our preliminary data indicate that YBX1 overexpression enhances oncogenic phenotypes such as proliferation, migration, and colony formation. Additionally, it upregulates oncogenic markers like CD44, PDL1, SNAIL, and TWIST, further promoting HCC progression. Conversely, YBX1 inhibition increases sensitivity to sorafenib, as evidenced by the downregulation of drug resistance markers in HCC cell lines. Kinases also play a critical role in drug resistance, and activation of Akt/mTOR-associated genes was observed in YBX1 overexpression models. Moreover, cholesterol metabolism pathways appear to be significantly impacted by YBX1. Specifically, sterol regulatory element-binding transcription factors (SREBF1 and SREBF2) and downstream lipid metabolism genes, such as COL1A1, are positively correlated with YBX1 expression and are activated in HepG2 and Huh7 sorafenib-resistant cells. Notably, YBX1 knockdown reversed the effects of SREBF2-associated lipid metabolism genes, reducing their role in drug resistance. Collectively, these findings suggest that YBX1 contributes to sorafenib resistance in HCC through cholesterol metabolism and oncogenic signaling. This research highlights YBX1 as a potential therapeutic target, with the promise of sensitizing sorafenib-resistant HCC cells and improving treatment outcomes.

#3075 Targeting endoplasmic reticulum stress pathways to combat enzalutamide resistance in prostate cancer.

A. O. Akinyemi, M. Alam, M. Howlader, J. Wang, L. Gu, X. Liu, Z. Li;
University of Kentucky, Lexington, KY

Prostate cancer (PCa) is a significant public health issue, ranking as the second leading cause of cancer-related death in men in the United States, with projections for 2024 estimating 299,101 new cases and 35,250 deaths. A critical driver of PCa progression, the androgen receptor (AR) signaling pathway remains a major therapeutic target, particularly in castration-resistant prostate cancer (CRPC). Although AR-targeted therapies such as abiraterone and enzalutamide were developed to delay the need for chemotherapy, they provide only modest survival benefits of approximately five and two months, respectively, emphasizing the need for more effective strategies. This research investigates a resistance mechanism in CRPC mediated by a kinase-driven phosphorylation of GRP78, a key chaperone protein that aids in cellular survival independent of conventional AR signaling pathways. In this study, we examine how this phosphorylation of GRP78 triggers post-translational modifications that support CRPC cell survival under AR-targeted therapy. Using both in vitro and in vivo approaches, we characterize this adaptive resistance pathway. In vitro assays using CRPC cell lines include RNA sequencing (RNA-Seq) for transcriptomic profiling, cell viability assays, proteasome activity measurements, and Western blot analysis to evaluate protein expression changes. Confocal microscopy and flow cytometry are employed to assess cellular responses, while kinase assays and mass spectrometry elucidate specific GRP78 modifications. Chromatin immunoprecipitation sequencing (ChIP-Seq) further investigates the impact of GRP78 modification on AR's genomic binding. In vivo, CRPC xenograft models are treated with enzalutamide, allowing us to assess tumor progression and validate cellular findings via immunohistochemistry (IHC) and RNA-Seq analysis. Preliminary data indicate that phosphorylation-induced modifications of GRP78 enhance CRPC cell resilience under AR inhibition, supporting a proteostasis mechanism that counters therapeutic pressure. Targeting this adaptive response pathway may offer a novel strategy to disrupt resistance and improve the effectiveness of AR-directed therapies in advanced CRPC. By advancing insights into the cellular reprogramming associated with AR resistance, this work contributes to identifying new therapeutic targets for enhanced PCa management.

#3076 A niche driven mechanism determines response to ATRA and a mutation-independent therapeutic approach forMDS and AML.

Ioanna Mosialou[1], Abdullah M. Ali[1], Alvaro Cuesta-Dominguez[1], Brian Chernak[1], Marta Galan-Diez[1], Mael Heiblig[2], Ellin Berman[3], Joseph G. Jurcic[1], Steven Kornblau[4], Guiliermo-Garcia Manero[4], Azra Raza[1], Stavroula Kousteni[1]

[1]Columbia University Irving Medical Center, New York, NY,[2]Centre Hospitalier Lyon Sud, Lyon, France,[3]Memorial Sloan-Kettering Cancer Center, New York, NY,[4]MD Anderson Cancer Center, Houston, TX

Myeloid cancers remain resistant to standard of care (SOC) and targeted therapies. An oncogenic signal from the niche, constitutive activation of β-catenin/JAG1 signaling in osteoblastic cells (osb-β-catenin), leads to myelodysplasia (MDS) and acute myeloid leukemia (AML) and occurs in ~40% of MDS and AML patients and patients with del(5q)-associated myeloid malignancies. We show that its levels increase with disease severity and correlate with MDS to AML transformation and a worse overall survival. Searching for regimens that block osb-β-catenin activity we identified all-*trans*-retinoic acid (ATRA), a regimen with disparate results in MDS and AML. By analyzing publicly available RNA-seq data and bone marrow biopsies collected from 14 ATRA-treated patients from four different study sites we found a strong association between inhibition of osb-β-catenin activity and/or Notch signaling in AML cells with ATRA, leading to AML improvement. An overall response rate of 100% was reached in patients with active baseline osb-β-catenin, as compared to 22% among patients without this pathway active. Responsiveness was observed across patients with diverse cytogenetic and mutational profiles belonging even to adverse risk groups. Improvement occurred despite a diverse ATRA dosing schedule in combination with other therapeutic agents (AZA, VEN, VPA). Indeed, whereas there was no association between response and the degree of global DNA hypomethylation or histone acetylation among patients treated in combination with AZA/VPA, we observed high association of treatment response with baseline osb-β-catenin activity (p=0.021). Moreover, first-line AZA/VEN treatment of an AML patient resulted in relapse and CR was reached only upon ATRA addition to AZA/VEN backbone. Supporting this conclusion, treatment with ATRA monotherapy of an MDS patient with high levels of active osb-β-catenin improved disease status and was associated with complete inhibition of osb-β-catenin activity and a parallel decrease in Notch signaling in the patient's MDS cells. The patient remained transfusion independent for at least 9 years. Mechanistically, ATRA-mediated inhibition of osb-β-catenin activity suppressed cell growth and survival and promoted differentiation of MDS/AML cells solely from patients with active osb-β-catenin without toxicity in healthy cells. Confirming findings in patient samples, ATRA administration in leukemic mice suppressed osb-β-catenin signaling thus improving disease outcome and prolonging survival by at least six-fold with no evidence of relapse and a superior safety profile to SOC. These results suggest that responsiveness to ATRA may be predicted by measuring activation of β-catenin in osteoblasts. Thus, repurposing ATRA use for the treatment of this specific group of patients may significantly improve disease outcome.

#3077 Pharmacological inhibition of NUAK1 and NUAK2 synergizes with chemotherapy in pancreatic cancer models by abrogating drug resistance and suppressing fibrosis.

Minji Seo, Jihye Yoon, Song-Eun Park, Jong-Won Lim, Sungho Park, Yuntae Kim, **Taeyoung Yoon**

OSCOTEC Inc., Seongnam-si, Korea, Republic of

Pancreatic ductal adenocarcinoma (PDAC) is one of the most aggressive and treatment-resistance cancers with a 5-year survival rates of around 10%. Since most PDAC cases are diagnosed at an advanced stage, current treatment options are essentially limited to chemotherapy, which is unfortunately barely effective. Therefore, the development of new, innovative therapies is desperately needed. PDAC is characterized by its desmoplastic nature and exceptionally high recurrence rates, both of which are also known to be furthered by chemotherapy. It is hypothesized that therapy-induced cell death exacerbates fibrosis and paradoxically facilitates resistance development. Therefore, concurrent inhibition of these pathways alongside cytotoxic therapy may enhance treatment outcomes in PDAC patients. NUAK family kinase1 and 2 are members of AMP-related kinase family, known to be implicated in cancer progression, cell adhesion, cell proliferation and metastasis. Elevated NUAK1/2 expression correlates with poor prognosis and patient survival rate in many cancer types including pancreatic cancer. Recently, it was also shown that NUAK1 inhibition by genetic knockdown or a chemical inhibitor reduced organ fibrosis via Hippo pathway modulation in mouse models. In this study, we demonstrate anti-chemoresistance and anti-fibrotic activities of P4899, a potent and selective NUAK1/2 dual inhibitor, in pancreatic cancer. Treatment of pancreatic cell lines with chemotherapeutic agents such as gemcitabine and cisplatin initially causes massive cell death, but the surviving cells undergo hyperploidy that eventually leads to repopulation of para-diploid cells, mimicking chemoresistance and tumor recurrence. In the presence of P4899, however, the number of the transient hyperploid cells as well as ensuing repopulation was dramatically reduced. Furthermore, administration of the orally bioavailable NUAK1/2 inhibitor in combination with gemcitabine in a mouse orthotopic PDAC model resulted in significant inhibition of tumor growth as well as reduction of collagen deposition and expression levels of fibrotic genes in tumor tissue. These data suggest that NUAK1/2 inhibition can effectively ameliorate desmoplasia and impede the development of chemo-resistance in pancreatic tumors, which warrants further investigation in the clinical setting.

#3078 Targeting a ROS-induced oxidation and O-GlcNAcylation cascade to overcome drug resistance across multiple cancer types.

Juanjuan Li[1], Huadong Pei[2], Feng Yao[1], Hemeng Zhang[3], Junfeng Ma[2]

[1]Renmin Hospital of Wuhan University, Wuhan, China,[2]Georgetown University Medical Center, Washington, DC,[3]The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China

Reactive oxygen species (ROS) are critical in lipid peroxidation and the initiation of ferroptosis, which significantly impacts chemotherapeutic drug resistance. However, the mechanisms by which ROS function and are sensed remain poorly understood. In this study, we identified that *O*-GlcNAc transferase (OGT), a key enzyme for protein *O*-GlcNAcylation, acts as a sensor for ROS induced by ferroptosis. The ROS-induced oxidation of OGT at C845 in its catalytic domain activates OGT. Once activated, OGT *O*-GlcNAcylates FOXK2, which enhances its interaction with importin α, promoting its nuclear translocation and subsequent transcription of SLC7A11, thereby inhibiting ferroptosis. Moreover, ferroptosis-induced activation of the ATM-CHK2 pathway and subsequent phosphorylation of FOXK2 further boost FOXK2 *O*-GlcNAcylation and SLC7A11 transcription. Clinically, the elevated OGT-FOXK2-SLC7A11 axis drives tumorigenesis and promotes resistance to chemoradiotherapy across various cancer types, including hepatocellular carcinoma (HCC). Our study uncovers a ROS-induced oxidation-O-GlcNAcylation cascade specific to ferroptosis, which integrates ROS signaling, O-GlcNAcylation, FOXK2-mediated SLC7A11 transcription, and chemoradiotherapy resistance. Targeting this cascade represents a promising approach to overcoming drug resistance in multiple cancer types.

#3079 Uncovering novel molecular mechanisms of PI resistance in multiple myeloma through multi-omics analysis.

Seungbin Han[1], Chien-Yun Lee[2], Lenka Besse[3], Umair Munawar[1], Shilpa Kurian[1], Andrej Besse[3], Ann-Sohpie Hainold[1], Silvia Nerreter[1], Cornelia Vogt[1], Johanna Thurner[2], Nina Rein[1], Max Koppel[1], Xiang Zhou[1], Larissa Haertle[1], Christoph Driessen[4], Hermann Einsele[1], Leo Rasche[1], Ondrej Slaby[3], Johannes Waldschmidt[1], Bernhard Kuster[2], Klaus Martin Kortum[1]

[1]Internal Medicine II, University Hospital Wurzburg, Wurzburg, Germany,[2]Technical University of Munich, Munich, Germany,[3]Masaryk University, Brno, Czech Republic,[4]Cantonal Hospital St. Gallen, St. Gallen, Switzerland

Background: Even with considerable advancements in multiple myeloma (MM) therapy, proteasome inhibitors (PIs) continue to be an indispensable treatment pillar in MM. However, the development of PI resistance remains a significant clinical challenge. Previous studies proposed different causes contributing to PI-resistance, though, these mechanisms explain only a subset of PI resistance cases. Hence, we employed a multi-omics approach to identify further molecular pathways underlying PI resistance in MM.
Methods: We applied proteomic analysis on PI-naïve parental cell line models and their Bortezomib (BTZ) and Carfilzomib (CFZ) resistant derivatives. RNA-sequencing data and the clinical outcome of MM patients were obtained from CoMMpass to derive the impact of differentially expressed proteins. Identified candidate protein was then overexpressed in MM cell line models and the drug sensitivity changes was measured through Alamarblue.
Results: Proteomic screening identified 14 significantly upregulated proteins in CFZ-resistant cells and 9 overexpressed proteins in BTZ-resistant cells. NQO1 was notably overexpressed in both CFZres and BTZres models, confirmed by Western blot and qPCR. To investigate the functional impact of NQO1 on PI sensitivity, we generated NQO1-overexpressing cell lines and assessed their response to BTZ and CFZ. These engineered cell lines exhibited increased IC50 values for both BTZ and CFZ compared to their parental wild-type counterparts, indicating that NQO1 overexpression confers resistance to proteasome inhibition. To validate the clinical relevance of NQO1 expression, we analyzed its impact on progression-free survival (PFS) in MM patients. Specifically, we compared PFS in patients with high NQO1 levels vs. normal/low level, in a subcohort of the CoMMpass dataset (n=409) receiving PI-based first-line therapy. Remarkably, Patients with high NQO1 expression demonstrated significantly shorter PFS (median: 582 days, $p < 0.0001$) compared to those with normal/low NQO1 levels (median: 1032 days). This adverse prognostic impact was comparable to or even worse than that observed in high-risk myeloma patients with del(17p) (median: 630 days). Importantly, this effect appeared specific to PI-based therapy, as no significant PFS difference was observed between high and normal/low NQO1 expressers in a separate cohort (n=79) receiving PI-free first-line treatment (median PFS: 844 days vs. 1096 days, $p = 0.6756$).
Conclusions: In summary, we identified NQO1 overexpression as a mechanism of proteasome inhibitor resistance in multiple myeloma. Overexpression of NQO1 *in vitro* confirmed its impact on PI sensitivity, increasing resistance to both BTZ and CFZ. Clinically, high NQO1 expression correlated with significantly shorter PFS in patients receiving PI-based therapy, proposing NQO1 as a functional mediator of PI resistance in MM.

#3080 PKM2 inhibition overcomes lapatinib resistance in HER2 overexpressing esophageal adenocarcinoma.

Annie Ritter[1], Md Sazzad Hassan[2], Elizabeth Heffernan[1], Niranjan Awasthi[2], Urs von Holzen[2]

[1]University of Notre Dame, South Bend, IN,[2]Indiana University School of Medicine (South Bend, IN), South Bend, IN

Background: The human epidermal growth factor receptor 2 (HER2) is overexpressed in esophageal adenocarcinoma (EAC) and is a major target for EAC therapies. Lapatinib blocking HER1 and HER2 pathways, fails to improve patient survival. The molecular mechanisms of this lapatinib resistance are still unclear. We therefore explored the role of the glycolytic enzyme pyruvate kinase M2 (PKM2), a key regulator of the Warburg effect, in the lapatinib resistance mechanism of EAC cells.
Methods: HER2/pHER2 expression status was evaluated by Western blot analysis in a panel of EAC cell lines (Flo-1, ESO26, OE19, OE33, SK-GT-2, ESO51, OACM5.1C, and LPR-OE19). The lapatinib-resistant OE19 (LPR-OE19) cell line was established from the OE19 cell line by intermittent exposure to increasing concentrations of lapatinib for a period over six months. We investigated the cell growth/migration inhibition and apoptotic signaling effects of treating HER2-overexpressing OE19, LPR-OE19, and OE33 cell lines with lapatinib, PKM2 inhibitor shikonin, and a chemotherapeutic agent nanoparticle albumin-bound paclitaxel (nab-paclitaxel) either alone or in combinations. Lactate production and cellular localization of PKM2/HSP40 were also detected. In addition, we explored the in-vivo antitumor efficacy following lapatinib, shikonin, and nap-paclitaxel mono and combination therapies in murine subcutaneous cell lines and patient-derived xenograft models of human EAC.
Results: LPR-OE19 cells showed significantly reduced sensitivity to lapatinib-induced cell growth/migration inhibition and apoptosis compared to parent OE19 cells. Augmented cell growth/migration inhibition and apoptosis were observed in LPR-OE19 cells compared to parent OE19 cells when lapatinib was combined with shikonin. Knockdown of PKM2 in LPR-OE19 cells abolished the reduced sensitivity of lapatinib-induced cell growth inhibition and abolished the augmented cell growth inhibition response when lapatinib and shikonin were combined. Knockdown of HSP40 in OE19 cells enhanced PKM2 expression. LPR-OE19 cells showed enhanced lactate production compared to parent OE19 cells. PKM2 and HSP40 co-localize with each other in the cell nucleus, suggesting that PKM2 bound to molecular chaperone HSP40. In subcutaneous xenografts, shikonin displayed a remarkable tumor regression compared to that of control as monotherapy, and shikonin in combination with either lapatinib or nab-paclitaxel showed a significant enhancement effect of tumor regression.
Conclusions: These data suggest that combination therapy of the PKM2 inhibitor shikonin with lapatinib or nab-paclitaxel should be tested as a potent option for lapatinib-resistant HER2-positive EAC patients and could be a novel treatment strategy for specific EAC. In addition, we suggest targeting HSP40-PKM2 interaction as an innovative therapeutic approach to overcome lapatinib resistance in EAC.

#3081 The multiciliated transcription factor FOXJ1 modulates microtubule dynamics and mediates taxane resistance in prostate cancer.

Ada Gjyrezi[1], Fang Xie[2], Daniel E. Fein[2], Maryam Labaf[2], Larysa Poluben[2], Olga Voznesensky[2], Aniket Gad[2], Eva Corey[3], Rupal S. Bhatt[2], Steven Balk[2], Paraskevi Giannakakou[1]

[1]Medicine, Weill Cornell Medicine, New York, NY,[2]Medicine, Beth Israel Deaconess Medical Center, Boston, MA,[3]Urology, University of Washington School of Medicine, Seattle, WA

Docetaxel is the first-line chemotherapy for metastatic castration-resistant prostate cancer, but clinically meaningful mechanisms of resistance remain to be established. We generated an in vivo model of docetaxel resistance using castration-resistant patient-derived xenografts and found increased expression of genes that drive development of multiciliated cells, including FOXJ1 and its effector genes, many of which regulate ciliary microtubules. Mechanistically, FOXJ1 overexpression conferred docetaxel resistance in vitro and in vivo, which was associated with decreased docetaxel-mediated microtubule bundling. Overexpression of a microtubule-associated FOXJ1-regulated gene (TPPP3) had similar effects. Conversely, FOXJ1 knockdown impaired basal microtubule function, enhanced taxane binding to microtubules, and increased docetaxel sensitivity. These results establish mechanistic causality between the FOXJ1 signaling axis, microtubule biology, and taxane resistance. Clinically, FOXJ1 gene amplification was increased in taxane-treated prostate cancer patients. Moreover, in the CHAARTED clinical trial of docetaxel combined with androgen deprivation for metastatic prostate cancer, higher baseline FOXJ1 was predictive of decreased survival in prostate cancer patients treated with docetaxel, further supporting clinical relevance. Together these findings identify a previously unrecognized clinically impactful mechanism of taxane resistance whose exploitation could stratify patients that will not benefit from taxane treatment.

#3082 Activation mevalonate pathway via HMGCS2 introduced resistance to molecular targeted therapy for cancer.

Y. Kato;
Yasuhiro Kato (Individual), Tokyo, Japan

Introduction: Recently, some oncogenic driver mutations found in any kinds of cancer. NTRK fusion is one of the oncogenic driver mutations express in any kinds of malignancy tumors and neurotrophic tropomyosin receptor kinase (NTRK) tyrosine kinase inhibitors (TKIs) is specific treatment for cancer harboring *NTRK* fusion. We investigated resistance mechanism of cancer harboring NTRK fusion to NTRK-TKI.

Method: We established resistant cells to NTRK-TKIs (larotrectinib, entrectinib and selitrectinib) using KM12 harboring *NTRK* fusion. We investigated resistant cells for finding resistant mechanism to NTRK-TKI.

Results: Whole exome sequence and microarray analysis conducted to resistant cells (KM12-LR, KM12-ER, and KM12-SR). Only KM12-LR have G595R as resistant solvent front mutation previously reported. We confirmed the overexpression of 3-hydroxy-3-methylglutaryl-CoA synthase 2 (HMGCS2) in resistant cell lines from result of microarray, western blotting and quantitative RT-PCR. SREBP2 and PPARα which associated mevalonate pathway showed lower expression correlated HMGCS2 expression in resistant cells. After knocking down of HMGCS2, sensitivity to NTRK-TKI recovered in KM12-ER and KM12-SR. Mevalonic acid reintroduced NTRK-TKI resistance in KM12-ER and KM12-SR. after knocking down HMGCS2. Simvastatin and silibinin showed synergic effect with NTRK-TKIs to resistant cells, and delayed emergence of resistance in KM12 cells. In vivo study, resistant tumor to NTRK-TKI created in mice showed HMGCS2 over expression. NTRK-TKI and simvastatin reduced resistant tumor growth compared with entrectinib alone in vivo.

Conclusion: Activation mevalonate pathway via HMGCS2 overexpression introduced resistance to NTRK-TKI. It found novel resistance mechanism to molecular targeted therapy. Statin showed possibly useful for overcoming resistance mechanism introduced by HMGCS2.

#3083 NT219 overcomes immune evasion-resistant mechanisms in head and neck squamous cell carcinoma (HNSCC).

Hadas Reuveni, Hava Ben David, Katy Sigalov, Daphna Miron

Purple Biotech Ltd., Rehovot, Israel

Background: NT219 is a small molecule that promotes insulin receptor substrate 1/2 (IRS) degradation and suppresses STAT3 phosphorylation, two major complementary signaling pathways that play a key role in cancer and drug resistance. We present NT219 suppressive effect on HNSCC tumor and tumor microenvironment (TME) and on cancer stem cells (CSC) which contribute to drug resistance and disease recurrence

Method: Tumor microarrays (TMA) of 54/57 HNSCC and 9 normal tissue cases were analyzed for pSTAT3(Y705) and IRS2 by IHC NT219 and cetuximab effect on CSC was assessed using 3D spheroid assay of HPV^- HNSCC lines, evaluating size (microscopic measurements), cell viability (CellTiterGlo) and stemness marker expression (FACS analysis). Ex vivo patient-derived tumor explant (PDE), treated with NT219 and/or nivolumab was analyzed for efficacy and cytokine secretion. In vivo efficacy was tested in a stem cell-enriched (NutriStem®) patient-derived xenograft (PDX).

Results: NT219 with cetuximab suppressed established spheroids of SCC-9 HNSCC, in terms of size (100% disintegration) and CSC viability (94% reduction), while cetuximab had no effect ($P<0.001$). NT219 alone showed a significant effect on CSC viability (82% reduction, $P<0.001$). HNSCC FaDu spheroids showed the same trend. Spheroids showed enrichment in OCT3/4 or NANOG positive CSC (4-fold vs 2D growth), completely reversed by NT219 and cetuximab. Inhibitory effect was also demonstrated in established FaDu spheroids including major stemness markers; OCT3/4, NANOG, SOX2, ALDH, CD166, CD44. In a stem cell-enriched PDX HNSCC model, NT219 synergized with cetuximab to suppress tumor growth. Accordingly, delayed tumor recurrence demonstrated. A significant upregulation of STAT3(Y705) phosphorylation and IRS1/2 were detected in tumor and/or TME fibroblasts and TILs vs normal tissue. PDX models demonstrated that blockage of both STAT3 and IGF1R/IRS pathways is required to overcome resistance to EGFR therapy in terms of survival and tumor size. In a HNSCC PDE resistant to nivolumab, NT219 and nivolumab combination induced synergistic tumor cell death (66%) accompanied by immuno-cytotoxic activation (10 and 1.5-fold increase of IL2 and granzyme B). Nivolumab-induced immunosuppressive effects (8-fold increase of IL-10, 2-fold decrease of TNFα) were completely blocked by the combination. In a phase 1 study of HNSCC patients treated with NT219 50-100 mg/kg and cetuximab standard dose weekly, significant differences in patient's biopsy pIGF1R and pSTAT3 were observed in 2 responders (PR) compared to the 4 progressed disease pts.

Conclusions: NT219 mitigates several immune evasion mechanisms including CSC-mediated resistance and tumor recurrence, and sensitizes resistant HNSCC tumors to PD1 and EGFR therapies. Upregulation of pIGF1R and pSTAT3 were correlated with patient response and suggested as potential biomarkers for NT219 treatment.

#3084 Claudin-11 promotes cisplatin resistance by inducing autophagy through activation of the PHF23-ERK signaling pathway in ovarian cancer cells.

Ha Yeong Chae[1], So Young Lee[1], Hyojin Jeong[1], Hye Ri You[1], Jinil Han[2], Young Kee Shin[3], Mi Jeong Kwon[1]

[1]Kyungpook National University, Daegu, Korea, Republic of,[2]Gencurix, Seoul, Korea, Republic of,[3]Seoul National University, Seoul, Korea, Republic of

Claudin-11, a member of claudins consisting of tight junction has been shown to be associated with prognosis and to play dual roles in cancer. However, its role in the response to anti-cancer agents is unknown. In this study, we investigated the role and mechanism of claudin-11 in cisplatin resistance in ovarian cancer. Kaplan-Meier survival analysis using The Cancer Genome Atlas data revealed that high *CLDN11* expression is significantly associated with poor prognosis in ovarian cancer. Claudin-11 expression was significantly upregulated in cisplatin-resistant ovarian cancer cells. Consistent with this, claudin-11 overexpression significantly decreased the sensitivity to cisplatin in ovarian cancer cells. Cisplatin-induced apoptosis was reduced in claudin-11-overexpressing ovarian cancer cells, which was associated with decreased DNA damage. Moreover, claudin-11 overexpression inhibited cisplatin-induced apoptosis by promoting autophagy through increased ERK phosphorylation in ovarian cancer cells. The cisplatin sensitivity of claudin-11-overexpressing cells was restored by co-treatment with chloroquine, an autophagy inhibitor, and cisplatin, indicating that claudin-11 promotes cisplatin resistance by inducing autophagy. RNA sequencing data analysis further showed that autophagy-related PHD finger protein 23 (*PHF23*) is significantly upregulated in claudin-11-overexpressing cells compared with vector-transfected cells. PHF23 knockdown reversed cisplatin resistance by inhibiting ERK phosphorylation and then cisplatin-induced autophagy and apoptosis in claudin-11-overexpression cell. Taken together, these results indicate that claudin-11 promotes cisplatin resistance by activating autophagy through the PHF23-ERK signaling pathway and thereby reducing apoptosis in ovarian cancer cell, suggesting that inhibition of claudin-11 may overcome cisplatin resistance in ovarian cancer.

#3085 Upregulation of TAGLN2-PI3K-AKT signaling promotes therapeutic resistance in glioblastoma through a positive feedback mechanism.

Ashok Kumar[1], Sasha Beyer[1], Bryan Perez-Soto[2], Anca-Ligia Grosu[3], Steffen Lindert[2], Heather R. Manring[1], Saikh Jaharul Haque[1], Arnab Chakravarti[1]

[1]Radiation Oncology, The Ohio State University Wexner Medical Center, Columbus, OH,[2]Department of Chemistry & Biochemistry, The Ohio State University, Columbus, OH,[3]Department of Radiation Oncology, University of Freiburg, Freiburg, Germany, Freiburg, Germany

Objective: Despite aggressive treatment with surgery, radiation and temozolomide chemotherapy glioblastoma (GBM) remains the most lethal tumor of the human brain, which is largely due to inevitable recurrence of treatment refractory tumor. Studies have shown that aberrant activation of AKT significantly contributes to the development of treatment resistance in GBM. Molecular profiling and in vitro studies from our group identified TAGLN2, an actin binding cytoskeletal protein, as a top upregulated gene in GBM. In other cancer types, TAGLN2 has been shown to activate the PI3K-AKT pathway resulting in treatment resistance. This study aims to explore how TAGLN2 drives treatment resistance in GBM.
Methods: PDX primary human GBM cell lines (08-387 and GBM 3359) were used. Co-immunoprecipitation (Co-IP) assays were performed to study the interaction of PTEN with TAGLN2 in vitro. Biacore/Surface plasmon resonance (SPR) analyses were performed to study binding affinity and kinetics of their interaction. Protein-protein interactions were validated by in silico (AlphaFold2) analysis. Protein expression was quantified by WB analysis. Cell viability was assessed by MTS assays.
Results: We have previously shown that RNAi-mediated knockdown (KD) of TAGLN2 significantly reduced cell proliferation, survival, clonal expansion and the invasive potential of GBM PDX cell lines in vitro and reduced tumor growth using preclinical in vivo models. We found that KD of TAGLN2 reduced the levels of activated/phosphorylated AKT (pAKT) in GBM cells resulting in downregulation of this pathway. Subsequently, we found that TAGLN2 physically associated with PTEN as evidenced by Co-IP, SPR and in silico analysis. Binding of TAGLN2 to PTEN may attenuate PTEN function resulting in the activation of downstream oncogenic pathways. mTORC2 and DNA-PK are known to phosphorylate and activate AKT resulting in the upregulation of downstream signaling. Here, we show that inhibition of these kinases either individually or in combination reduced TAGLN2 protein levels in GBM cells in vitro. Importantly, direct inhibition of Akt phosphorylation also resulted in the reduction of TAGLN2 protein levels indicating that activated Akt stabilized TAGLN2 (likely by phosphorylation), which in turn promoted oncogenic pathways via a positive feedback mechanism. Also, KD of TAGLN2 increased the sensitivity of GBM cells to both TMZ and RT as assessed by multiple in vitro models.
Conclusion: Taken together, our data suggest that Transgelin-2 promotes chemo-radiation treatment resistance in GBM through a novel positive feedback mechanism that involves the TAGLN2-PTEN-PI3K-AKT axis. Therefore, TAGLN2 may serve as potential therapeutic target in GBM and to this end, development of small molecule inhibitors of TAGLN2 is actively underway in our laboratory.

#3086 TFAP2C promotes mitochondrial fitness required for sustained kinase reprogramming in endocrine therapy resistance in breast cancer.

Attila Szenasi, Austin Whitman, Santiago Haase, Philip Spanheimer

University of North Carolina, Chapel Hill, NC

Endocrine therapy resistance (ETR) remains a formidable challenge in the treatment of estrogen receptor-positive (ER+) luminal breast cancer, frequently leading to therapeutic failure. Our previous research identified the transcription factor TFAP2C as a key regulator of the antioxidant enzyme glutathione peroxidase 1 (GPX1), as well as c-ErbB2/HER2, RET, and EGFR, which lead to ERK/MAPK activation and promote ETR. Here, we aimed to elucidate the role of TFAP2C in the redox regulation of kinase reprogramming in acquired ETR. Our current study reveals that TFAP2C acts as a metabolic switch, triggering cellular reprogramming and redox modulation of kinase signaling through post-translational cysteine modifications. TFAP2C knockdown in tamoxifen-resistant cell lines and patient-derived organoids induces mitophagy, leading to reduced mitochondrial content, metabolic reprogramming, and altered Reactive oxygen species (ROS) profiles via GPX1 and SOD1 signaling. This disruption enhances phosphatase activity in the PI3K and MAPK pathways, resulting in cell cycle arrest and attenuated HER2- and EGFR-mediated signaling, both of which are pivotal for sustaining ETR. This study not only underscores the role of TFAP2C as a central player in maintaining the metabolic and signaling adaptations required for kinase reprogramming associated with ER+ targeting therapies, but also highlights the broader implications of mitochondrial redox signaling in the etiology of ETR, providing a novel avenue for therapeutic intervention.

#3087 Cancer-associated fibroblasts promote resistance to chemotherapy through the p53/ERK1/2/DKK1 pathway.

Zhijie Yin, Yuning Zhou, Xudong Zhu, Chi Wang, Heidi L. Weiss,B. Mark Evers, Qingding Wang

Markey Cancer Center, The University of Kentucky, Lexington, KY

Introduction: Chemotherapy constitutes the cornerstone of adjuvant therapy for colorectal cancer (CRC); however, acquired resistance issues can lead to a decrease in the efficiency of chemotherapy. Dickkopf-1 (DKK1) promotes MDSC infiltration, immunosuppression, and cancer relapse. Cancer-associated fibroblasts (CAFs) play a pivotal role in the tumor microenvironment. The purpose of this study was to examine whether CAFs play a critical role in acquired chemotherapy resistance.
Methods: CAFs were treated with either 5-FU, oxaliplatin or sn38 in a time- and dose-dependent manner. Expression of DKK1, p53, fibroblast activation protein (FAP), and phosphorylated ERK1/2, JNK, p38 were determined by either RNA-seq, western blot, real-time (RT)-PCR, ELISA, or immunofluorescence (IF) staining. To determine whether targeting DKK1 would enhance the efficacy of 5-FU treatment, $APC^{f/f}$; CDX2-Cre/ERT2 mice were injected with tamoxifen to induce adenoma formation followed by treatment with 5-FU in combination with administration of either normal IgG or anti-DKK1 antibody. Tumor tissues were harvested and flow cytometric analyses performed.
Results: Treatment of CAFs with either 5-FU, oxaliplatin, or sn38 (an active metabolite of irinotecan) increased DKK1 expression and secretion, suggesting a general induction of DKK1 by chemotherapeutic agents. Treatment with these agents resulted in the activation of MAPK as noted by the increased phosphorylation of ERK1/2, JNK, and p38. Inhibition or knockdown of MEK/ERK1/2, but not JNK and p38, blocked the induction of DKK1 expression, suggesting that chemotherapy increased DKK1 expression through activation of ERK1/2 signaling pathway in CAFs. Consistently, elevated levels of phospho-ERK were found in CAFs in surgically resected samples from patients treated with neo-adjuvant therapy prior to surgery compared to non-chemotherapy controls as determined by double IF staining for phospho-ERK1/2 and FAP. Chemotherapeutic agents induce DNA damage-related upregulation of p53 in CAFs. Knockdown of p53 blocked increased ERK1/2 phosphorylation and DKK1 expression after treatment with the chemotherapeutic agents. These results suggested that chemotherapeutic agents increased DKK1 expression through p53-dependent activation of ERK1/2. Treatment with 5-FU increased levels of DKK1 in plasma, and coincidently, increased myeloid-derived suppressor cell (MDSC) tumor infiltration as determined by FACS analysis; these increases were blocked by treatment with anti-DKK1 neutralizing antibody. Moreover, anti-DKK1 antibody enhanced the antitumor efficacy of 5-FU as noted by the significantly decreased tumor size and numbers.
Conclusions: Our current study identified a novel mechanism contributing to chemotherapy resistance. Importantly, our findings provide evidence for targeting ERK1/2/DKK1 to counteract chemotherapy resistance for CRC treatment.

#3090 miRNA-221-5p-mediated epigenetic regulation promotes chemoresistance and offers therapeutic potential in ovarian cancer.

Tasmin Rahman Omy, Naresh Sah, Mark Reedy, Ganesh Acharya, Komaraiah Palle

Texas Tech University Health Sciences Center, Lubbock, TX

Epithelial ovarian cancer (EOC) is a highly aggressive malignancy and the leading cause of gynecological cancer-related deaths. The majority of patients are diagnosed at advanced stages (III-IV), where treatment involves surgical debulking followed by platinum-based chemotherapy. While initial responses to therapy are often favorable, over 70% of advanced-stage EOC patients experience recurrence, typically accompanied by resistance to standard of care treatments. This chemoresistance significantly limits therapeutic success and worsens patient prognosis. Understanding the molecular mechanisms driving resistance is critical for developing effective therapeutic strategies. Emerging evidence highlights the role of miRNAs in regulating gene expression networks associated with DNA damage repair and chemoresistance. miRNA-221-5p has been implicated in modulating tumor progression and therapeutic responses in various cancers. Here, we investigate its role in ovarian cancer, focusing on regulating RAD18 and RAD51—key mediators of DNA damage tolerance and homologous recombination repair (HRR). Our analysis of miRNA expression in a panel of human ovarian cancer cell lines revealed low to undetectable levels of miRNA-221-5p, coupled with elevated expression of DNA damage response and repair genes such as **RAD18** and **RAD51**. Our experimental data demonstrate that miRNA-221-5p regulates RAD18 and RAD51 transcripts through 3'-UTR, leading to their post-transcriptional repression and subsequent restoration of ovarian cancer cell sensitivity to platinum drugs. Mechanistically, our results confirm that miRNA-221-5p epigenetically regulates RAD18- and RAD51-mediated DNA damage tolerance and homologous recombination repair. Importantly, restoring miRNA-221-5p downregulates RAD18 and RAD51 and sensitizes chemoresistant ovarian cancer cells to platinum drugs, offering a promising strategy to enhance therapeutic outcomes. Overall, our data demonstrate that miRNA-221-5p is a critical regulator of chemotherapy-induced epigenetic and transcriptional alterations, making it a prospective therapeutic target for overcoming chemoresistance and avoiding EOC recurrence.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: The Microenvironment in Therapeutic Response
Poster Session

#3093 Molecular profiling of tisotumab vedotin-treated patients identified immune pathways associated with clinical activity, supporting the multimodal mechanism of action.

Sriram Sridhar[1], Guy Roukens[1], Christina Yu[1], Han Si[1], Steven Xu[1], Lauren Brady[1], Merzu Belete[1], Mark Bieda[2], Khyati N. Shah[3], Regina Aquino[1], Denise Gallagher[1], Brandon Higgs[1], Mark Fereshteh[1], Maria Jure-Kunkel[1], Jeffrey R. Harris[1]

[1]Genmab US, Inc., Plainsboro, NJ,[2]Pfizer Inc., Bothell, WA,[3]Pfizer Inc., South San Francisco, CA

Introduction: Tisotumab vedotin (TV) is an antibody drug conjugate comprised of a human tissue factor (TF)-specific IgG1κ monoclonal antibody chemically conjugated via a protease-cleavable valine-citrulline linker to the microtubule-disrupting agent monomethyl auristatin E. TV is approved in the US based on the pivotal single arm innovaTV 204 study and the randomized phase 3 innovaTV 301 study for patients with recurrent/metastatic cervical cancer who have progressed on/after chemotherapy. The purpose of this study was to explore the tumor microenvironment of patients with cervical cancer for characteristics associated with immune-mediated mechanisms of action (MoA) of TV.
Methods: RNA sequencing was performed on available pre-treatment biopsies from 41 patients enrolled in the innovaTV 204 study. Differentially expressed genes and gene signatures were identified by comparing responders (per RECIST v1.1, complete or partial response) and non-responders (stable or progressive disease) using a linear model adjusting for clinical factors, where mean fold differences and nominal p-values between groups were determined. Associations with overall survival (OS) were determined using a Cox proportional hazards model. To further explore signatures involved in TV MoA, Fc-mediated effector functions of TV were analyzed using tumor cell lines with varying TF expression levels co-cultured with variations of TV/tisotumab antibodies and immune cells.
Results: Mean levels of a natural killer (NK) cell signature were higher in TV responders vs. non-responders. The NK cell signature, as well as an M1 macrophage and monocyte signatures were also associated with better OS among patients from innovaTV 204. Levels of these signatures in untreated patients with cervical cancer from TCGA were not associated with better OS, suggesting that their link with this outcome was specific to TV treatment. Immune cell effector mechanisms were confirmed in vitro by assessing viability of tumor cell with various TF expression levels co-cultured with immune cells. Tumor cell viability analysis suggested TV may contribute to immune cell-mediated clearance of target tumor cells via Fc-mediated effector mechanisms, which was reduced with an Fc-inert variant of TV.
Conclusions: Immune gene signatures associated with the Fc-mediated effector mechanisms of antibody-dependent cellular cytotoxicity (NK cells) and antibody-dependent cellular phagocytosis (macrophages/monocytes) were associated with improved OS and overall response rate in innovaTV204 patients. Preclinical results demonstrate Fc-dependent immune cell engagement as a MoA of TV. Together, these results provide additional evidence of TV's multimodal MoA in patients with advanced cervical cancer.

#3094 Aurora-A inhibition sensitizes HPV-driven cancers to anti-CTLA-4 immunotherapy by modulating the tumor immune microenvironment.

Soma Ghosh[1], Madison P. O'Hara[1], Tuhina Mazumdar[1], Lacin Yapindi[1], Li Shen[1], Jing Wang[1], Mitchell J. Frederick[2], Jagannadha K. Sastry[1], Faye M. Johnson[1]

[1]UT MD Anderson Cancer Center, Houston, TX,[2]Department of Otolaryngology, Baylor College of Medicine, Houston, TX

About 5% of cancers are caused by human papillomavirus (HPV), most of which are resistant to immune checkpoint inhibitors (ICIs). Alisertib (Ali), an Aurora kinase A inhibitor, may sensitize these cancers to ICIs by inducing apoptosis and DNA damage. This study investigates combining Ali with ICIs to enhance antitumor immunity and overcome resistance. We assessed Ali's effects on apoptosis, DNA damage, and immunogenic cell death in HPV-positive cancer cell lines. Ali was tested alone or with ICIs in the mEER model, a surrogate for HPV+ oropharyngeal cancers. Changes in the tumor immune microenvironment (TIME) were analyzed by flow cytometry. RNA-seq evaluated gene expression across four groups: control, Ali, anti-CTLA-4, and combination. Gene set enrichment and Gene Ontology (GO) analyses identified key biological processes.Combination therapy with Ali and anti-CTLA-4 significantly reduced tumor size and improved survival, with 75% of treated mice surviving at 60 days compared to 0% of controls. Ali induced increased cleaved caspase-3 and PARP expression in tumor tissues, indicating enhanced cancer cell apoptosis. Flow cytometry showed enhanced T-cell polyfunctionality, with increased IFN-γ and granzyme production in tumor-infiltrating lymphocytes, along with reduced T-cell exhaustion (e.g., LAG3). A significant reduction in the Gr-1low Ly6G+ granulocytic subset of myeloid-derived suppressor cells (MDSCs) suggested an improved immune microenvironment. RNA-seq identified 22,059 protein-coding genes with ≥1.5-fold increase compared to controls. Of these, 400 genes were upregulated by Ali, 3 by anti-CTLA-4, and 640 by the combination, with 191 genes upregulated in both Ali and combination groups. GO analysis revealed that shared genes activated immune-related processes like cell surface receptor signaling, macrophage activation, and T-cell cytokine regulation. In the Ali group, immune activation was linked to cytokine production and immune effector responses, while the combination showed enrichment for metabolic processes, suggesting metabolic reprogramming as a mechanism for enhanced immune responses and efficacy. The combination therapy increased CD8+ central memory T-cells, CD4+ memory T-cells, and elevated naive CD4+ T-cells, indicating enhanced T-cell activation and recruitment to the tumor, correlating with increased immune cell infiltration and improved survival. The combination of Ali and anti-CTLA-4 enhances outcomes in an HPV-driven murine model by boosting immune activation and reshaping the TIME. RNA-seq analysis shows that Ali drives immune responses, further amplified by anti-CTLA-4, promoting both immune and metabolic reprogramming. These findings suggest that combining Ali with ICI could overcome resistance and improve therapeutic outcomes in HPV-positive cancers.

#3095 Comparative analysis of WRN inhibitors HRO761 and VVD-133214 in a cancer cell panel: insights into MSI status-dependent drug responses.

Lili Chai, Tingting Yang, Huawei Pan, Wei Liu, Zhengtai Li, Xiaojian Wang, **Tj (Tiejun) Bing**

ICE Bioscience, Inc., Beijing, China

High-throughput screening of a cancer cell panel represents a pivotal instrument in the armamentarium of drug discovery and development. The sensitivity profiles of these cell lines serve as a cornerstone for the refinement of in vivo model systems and for the stratification of patient cohorts in clinical trials. Werner Syndrome RecQ Helicase (WRN), a member of the RecQ helicase family, is instrumental in the preservation of genomic integrity. Its multifaceted role encompasses DNA repair, replication, recombination, and telomere maintenance. WRN has garnered significant attention as a potential therapeutic nexus in oncology, particularly within the context of tumors exhibiting microsatellite instability (MSI). The synthetic lethality between WRN and MSI has been the subject of intensive research, demonstrating that WRN inhibition is selectively toxic to cancer cells harboring a high microsatellite instability (MSI-H) phenotype, which is a characteristic observed across a spectrum of malignancies, including colorectal, endometrial, and gastric cancers.

The present investigation assesses the therapeutic potential of two advanced WRN inhibitors, HRO761 and VVD-133214, within a meticulously curated panel of cancer cells that display a continuum of MSI and microsatellite-stable (MSS) statuses, as well as HRO761 resistant cell lines. Employing cell viability assays, we conducted a comparative analysis of the growth-inhibitory effects of these compounds on MSI and MSS cell lines. Our data reveal a pronounced anti-neoplastic effect of both HRO761 and VVD-133214 in some MSI-H cell lines, juxtaposed with a diminished impact on MSS cell lines. Further, transcriptomic profiling elucidated discrete transcriptional landscapes modulated by each inhibitor, shedding light on their divergent pharmacological mechanisms. This study not only showcases our proficiency in high-throughput screening and bioinformatics but also contributes a wealth of knowledge regarding the MSI-dependent therapeutic responses to WRN-targeted agents, potentially informing future clinical strategies in cancer treatment.

#3096 The RXR agonist MSU-42011 and the MEK inhibitor selumetinib reduce tumor burden by decreasing pERK levels and modulating immune cell populations within the NF1 tumor microenvironment.

Pei-Yu Peggy Hung[1], Jessica A. Moerland[1], Karen T. Liby[2]

[1]Michigan State University, East Lansing, MI,[2]IU School of Medicine, Indianapolis, IN

Neurofibromatosis type 1 (NF1) is a common genetic disease that predisposes approximately 50% of affected individuals to develop plexiform neurofibromas (PNFs), which can progress to highly aggressive malignant peripheral nerve sheath tumors (MPNSTs) in approximately 10% of patients. NF1 is caused by mutations in the tumor suppressor gene *NF1*, which encodes for neurofibromin, a negative regulator of RAS activity. Selumetinib, a specific inhibitor of MEK1/2, is the only FDA-approved drug for NF1-associated PNFs. However, the anti-tumor effects of selumetinib are limited in MPNSTs, and the drug has dose-limiting side effects. Deficiency of the *NF1* gene not only promotes tumorigenesis but also has broad effects on the immune cells and cytokine signaling driven by hyperactive RAS signaling. Because macrophages account for almost half of cells in NF1 lesions and their infiltration correlates with disease progression, we hypothesized that targeting tumor-promoting immune cells is an alternative approach for treating NF1. The novel retinoid X receptor (RXR) agonist MSU-42011 reduces tumor growth in experimental Kras-driven cancers by decreasing pERK expression, reducing tumor-promoting immune cells like CD206+ macrophages and regulatory T cells, and increasing activated cytotoxic T cells. Here, we treated NF1-deficient cells and macrophages with MSU-42011 and selumetinib, either alone or in combination, using monoculture and conditioned media (CM) conditions. In human PNF and mouse MPNST cells, treatment with 200 nM MSU-40211 or 50 nM selumetinib for 3 hours reduced pERK protein levels compared to untreated controls, and the combination treatment enhanced this reduction in pERK protein levels. Additionally, there was a trend toward reduction in cell viability with increasing drug concentrations after 72 hours of the combination treatment. Moreover, CM from human and mouse PNF cells increased the mRNA expression of monocyte chemoattractant *CCL2* and the secretion of IL-6 and TNFα in human THP1 monocytes/macrophages and bone marrow derived macrophages (BMDM). Notably, MSU-42011 and selumetinib alone inhibited *CCL2* mRNA expression in THP1 macrophages and BMDM stimulated with CM from human and mouse PNF cells, respectively, and the inhibition of *CCL2* mRNA expression was greatest with the combination treatment. The combination of MSU42011 and selumetinib also significantly reduced tumor growth and reduced pERK levels and tumor-promoting CD206+ macrophages in both a LL2 model of lung cancer driven by an activating *Kras* mutation and a syngeneic mouse model of MPNST. Based on the similarities in RAS activation and immune cell infiltration in NF1 and lung cancer, our next step is to confirm the immunomodulatory and anti-tumor effects of MSU-42011 and selumetinib in a genetically engineered model of PNF and MPNST.

#3097 MNK1/2 kinase expression in immune cells dictates tumoral response to MNK inhibitors.

Thao D. Pham, Apurba Majumder, Alejandra M. Marinelarena, Jeffrey H. Becker, Hidayatullah G. Munshi

Medicine, Northwestern University, Chicago, IL

Background: MAPK-interacting serine/threonine-protein kinase 1 and 2 (MNK1 and MNK2) are downstream effectors of the MEK/ERK and p38 MAPK pathways. Increased expression and activity of MNK kinases are linked to tumor growth and therapeutic resistance. As a result, several classes of MNK inhibitors (MNKi) have been developed and evaluated preclinically. Previously, we reported that treatment of murine pancreatic tumors with MNKi resulted in increased tumoral infiltration of PD-1^{hi}CD8+ T cells. We further found that MNKi-induced increase in immunosuppressive tumor-associated macrophages (TAMs) accounted for the infiltrating T cell exhaustion. Finally, co-treatment with MNKi and anti-PD-1 rescued T cell activity and sufficiently controlled tumor growth. However, the extent to which MNKi efficacy relies on the immune cells was not clearly defined. In this study, we set out to better understand the roles of MNK kinases in T cells and macrophages, and how they contribute to MNKi anti-tumor efficacy.

Methods: We evaluated the proliferation and effector functions of bone marrow-derived macrophages (BMDMs) and splenocyte-derived T cells collected from either mice with wild-type background or mice with body-wide knockout (KO) of MNK1, MNK2, or both MNK1 and MNK2 expression. In addition, we assessed murine pancreatic tumor growth in wild-type, MNK1-, MNK2-, or MNK1/2-KO and their response to anti-PD-1 therapy, either alone or in combination with MNKi.

Results: We first found that BMDMs isolated from MNK1-, MNK2-, or MNK1/2-KO (collectively referred to as MNK^{KO} hereon) mice are more potent at suppressing T cell proliferation in vitro. Interestingly, T cells isolated from MNK^{KO} spleen demonstrated higher proliferative capacity and activation following CD3/CD28 ligation. Compared to the wild-type, MNK^{KO} T cells are also capable of better proliferation when co-cultured with MNK^{KO} BMDMs. Similarly, T cells isolated from the tumor-bearing MNK^{KO} mice showed enhanced effector functions compared to those isolated from the wild-type mice. Significantly, tumor-bearing MNK^{KO} mice showed an exceptional response to an anti-PD-1 antibody, whereas the wild-type mice did not respond to the treatment. Finally, the addition of a MNKi was found to potentiate anti-PD-1 therapy in the wild-type, but not the MNK^{KO}, mice.

Conclusion: Together, these new findings demonstrate previously unknown roles of MNK kinases in T cells, macrophages, and their crosstalk within the tumor microenvironment. These data also suggest that while MNKi have been designed to target cancer cells, their reported efficacy relies primarily on the immune cells, specifically T cells. Thus, efforts to enhance MNKi efficacy should focus on combining these drugs with immune-modulatory agents, particularly those that can boost T cell activity or suppress immunosuppressive macrophages.

#3098 Linker cleavable enzymes determine anti-tumor activity of trastuzumab deruxtecan in HER2-positive lung cancer and HER2-low breast cancer.

Akari Shiraishi[1], Asumi Iesato[2], Yuki Takahashi[3], Ken Uchibori[4], Tomo Osako[5], Reo Maruyama[6], Makoto Nishio[4], Ryohei Katayama[1]

[1]Div of Experimental Chemotherapy, Cancer Chemotherapy Center, Japanese Foundation for Cancer Research, Tokyo, Japan,[2]NEXT-Ganken program, Japanese Foundation for Cancer Research, Tokyo, Japan,[3]Technical Research Institute, TOPPAN Holdings Inc., Tokyo, Japan,[4]Department of Thoracic Medical Oncology, The Cancer Institute Hospital, Japanese Foundation for Cancer Research, Tokyo, Japan,[5]Division of Pathology, Cancer Institute, Japanese Foundation for Cancer Research, Tokyo, Japan,[6]Department of Cancer Epigenomics, Cancer Institute, Japanese Foundation for Cancer Research, Tokyo, Japan

HER2 genetic aberrations are found across various cancer types. Trastuzumab deruxtecan (T-DXd), an anti-HER2 antibody-drug conjugate (ADC), has been approved for the treatment of HER2-amplified breast and gastric cancers, HER2-mutant lung cancer, and HER2-overexpressing solid tumors. The approval of T-DXd has recently been expanded to include patients with HER2-low breast cancer. In addition, a clinical trial in lung cancer has demonstrated that the efficacy of T-DXd is not correlated with HER2 expression or specific genetic mutations. These findings suggest the presence of factors beyond HER2 expression that affect T-DXd sensitivity. To identify novel determinants of T-DXd efficacy in HER2-positive cancers, we first evaluated its anti-tumor activity in *in vitro* and *in vivo* using patient-derived HER2-positive lung cancer cell lines, JFCR-007 and JFCR-381. Interestingly, these cells showed significant shrinkage only by a single dose of T-DXd when implanted in BALB/c-nu mice, they were resistant to T-DXd in a regular 2D culture condition. Therefore, we hypothesized that tumor microenvironment affected T-DXd sensitivity. Cancer cells in patient tumor tissue are surrounded by non-cancerous cells, so we used a three-dimensional (3D) layered co-culture model with fibroblasts and extracellular matrix (ECM). We developed a 3D-in model, in which cancer cells are mixed with fibroblasts and ECM. We also made 3D-on, in which cancer cells were layered on the top of approximately 30 layers of fibroblasts, and 3D-out, in which cancer cells were seeded outside the chamber insert filled with 30 layers fibroblasts. Strikingly, the two lung cancer cell lines became sensitive to T-DXd in the 3D-in and the 3D-on state compared to the 3D-out model. Next, this co-culture model was applied to the HER2-low breast cancer, for which T-DXd has been shown to significantly prolong progression-free survival (PFS) in more than half of cases. We therefore established HER2-knockout and -low expressing breast cancer cell lines (HCC1954 and MDA-MB-453) using the CRISPR/Cas9 system followed by sorting with cell sorter. These HER2-low and -null cells were resistant to T-DXd in 2D culture state compared to parental cells. However, they became sensitive to T-DXd when cultured in 3D-in and 3D-on state. To identify the mechanism by which cancer cells become T-DXd-sensitive in 3D co-culture systems, we focused on cathepsins, lysosomal peptidases that cleave the T-DXd linker. The cathepsin subtypes capable of cleaving the amino acid sequence in the T-DXd linker were knocked down and examined the T-DXd sensitivity. Notably, cancer cells exhibited resistance to T-DXd when some cathepsin subtypes were individually knocked down. Collectively, our results suggest that certain types of cathepsins in the tumor microenvironment may play a critical role in the anti-tumor effects of T-DXd.

#3099 Predicting response to trastuzumab deruxtecan in breast cancer using flow cytometry.

Daniel S. Peiffer[1], Muriel Laine[2], Long Nguyen[1], Natalia Povarova[2], Frederick M. Howard[3], Nan Chen[3], Kimberly Cole[4], Olufunmilayo I. Olopade[3], Rita Nanda[3], Geoffrey L. Greene[2]

[1]The University of Chicago Medicine Comprehensive Cancer Center, Chicago, IL,[2]Ben May Department of Cancer Research, The University of Chicago Medicine Comprehensive Cancer Center, Chicago, IL,[3]Medicine, The University of Chicago Medical Center, Chicago, IL,[4]Pathology, The University of Chicago Medical Center, Chicago, IL

Background: Historically, characterization of HER2 status has focused on stratifying tumors that over express HER2, known as HER2-positive (HER2+) breast cancer (BC), and those that do not, known as HER2-negative (HER2-) BC. Approximately half of all BCs, considered HER2-, express low levels of HER2 by immunohistochemistry (IHC). Although HER2-low BCs are resistant to traditional HER2-targeted therapies, recent trials have demonstrated they are sensitive to the antibody drug conjugate (ADC) trastuzumab deruxtecan (T-DXd). Tumor expression of HER2 was hypothesized to be required for response to T-DXd, however studies have demonstrated its efficacy in patients with tumors that stained <1+ on IHC, considered HER2-zero (HER2-0) disease. We hypothesize that the HER2 heterogeneity in HER2-low and HER2-0 tumors makes IHC a suboptimal prediction tool. Thus, there is a clinical need for other quantification methods to determine if HER2 represents a valid biomarker to predict response to T-DXd.
Methods: We measured HER2 levels by flow cytometry (FC) in IHC-determined HER2-low and HER2-0 BC cell lines and patient-derived organoids (PDOs) and correlated the results to T-DXd sensitivity in vitro. To determine if HER2 is required for response to T-DXd, ERBB2 knocked down by siRNA and CRISPR-CAS9 HER2-knock out (HER2-KO) variants from the HER2-low and HER2-0 parental cell lines and PDOs were generated. To model intratumor HER2 heterogeneity, mixtures of HER2 depleted cells with control cells were made to assess T-DXd efficacy in tumors with decreasing amounts of HER2-expressing cells. To assess ADC uptake, cell lines and PDOs were treated with fluorescently tagged T-DXd and intracellular ADC levels were measured by immunofluorescence. Relative amounts of deruxtecan deposition in the TME were quantified by mass spectrometry. In vivo studies using mixtures of CAS9-control and HER2-KO HER2-low cells implanted into NSG mice are ongoing.
Results: FC quantification of HER2 levels across BC cell lines and PDOs were reproducible and agreed with IHC results. Levels of HER2 expression directly correlated with sensitivity to T-DXd, and HER2 expression was required for response. Cell mixtures of HER2 knockdown + SCBi-control cells or CAS9-control and HER2-KO cells were more representative of PDO HER2 heterogeneity as quantified by FC. Growth assays of cell mixtures showed sensitivity to T-DXd was the same regardless of if there were 100%, 50% or <25% HER2-expressing cells.
Conclusions: FC represents a novel method for predicting tumor cell response to T-DXd as it can reproducibly quantify HER2 heterogeneity within the TME. Our results suggest that small amounts of HER2-expressing cells are sufficient to elicit response to T-DXd, which may be missed on IHC. Thus, use of techniques like FC to quantify HER2 levels may identify T-DXd responders in the IHC-defined HER2-0 population, thus broadening the eligible patient population that benefits.

#3100 Spatially resolved effects of oligonucleotide therapeutics on cellular phenotypes in cancer tissues.

Corinne Ramos, Sandra Boute, Amandine Gerstenberg, Richard Ruez

Aliri, Lille, France

Introduction: Oligonucleotide therapeutics, such as antisense oligonucleotides (ASOs) and small interfering RNAs (siRNAs), are promising tools for targeting oncogenic pathways in cancer. However, their impact on tumor microenvironment (TME) architecture and cellular phenotypes within cancer tissues remains insufficiently understood. This study integrates oligonucleotide-based treatments with advanced spatial phenotyping to explore their effects on cancer tissues at a high-definition, single-cell scale.
Methods: Cancer tissues treated with oligonucleotide therapeutics were analyzed using multiplexed immunohistochemistry (mIHC) and spatial transcriptomics. Cellular phenotypes, including immune and stromal cell populations, were characterized in situ to assess changes in the TME. High-resolution imaging and transcriptomic profiling were used to localize therapeutic effects, while computational analysis integrated phenotypic and molecular data to uncover spatially resolved mechanisms.
Results: Oligonucleotide treatment led to distinct spatial alterations in the TME, including reprogramming of tumor associated macrophages and increased infiltration of cytotoxic T cells in peritumoral regions. Spatial transcriptomics revealed suppression of target oncogenes, alongside upregulation of immune activation pathways in responsive regions of the tissue. Notably, these effects were localized to specific niches, suggesting cell-type-specific and spatially restricted therapeutic responses.
Conclusion: This study highlights the power of integrating oligonucleotide therapeutics with spatial phenotyping to uncover their impact on the TME in cancer tissues. The findings provide valuable insights into the spatial dynamics of oligonucleotide therapy, paving the way for more effective design and deployment of these treatments in oncology.

#3101 Multitargeting of SHMT2 and purine biosynthesis is an effective antitumor treatment under hypoxia.

Mathew Joseph Schneider[1], Carrie OConnor[1], Xun Bao[1], Md. Junayed Nayeen[2], Zhanjun Hou[1], Jing Li[1], Aleem Gangjee[2], Larry Matherly[1]

[1]Oncology, Wayne State University School of Medicine, Detroit, MI,[2]Division of Medicinal Chemistry, Duquesne University, Pittsburgh, PA

These studies investigate the antitumor effects of targeting serine hydroxymethyltransferase (SHMT) 2 under hypoxia, the downstream metabolic consequences, and how to exploit unique metabolic vulnerabilities for cancer therapy. Mitochondrial one-carbon (C1) flux through SHMT2 and 5,10-methylene tetrahydrofolate (THF) dehydrogenase 2 (MTHFD2) is the major source of C1 units in cancer cells. In mitochondria, THF serves as a cofactor for the catabolism of serine by SHMT2 to produce glycine and 5,10-methylene-THF which is subsequently metabolized by MTHFD2 and MTHFD1L. The major products of this mitochondrial C1 flux include formate and NADH, along with glycine for protein, purine and glutathione (GSH) synthesis. Thus, mitochondrial C1 metabolism is important for maintaining redox homeostasis and scavenging reactive oxygen species (ROS). Under hypoxic conditions, the flux through SHMT2 and MTHFD2 is the major source of NADH; therefore, inhibition of SHMT2 under hypoxia may increase oxidative stress resulting in cell death. However, inhibition of SHMT2 under hypoxia may facilitate cell growth as a result of aspartate accumulation due to depletion of NADH and suppression of the TCA cycle. Aspartate accumulation preserves de novo purine biosynthesis under these conditions via donation of an amine group to IMP. We discovered novel 5-substituted pyrrolo[3,2-*d*]pyrimidine multitargeted antifolates (e.g., AGF347) which inhibit SHMT2 in the mitochondria in addition to cytosolic targets (SHMT1 and folate-dependent enzymes in purine biosynthesis). We hypothesized that these agents may overcome inherent challenges of targeting SHMT2 under hypoxia, reflecting their inhibition of purine biosynthetic targets to preserve antitumor activity. Further, since all current SHMT2 inhibitors also inhibit SHMT1, to uncover the respective impacts of inhibiting these homologous enzymes, we utilized tetracycline-inducible SHMT1 or SHMT2 HCT116 tumor cell models to simulate selective inhibition of these targets by removal of doxycycline. We demonstrate that the pyrrolo[3,2-*d*]pyrimidine compounds retain potent antitumor efficacy under hypoxia, as reflected in inhibition of cell proliferation and colony formation. We assessed the metabolic consequences of antifolate treatment under hypoxia and normoxia by measuring malate, aspartate, and purine levels by LC-MS/MS in addition to effects on ROS and GSH levels. We also demonstrated that loss of SHMT2 activity alone is sufficient for anticancer effects under both normoxia and hypoxia, whereas loss of SHMT1 alone had no effect. These studies demonstrate the considerable promise of multitargeted pyrrolo[3,2-*d*]pyrimidine antifolates for cancer therapy under conditions under which standard-of-care agents may be less effective.

#3102 Spliceosome perturbation enhances immunotherapy in SCLC by triggering ZBP1-driven necroptosis in cancer-associated fibroblasts.

Xinpei Jiang[1], Xueying Ma[2], Yunyun Zhou[3], Siddharth Balachandran[4], Israel Canadas[2]

[1]Center for Immunology, Cancer Epigenetics Institute, Nuclear Dynamics and Cancer Program, Lewis Katz School of Medicine at Temple University, Fox Chase Cancer Center, Philadelphia, PA,[2]Center for Immunology, Cancer Epigenetics Institute, Nuclear Dynamics and Cancer Program, Fox Chase Cancer Center, Philadelphia, PA,[3]Fox Chase Cancer Center, Philadelphia, PA,[4]Center for Immunology, Fox Chase Cancer Center, Philadelphia, PA

Small cell lung cancer (SCLC) is the most lethal form of lung cancer with a 5-year overall survival of 5%. Despite advancements in immunotherapy, SCLC is characterized by an immunologically ‘cold’ tumor microenvironment (TME) and the majority of SCLC patients remain unresponsive to these treatment strategies. This combination of poor survival outcomes and limited therapeutic options underscores the critical urgency of identifying innovative strategies to treat SCLC. A potential approach to activate an innate immune response within tumors is by promoting the accumulation of endogenous "virus-like" nucleic acids in cancer cells, thereby initiating an antiviral response, concept known as ‘viral mimicry’. Here, we demonstrated that targeting the spliceosome component SF3B1 is an effective strategy to induce viral mimicry not only in cancer cells but also in cells from the TME, including cancer associated fibroblasts (CAFs). SF3B1 inhibition induced the formation of Z-form RNAs (Z-RNAs), which are unique, left-handed dsRNA species and necroptosis-activating ligands for Z-DNA binding protein 1 (ZBP1). Notably, we found that SF3B1 inhibition triggered ZBP1-dependent necroptosis, a highly immunogenic cell-death, through the RIPK3- ZBP1-MLKL axis in necroptosis-competent cancer cells and patient-derived CAFs. In vivo, SF3B1 inhibition promoted a decreased tumorigenicity and increased immunogenicity, as well as ZBP1-driven necroptosis in CAFs, enhancing response to immune checkpoint blockade (ICB). These findings have significant implications for inducing viral mimicry in immunologically "cold" tumors. Since SF3B1 inhibition can trigger necroptosis by targeting any necroptosis-competent cell, including CAFs within the TME, our results suggest that this approach could create a more immunogenic TME in all SCLC patients, regardless of whether their tumor cells have impaired necroptosis signaling. Thus, SF3B1 inhibitors and potentially other spliceosome-targeted therapies represent a promising strategy with exceptional translational potential for inducing necroptosis and enhancing ICB responsiveness in aggressive “cold” tumors, such as SCLC.

#3103 Perspectives of novel tissue engineering technologies for next generation cancer therapeutics.

Preeya D. Katti

American University of the Caribbean, Cupecoy, Sint Maartin

Cancer is the second leading cause of death in the United States, behind cardiovascular disease. For the first time, new cancer cases in the US will exceed 2 million in 2024 while 611,720 cancer deaths are projected for 2024. Further, the global economic burden of cancer is estimated to reach $25.2 trillion by 2050. Cancer metastases are responsible for 90% of the deaths due to cancer. While the discovery of new biomarkers for early detection, also enhanced by recent efforts in machine learning for image diagnostics, of various cancers, such as breast cancer, has improved mortality rates; therapeutics in the event of metastasis are limited. Further, *in vivo,* experiments for metastasis are primarily limited by the need for intracardiac injections to initiate metastasis and the use of immunocompromised animals. Tissue engineering, the holy grail of regenerative medicine, presents an innovative technology in the cancer metastasis arena. Besides providing a novel means for reconstruction surgeries, tissue engineering technologies enable the development of robust and reliable *in vitro* models of metastasis that present new tools to evaluate cancer pathophysiology to assess specific cancer phenomena such as adhesion to metastatic site and migration of cells and cell clusters. We demonstrate here current emerging technologies that are expected to greatly impact the mortality of patients with metastasis. These include two specific developments in the tissue-engineered *in vitro* models. These include the development of an accurate tumor microenvironment and the development of fluid-flow-enabled systems that exert physiologically relevant shear stresses on the cancer cells and tumors. While 5,541 articles (as reported by the National Library of Medicine) illustrate various in vitro models of cancer metastases developed using tissue engineering, only 58 report the concurrent use of flow characteristics in conjunction with the development of accurate tumor microenvironment, and 45 of those just in the past decade. The role of fluid flow-derived shear stresses during extravasation and tissue invasion are key factors that initiate and propagate the metastasis cascade. We present a state-of-the-art analysis of current tissue engineering technologies that are at the forefront in the development of tumor models of breast, prostate, colon, and pancreatic cancer metastases as a tool for screening therapeutic agents. Micro-engineered tumor environments enabled using microfluidics cancer-on-a-chip also offer advantages of a concurrent tumor microenvironment mimicry in combination with fluid-based cancer transport, which resulted in 213 publications with 185 in the last decade. The concurrent gene and protein analysis enabled via fluid flow-based bioreactors with tissue-engineered scaffolds makes this a promising technology, and it is expected to test new therapies that will help reduce the large cancer burden.

#3105 Unveiling the potential of humanized bispecific antibody: a novel approach to tumor suppression in oncology.

Anna Jablonska, Damian Kolakowski, Tomasz Kornatowski, Aleksandra Sowinska, Sylwia Wieczorek, Krzysztof Lacek, Filip Mitula, Bartosz Wiernicki, Olga Abramczyk, Maciej Wieczorek, Delfina Popiel

Celon Pharma SA, Kazun Nowy, Poland

Background: AXL is a critical regulator in tumor progression, contributing to proliferation, invasiveness, epithelial-mesenchymal transition (EMT), angiogenesis, and immune modulation. High AXL levels are associated with poor prognosis in aggressive cancers. Concurrently, PD-L1 can suppress the antitumor immunity by binding to PD-1 on immune cells, a pathway already targeted by several immunotherapies. However, recent studies indicated that PD-L1's role extends beyond PD-1 binding. It seems to be involved in regulation of tumor growth, stemness, immune modulation, and DNA damage responses, many independently of PD-1. Our humanized bispecific antibody (BsAb), CPL976H, offers a unique dual-target approach by inducing internalization and lysosomal degradation of both PD-L1 and AXL, effectively diminishing their cell surface expression.
Methods: The BsAb CPL976H was engineered in a VHH-Fc-VHH format, incorporating dual VHH domains against PD-L1 and AXL. The antibody's activity, specificity, internalization, and target degradation were assessed using Western blot and flow cytometry across multiple cancer cell lines with varying target expression profiles (e.g., MDA-MB231, MCF7, A549, H1299), and after target induction with INFγ or its silencing with siRNA. RT-PCR and Western blot analyses were performed to assess impact on EMT and immune-modulating pathways.
Results: CPL976H demonstrated specific, high-affinity binding to PD-L1 and AXL on diverse cancer cell lines, inducing rapid internalization and lysosomal degradation of these targets. What is important, we were able to achieved efficient targets degradation in sub-nanomolar concertation's. This degradation led to downstream modulation of critical pathways, particularly those governing EMT and immune evasion. Notably, CPL976H impacted PD-L1 and AXL signaling disrupting cellular processes essential for tumor survival, regardless of PD-1 interaction, indicating its potential efficacy in PD-L1/PD-1 blockade-resistant cancers.
Conclusions: CPL976H represents a groundbreaking advancement in oncology by targeting PD-L1 and AXL through a novel mechanism that extends beyond traditional PD-L1/PD-1 inhibition. This bispecific antibody not only mitigates immune escape but also disrupts crucial survival pathways within the tumor, offering a potent therapeutic option for patients with resistance to conventional PD-L1/PD-1 therapies. Its pronounced internalization capabilities make CPL976H a promising candidate for antibody-drug conjugate (ADC) development, which could further amplify its antitumor effects. Notably, in vivo studies confirmed the high efficacy of CPL976H, both as a standalone antibody and as an ADC, demonstrating significant tumor-suppressive effects. This *in vivo* validation underscores CPL976H's potential to reshape the therapeutic landscape for challenging oncologic cases.

#3106 The first-in-class PRX3 inhibitor RSO-021 modulates the protein composition of malignant pleural effusions by increasing immunomodulating phenotypes and decreasing epithelial to mesenchymal protein expression.

Terri Messier[1], Bradley Cech[2], Joanna Dzialo[3], Charlotte Poile[3], Apostolos Nakas[4], Kudzayi Kutywayo[3], Aleksandra Bzura[3], Jan Rogel[3], Victoria Gibson[1], Ying Wai Lam[5], George Naumov[6], Dean Fennell[3], Christopher C. Landry[2], **Brian Cunniff**[1]

[1]Larner College of Medicine at The University of Vermont, Burlington, VT,[2]Department of Chemistry, The University of Vermont, Burlington, VT,[3]University of Leicester, Leicester, United Kingdom,[4]University Hospitals of Leicester, Leicester, United Kingdom,[5]Department of Biochemistry, The University of Vermont, Burlington, VT,[6]RS Oncology, Cambridge, MA

Malignant pleural effusion (MPE) is the buildup of fluid, cellular material, cytokines, and excreted proteins in the pleural space due to tumor burden. Approximately 90% of pleural mesothelioma (PM) patients and 20% of all advanced cancer patients will present with an MPE. The composition of MPE has been shown to be predicative of tumor burden and response to therapy. In the ongoing MITOPE phase 1/2 clinical trial, RSO-021 is being tested for efficacy in patients with MPE arising from mesothelioma or other metastatic tumors to the lung (NCT05278975). Results from the Phase 1 trial of RSO-021 showed promise that this approach may extend survival of PM patients (J Clin Oncol. Vol 42, 16). RSO-021 is delivered via an intrapleural catheter, limiting systemic exposure. RSO-021 is an inhibitor of the mitochondrial antioxidant enzyme peroxiredoxin 3 (PRX3) which protects tumor cells from oxidative stress induced apoptosis. Covalent inhibition of PRX3 with RSO-021 has shown cytotoxic activity in cell, mouse models, and human clinical trials, giving promise to a new therapy for aggressive cancers. To evaluate patient responses to RSO-021, we conducted mass spectrometry (MS) of MPE from patients pre and post RSO-021 treatment and identified a composition of proteins with differential abundance related to RSO-021 treatment. These data correlated with cytokine ELISA assays conducted with the same fluid. In addition, RNA sequencing of tumor explants identified common immunologic responses, stress response pathways and downregulation of pro-metastatic markers. Using Metascape Gene Annotation software we determined enrichment pathways for differential levels of abundant peptides within the PE fluid collected pre and post treatment. Pathways increased by RSO-021 include neutrophil degranulation, cell killing, hydrogen peroxide metabolic processes, aerobic glycolysis, and apoptosis. These findings support our current data for the proposed MOA of RSO-021. Increased levels of the cytokine resistin were identified in treated patient MPE by proteomics and ELISA assays. Resistin has been shown to activate tumor associated macrophages to increase anti-tumor activity in mesothelioma. Lastly, across cell lines, tumor explants and humans treated with RSO-021 we find significant downregulation of proteins related to the epithelial to mesenchymal transition (EMT) including TGFBI and periostin. Studies are underway correlating patient responses to MPE composition to identify biomarkers of sensitivity and resistance to RSO-021. Together, these data show the positive effects of RSO-021 on anti-tumor protein signatures related to tumor immunophenotypes and EMT and support the continued investigation of RSO-021 in MPE associated solid tumors.

#3107 Nuciferine inhibits proliferation, invasion, and migration of colorectal cancer cells via the RBM15-JAG2 axis.

KaiHe Zhu[1], JiaPeng RU[1], Yichen Zhang[2], Fangyue Guo[3], Mengying Liu[1], Shize Xiao[1], Xufeng Wang[4], Jing Wu[3], Peizhi Ma[3], Pei Li[1], **Shanfeng Zhang**[1]

[1]Zhengzhou University of Basic Medical College, Zheng Zhou City, China,[2]Henan Institute of Medical Sciences, Zheng Zhou City, China,[3]Department of the First Clinical Medicine, Zhengzhou University, Zheng Zhou City, China,[4]Practice Base of Basic Medical Innovation and Entrepreneurship Education in Henan Province, Zheng Zhou City, China

Background: Colon cancer is the third most common cancer globally, with high incidence and mortality rates. Dietary supplementation therapy, due to its safety, painlessness, high patient acceptance, and practical efficiency, often becomes an adjunctive treatment for colon cancer. Therefore, developing new health foods and exploring new treatment mechanisms are of great significance for the adjuvant treatment of colon cancer. Methods: This study investigated the effects of nuciferine treatment and RBM15 inhibition on the m6A modification of JAG2 using MeRIP-qPCR and actinomycin D experiments. Additionally, the impact on the biological behavior of colorectal cancer cells was assessed through plate colony formation assays, scratch assays, Transwell assays, and Western blot analyses.
Results: In this study, through transcriptome sequencing, RBM15 was discovered as a potential target of Nuciferine. The RBM15/JAG2 regulatory axis was found through bioinformatics analysis. Through total m6A detection, MeRip-qPCR, and actinomycin D experiments, it was confirmed that Nuciferine inhibits colon cancer by suppressing the m6A modification of JAG2 by methyltransferase RBM15. Additionally, plate colony experiments, scratch experiments, Transwell experiments, and Western blot experiments demonstrated that Nuciferine can inhibit the proliferation, invasion, and metastasis of colon cancer. In vivo experiments showed that Nuciferine has the effect of inhibiting the proliferation and metastasis of colon cancer.
Conclusion: The results of this study indicate that nuciferine inhibits the proliferation, invasion, and migration of colorectal cancer cells by regulating RBM15 expression to mediate JAG2 m6A methylation. Therefore, Nuciferine is an ideal health food for adjuvant treatment of colon cancer.

#3108 Imipridones ONC201, ONC206, and ONC212 promote immune-mediated cell death and anti-tumor activity in biliary tract cancer models *in vitro*.

Archana Saxena[1], Alexis J. Lannigan[1], Grace Sun[1], Jasper Chan[1], Jane Trainor[1], Lanlan Zhou[1], Varun V. Prabhu[2], Wafik S. El-Deiry[1], Alexander G. Raufi[1]

[1]Legorreta Cancer Center at Brown University, Providence, RI,[2]Chimerix Inc., Durham, NC

Background: Biliary tract cancers (BTCs) are an aggressive group of malignancies with 5-year survival rates of less than 2% in those diagnosed with metastatic disease. Chemoimmunotherapeutic approaches have limited efficacy highlighting an urgent need for novel approaches. Imipridones (Dordaviprone/ONC201, ONC206, and ONC212) have demonstrated promising antitumor activity in multiple preclinical cancer subtype models but remain underexplored in BTCs. ClpP agonist and DRD2/3 antagonist ONC201 exerts antitumor effects by upregulating TRAIL, activating the Integrated Stress Response (ISR), inhibiting AKT/ERK signaling, disrupting oxidative phosphorylation, and altering cancer cell metabolism. Second-generation imipridones (ONC206, ONC212) show enhanced potency relative to ONC201. To further investigate their therapeutic potential, we employed co-culture systems with natural killer (NK) cells to evaluate the immunomodulatory effects of these compounds. Additionally, the roles of ferroptosis, necroptosis, and autophagy modulation in sensitizing BTC cells to apoptosis and immune-mediated destruction were explored.

Methods: Two BTC cell lines, RBE and HuCCT1, were tested for drug sensitivity and synergy using the CellTiter-Glo® luminescent cell viability assay. for imipridones (ONC201, ONC206, ONC212) and trametinib. Co-culture experiments involved RBE cells (blue CMAC dye) and NK-92MI cells (green CMFDA dye), treated with ONC201 (2.53 μM), ONC206 (917 nM), ONC212 (46.99 nM), and trametinib (5.94 μM). Live/dead fluorescent imaging was conducted at 0, 24, 48, and 72 hours using DAPI, FITC, and cherry red channels on the ImageXpress® system. Cell death pathways were analyzed in RBE and HuCCT1 cells treated with ONC201, ONC206, or ONC212 (100 μM) alone or combined with inhibitors (Ferrostatin-1, Z-VAD-FMK, Bafilomycin A1, Necrostatin-1s).Cell viability was measured after 72 hours with the CellTiter-Glo® Assay.

Results: Imipridones and MEK inhibitors exhibit potent antineoplastic effects in BTC cell lines. In RBE cells, half maximal inhibitory concentrations (IC50) were 2.53 μM (ONC201), 917 nM (ONC206), 46.99 nM (ONC212), and 5.94 μM (trametinib), while in HuCCT1 cells, they were 1.97 μM (ONC201), 1.06 μM (ONC206), 38.95 nM (ONC212), and 3.71 μM (trametinib). Imipridones (ONC201 and ONC212) with trametinib showed synergy in HuCCT1 cells. ONC201 primarily results in cell death through apoptosis, and further analysis of alternative cell death pathways including ferroptosis, necroptosis, and autophagy is underway. RNA-seq studies are also ongoing. Imipridones enhanced NKcell-mediated tumor death. These findings underscore the therapeutic potential of imipridones in BTC, driven by immune-mediated signaling and offering promising prospects for future treatment strategies.

#3109 Pre-clinical efficacy of tumor treating fields and imipridones in glioblastoma and colorectal cancer cell lines.

Viva Voong, Tyler Roady, Connor Purcell, Vida Tajiknia, Lanlan Zhou, Shengliang Zhang, Wafik El-Deiry

Legorreta Cancer Center at Brown University, Providence, RI

Tumor treating fields (TTFields) utilize alternating electric fields of intermediate frequency and low intensity to disrupt cell division, demonstrating strong promise for tumor treatment. Currently, TTFields are approved for glioblastoma, unresectable mesothelioma and metastatic non-small cell lung cancer following progression on or after platinum based chemotherapy. This project aims to explore the synergistic effects and molecular mechanism of TTFields and imipridones in vitro using colorectal and glioblastoma cell lines. Imipridones are a class of anti-cancer drugs that target ClpP and GPCRs and lead to p53 independent apoptosis through chronic activation of the integrated stress response pathway. Both imipridones and TTFields have been shown to inhibit AKT and ERK phosphorylation. Thus, we theorized that co-treatment will have a synergistic effect.

We performed ATP-based (Cell Titer Glo) viability assays to determine the IC50 dosage for imipridones ONC201, ONC206 and ONC212 in HT29 and HCT116 colorectal cancer (CRC) cell lines and U251 and T98G glioblastoma (GBM) cell lines. We then treated cells with imipridones at the identified IC50 doses either alone or together with 200kHz TTFields and collected cell lysate after 72 hours.

We found differences in AKT phosphorylation across our treatment conditions (control, ONC201, ONC206, ONC212, TTF, TTF + ONC201, TTF + ONC206, and TTF + ONC212). These findings are significant in guiding future in vivo experiments and offering insight on whether TTField and imipridone treatment can be further explored in clinical trials.

#3110 A clinically actionable lipid metabolic approach in potentiating the response to anti-androgen therapy in a castration resistant prostate cancer model.

Cynthia Sprenger[1], Silvia Rodrigues[2], Ali Talebi[3], Kathryn Soriano Epilepsia[1], Shihua Sun[1], Caroline Fidalgo Ribeiro[4], Fabio Socciarelli[2], Jonas Dehairs[3], Lisa Butler[5], Johannes V. Swinnen[3], Massimo Loda[2], Stephen Plymate[1]

[1]University of Washington, Seattle, WA,[2]Weill Cornell Medicine, New York, NY,[3]KU Leuven, Leuven, Belgium,[4]Bristol Myers Squibb, San Diego, CA,[5]University of Adelaide, Adelaide, Australia

Purpose: Despite better management of prostate cancer (PCa) and good response rates to androgen deprivation therapies (ADT), patients that progress towards metastatic disease remain refractory to therapy with poor prognosis. There is a significant unmet need in sensitizing castrate-resistant PCa (CRPC) to agents such as enzalutamide (ENZ). A significant body of literature has shown saturated fatty acids (SFA) and mono-unsaturated fatty acids (MUFA) protect cancer cells from the deleterious effects of reactive oxygen species (ROS), and conversely, membrane poly-unsaturated fatty acids (PUFA) promote it. Considering that PCa is driven by androgen signaling, and that AR is upstream of lipogenesis and therefore SFA and MUFA production, we aimed to develop a pharmacological approach to sensitize CRPC to treatment, using a combination of the fatty acid synthase (FASN) inhibitor TVB-3664, enzalutamide (ENZ), and the ROS inducer arsenic trioxide (ATO).

Experimental Design: We treated castration sensitive (CS) and CRPC cell lines with combinations of TVB, ENZ and ATO and recorded live and dead cell counts. We then tested these treatments in vivo on a therapy resistant patient derived xenograft, LuCaP35 CR. We used a phospholipidomics approach to evaluate the effect of these treatments individually and in combination on membrane lipid profiles of the LuCaP35CR tumors.

Results: CS cell lines were sensitive to single agent treatments with ENZ ($p<0.0001$), ATO ($p<0.0001$) and TVB ($p<0.01$ to $p<0.0001$); combination therapies also reduced cell proliferation significantly (all $p<0.0001$). CR lines were resistant to ENZ but responded to TVB ($p<0.0001$) and ATO treatments ($p<0.0001$); combined treatments also reduced the number of live cells (all $p<0.0001$). In the pre-clinical LuCaP35CR model, TVB exposure led to a sensitization to ENZ, which was augmented by further exposure to ATO. The triple combination kept tumors at the baseline volume throughout treatment ($p<0.0001$). Phospholipidomics demonstrated that TVB directed FASN inhibition, alone and in combination with ENZ and ATO, led to a significant decrease in membrane MUFA ($p<0.0001$) and a significant increase in membrane PUFA ($p<0.0001$). In addition, there was a significant decrease in AR expression in the ENZ+TVB treated tumors compared to control ($p<0.0001$), ENZ alone ($p<0.001$), or TVB alone ($p<0.0001$).

Conclusions: We adopted a therapeutic strategy in rendering CRPC ROS sensitive. Specifically, we used the FASN inhibitor TVB-3664 to elevate membrane PUFA, together with ENZ and the ROS elevating drug ATO. Critically, this clinically actionable combination therapy dramatically decreased the growth of pre-clinical cell lines and PDX models. Our results demonstrate the applicability and potential of a ROS sensitizing strategy in the treatment of CRPC.

#3111 PI3K-dependent GAB1/Erk phosphorylation renders head and neck squamous cell carcinoma sensitive to PI3Kα inhibitors.

Xu Zhang[1], Jiao Xu[1], Xuan Wang[1], Lan Xu[1], Xi Zhang[1], Yi Wang[1], Shujuan Jiang[2], Yixiang Zhang[2], Jian Ding[1], Chen Qing[3], Linghua Meng[1]

[1]Shanghai Institute of Materia Medica, Shanghai, China,[2]Haihe Biopharma, Shanghai, China,[3]Kunming Medical University, Yunnan, China

Head and neck cancer is the seventh most common cancer in the world, of which about 90% are head and neck squamous cell carcinoma (HNSCC). Frequent alterations of *PIK3CA* in HNSCC suggest that PI3Kα is a promising target for HNSCC treatment. CYH33 is a novel PI3Kα-selective inhibitor discovered by our group, which is currently undergoing a phase I clinical trial (NCT03544905) for the treatment of advanced solid tumors, including HNSCC. However, there is an urgent need to elucidate its mechanism of action and improve its efficacy against HNSCC. In this study, we found CYH33 displayed promising but variable therapeutic activity against HNSCC. Inhibition of PI3K/Akt pathway by CYH33 was not sufficient for its activity against HNSCC. Tandem-Mass-Tag (TMT) proteomics and phosphoproteomics were performed to reveal comprehensive regulation of kinome by CYH33. Among them, phosphorylation of MAPK1/Erk at activation sites (T185/Y187) were significantly attenuated by CYH33 in sensitive HNSCC cells. CYH33 significantly suppressed phosphorylation of Erk in sensitive but not resistant cells. Further inhibition of Erk phosphorylation enhanced the activity of CYH33 against HNSCC. Signaling network of differentially phosphorylated proteins illustrated that phosphorylation at multiple sites (Y659, Y406, S651, S648) of the adaptor protein GAB1, which integrates the signaling from PI3K and receptor tyrosine kinases, were significantly downregulated upon CYH33 treatment. CYH33 dose-dependently suppressed the phosphorylation of GAB1 at Y659 in sensitive HNSCC cells, whereas it had little effect in resistant cells. We found that CYH33 attenuated the membrane localization and phosphorylation of GAB1, resulting in reduced Erk phosphorylation and ultimately inhibiting the proliferation of sensitive cells. Meanwhile, activation of EGFR induced GAB1 phosphorylation independent of PI3K in HNSCC. Concurrent inhibition of EGFR synergistically potentiated the activity of CYH33 against HNSCC.In conclusion, we found that PI3Kα-selective inhibitor CYH33 displayed potent activity against HNSCC, which was associated with inhibition of Akt signaling as well as attenuation of PI3K-dependent GAB1/Erk phosphorylation. Simultaneous inhibition of GAB1 phosphorylation independent of PI3K potentiated the anti-HNSCC activity of CYH33. These findings revealed the insight mechanism of CYH33 against HNSCC and provided rational combination regimen for HNSCC.

#3112 Pralsetinib induces opportunistic infection in RET fusion-positive NSCLC patients via inhibition of IL-2 production by blocking Jak3/Stat5 activation.

Shinkyo Yoon[1], **Hyun-Min Ryu**[1], Eunjin Lee[1], Yunkyung Sung[1], Ho-Su Lee[2], Ji Eun Park[3], Chang Hoon Lee[4], Seyoung Seo[1], Sang-We Kim[1], Kang-Seo Park[1], Dae Ho Lee[1]

[1]Oncology, Asan Medical Center (AMC), Seoul, Korea, Republic of,[2]Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, Korea, Republic of,[3]Radiology and Research Institute of Radiology, Asan Medical Center (AMC), Seoul, Korea, Republic of,[4]Oncology, SCBio, Daejeon, Korea, Republic of

Background: Oncogenic alteration in RET, representing 1-2% of NSCLC, is an important target. Pralsetinib is a selective RET inhibitor targeting RET fusions. We present a case series on opportunistic infections and the mechanism of immunosuppression.
Methods: From October 2021 to March 2022, we administered pralsetinib to a total of 15 patients with NSCLC harboring RET fusion. We retrospectively analyzed the clinical efficacy and adverse events related to pralsetinib. To investigate pralsetinib's impact on T-cells, we examined cytokine release using ELISA from Jurkat T (JT) cells after pralsetinib treatment. To test if Stat5 binds to the IL-2 promoter, we conducted Chromatin Immunoprecipitation (ChIP).
Results: Out of 18 patients with measurable disease, 14 (93%) achieved a partial response. With a median follow-up duration of 8.7 months, four cases of opportunistic infections occurred. Notably, three patients (16.6%) experienced invasive pulmonary aspergillosis, and one patient (5.5%) experienced cytomegalovirus pneumonia. To investigate mechanisms behind these observations, we aimed to replicate conditions similar to those of activated T cells. Thus, JT cells were treated with PMA and ionomycin to induce IL-2 release through NFAT, AP-1, and NF-κB binding to the IL-2 promoter. After ~2 weeks of pralsetinib treatment, Jak3 signaling was inhibited, leading to decreased IL-2 release by downregulating transcription factors associated with IL-2 production, such as JunB/c-Jun and Stat5, which are downstream components of Jak3 signaling. Additionally, to investigate the direct correlation between Jak3 and IL-2 release, JT cells were treated with ritlecitinib, a Jak3-selective inhibitor, for ~2 weeks. Like pralsetinib, a reduction in IL-2 release was observed. Furthermore, based on the evidence that Stat5 inhibition leads to reduced IL-2 release, we showed that Stat5, a direct downstream component of Jak3, binds to the IL-2 promoter during activation of Jurkat T cells.
Conclusion: Pralsetinib, not Selpercatinib, inhibits additional IL-2 production by blocking Jak3/Stat5 activation triggered by IL-2 released during early T cell activation. Consequently, Jak3 inhibition by pralsetinib suppresses IL-2 release by inhibiting the activation of transcription factors for IL-2, such as JunB/c-Jun and Stat5, thereby inducing opportunistic infections, including invasive pulmonary aspergillosis (IPA), cytomegalovirus (CMV) pneumonia, CMV viremia, and pneumocystis pneumonia.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Therapeutic Approaches to Attack the Tumor Microenvironment Poster Session

#3118 IBI3026, a first-in-class anti-PD-1/IL-12 fusion protein, demonstrates the potential to be a new immuno-oncology therapy by releasing the break in immune response and strongly activating T and NK cells in the tumor microenvironment.

Xinran Liu, Fenggen Fu, Shuaixiang Zhou, Weiwei Wu, Haoyu Wen, Yang Liu, Min Wu, Meng Ni, Yan Liu, Enhong Zhong, Yayao Yan, Ying Zhang, Zhihai Wu, Yuting Wei, Kaijie He

Innovent Biologics (Suzhou) Co. Ltd, Jiangsu, China

Interleukin 12 (IL-12) is a cytokine that is able to activate both innate (NK cells) and adaptive (T cells) immunities, making it an ideal candidate for immuno-oncology therapy. Administration of IL-12 drugs locally has shown promising clinical results in treating tumors. However, when applying IL-12 systemically, severe dose-limiting toxicities are induced, greatly impeding the drug development process and its potential in cancer treatment. Herein, we designed IBI3026, an immune agonist that targets both IL-12 receptor and PD-1. By weakening the potency of IL-12, the safety profile of IBI3026 is extensively improved, guaranteeing the feasibility of systemic drug administration. By incorporating a high affinity, bivalent anti-PD-1 antibody, in addition to blocking PD-1/PD-L1 signaling pathway, IBI3026 could be efficiently enriched to PD-1+ T cells for maximal IL-12 activation in the tumor microenvironment. This “cis-activation” mode largely widened the therapeutic window of IL-12. *In vitro*, IBI3026 potently activates CD3/CD28-pretreated human PBMCs (hPBMCs) by showing strong STAT4 phosphorylation and high IFN-gamma secretion, while leaving untreated hPBMCs intact. In EMT6 (triple-negative breast cancer) and CT26 (colorectal cancer) cell line-derived xenograft (CDX) models, IBI3026 mouse surrogate strongly inhibited tumor growth with complete response in nearly all mice. In humanized A375 (melanoma) and BxPC-3 (pancreatic cancer) CDX models, IBI3026 showed much stronger tumor inhibitory effects than IBI308 (anti-PD-1 monoclonal antibody) and showed good safety profiles. In pilot toxicity studies, cynomolgus monkeys were administered 3 weekly doses of 10, 30, 80, and 150 mg/kg IBI3026 intravenously. No mortality or serious toxicities were observed in any group. The highest non-severely toxic dose (HNSTD) of IBI3026 is 150 mg/kg and the calculated therapeutic index is 63. These results demonstrate the good safety profile of IBI3026. In conclusion, IBI3026 is a first-in-class anti-PD-1/IL-12 immune agonist with high tumor inhibition potential and excellent safety profiles.

#3119 Next-generation multi-specific and conditionally activated CD3 Switch-DARPins with CD2 co-stimulation to tackle the current limitations of T cell engagers in solid tumors.

M. Bianchi[1], M. Franchini[1], T. Lekishvili[1], E. Tselempi[1], J. Robinson[1], Y. Kaufmann[1], G. Ems[1], C. Friang[1], C. Tissier[2], M. R. Muller[1], A. Link[1], C. Borg[2], A. Croset[1], V. Calabro[1], A. Goubier[1], **M. Guzman Ayala**[1];

[1]Molecular Partners AG, Schlieren, Switzerland, [2]UMR1098 INSERM, University of Bourgogne Franche-Comte, Besancon, France

Introduction: T-cell engagers (TCE) are powerful and clinically validated cancer therapeutics but are limited by high toxicity, lack of tumor-specific targets, and presence of exhausted/dysfunctional T cells particularly in solid tumors. Our CD3 Switch-DARPin platform provides a logic-gated “on/off” function (“Switch”) to increase tumor specificity and enable strong CD3 engagement and activation without compromising safety. Additionally, a DARPin with a co-stimulatory function can be added to enhance T-cell responses, especially in the context of an adverse tumor microenvironment. Using ovarian cancer (OC) as a proof-of-concept indication, we designed a multi-specific CD3 Switch-DARPin with CD2 co-engagement (CD2 x CD3 Switch-DARPin) which targets two tumor-associated antigens (TAAs); mesothelin and EpCAM. The logic-gated function of our Switch-DARPin ensures that the CD3 moiety is able to bind and activate T cells only when the TAAs are expressed on target cells. Herein we present a Switch-DARPin TCE that safely sustains anti-tumor efficacy, providing new TAA options and expanding TCE use in solid tumors.

Methods: RNAseq phenotypic analyses of OC patient samples were validated on resected tumors and ascites using flow cytometry and immunohistochemistry. The specific activity and safety of our CD2 x CD3 Switch-DARPin were assessed *in vitro* and *ex vivo* using reporter cells, primary human T cells from healthy donors and OC patient ascites, whole blood cytokine release assays, and *in vivo* in PBMC-humanized NXG mice engrafted subcutaneously with mesothelin- and EpCAM-expressing cells.

Results: Our analysis confirmed that mesothelin and EpCAM are highly co-expressed in OC tumors. Furthermore, reduced expression of CD28 compared to CD2 on tumor-infiltrating lymphocytes, combined with CD58 downregulation on primary tumors and ascites, support the use of CD2 as a co-stimulatory receptor for T cell engagement in OC. Functionally, the CD2 x CD3 Switch-DARPin abrogated TAA-independent T-cell activation and reduced potential on-target off-tumor toxicity, while CD2 co-engagement sustained T-cell response and prevented T-cell dysfunction. Notably, *in vivo,* the CD2 x CD3 Switch-DARPin induced significant tumor regression without causing systemic release of cytokines in the blood. In contrast, a control molecule without the Switch led to systemic cytokine release and showed no antitumor efficacy, likely due to fratricide-mediated depletion of T cells.

Conclusions: Our CD3 Switch-DARPin platform provides a novel approach for sustained tumor-specific T-cell engagement, by combining a logic-gated on/off Switch mechanism with CD2 co-stimulation. This allows immune activation to be directed to tumors, increasing efficacy and safety and paving the way for new opportunities for cancer treatment.

#3120 Evaluation of PYX-201, an EDB+FN-targeting ADC, in a comprehensive PDX mini-trial study enables identification of gene signatures associated with anti-tumor activity.

Amanda Facklam, Justin Trickett, Sara Lewandowski, Chuan Shen, Frank Wang, Marsha Crochiere, Nicolas Severe, Jan Pinkas

Pyxis Oncology, Boston, MA

PYX-201, a first-in-concept non-cellular targeting antibody-drug conjugate (ADC), is currently being tested in a Phase 1 clinical trial in a variety of solid tumors (NCT05720117). PYX-201 is designed to bind specifically to the extra-domain B splice variant of fibronectin (EDB+FN), a component of the extracellular matrix found in various solid tumors with absent or low expression in normal adult tissue (Hooper, 2022). Extracellular proteases can cleave the valine-citrulline peptide linker to release the optimized toxic payload Auristatin0101 into the tumor microenvironment which diffuses into tumor cells and induces cell killing. A comprehensive mini-trial study has been conducted to measure PYX-201 anti-tumor efficacy in multiple patient-derived xenograft (PDX) mouse models selected from ten solid tumor indications. Building on our previous analysis (Severe, 2024), full mini-trial results demonstrate that PYX-201 (3mg/kg, Q4Dx4) was well tolerated and resulted in broad anti-tumor activity as calculated by the Tumor Growth Inhibition percentage (%TGI) at study end for each individual PDX model. Our results show that 25% were non-responders (TGI<25%), 30% moderate (25% <TGI<70%), 20% strong (70%<TGI<90%) and 25% very strong responders (TGI>90%). Remarkably, PDX models with very strong PYX-201 responses (TGI>90%) were found across 9/10 solid tumor indications. Additionally, mice with complete responses to PYX-201 (tumor volume reached 0mm^3 for at least two consecutive measurements) were found across several tumor indications. To investigate gene expression changes relevant to PYX-201 mechanism of action, a satellite mouse was included on study for tumor collection for each PDX model prior to treatment. To determine which gene signatures may be associated with PYX-201 response, analysis was performed on RNA extracted from satellite tumor samples. The Nanostring ADC Development panel was selected for expression analysis across 750 human genes. A comparison between PDX models with very strong PYX-201 responses (TGI>90%) to PYX-201 non-responders (TGI<25%) with all tumor indications combined identified several genes which were differentially expressed. In addition, gene set analysis was performed to identify gene categories which were associated with PYX-201 response. The gene sets with the greatest number of differentially expressed genes in our analysis were tumor stroma and enzymes, indicating these categories are important for PYX-201 response in pre-clinical PDX models. Overall, PYX-201 showed broad anti-tumor activity in PDX pre-clinical models, suggesting it is a promising ADC for further testing across solid tumor indications. Furthermore, tumor stroma and protease genes were associated with PYX-201 activity in PDX models, providing further insight into PYX-201 mechanism of action.

#3121 DWP217, a novel Arginase inhibitor enhancing tumor immunity through tumor microenvironment reprogramming.

Seung Jae Jeong[1], Wolyoung Kim[1], Ji-Hae Kim[1], Sujin Ha[1], Youngwoo Choi[1], Jiyoon Seok[1], Ye Gi Han[1], Jong Cheol Shon[1], Hyoungrok Bak[1], Eunmi Hong[2], Jonghyeon Son[2], Kyung Seok Oh[1], Ji-Duck Kim[1], Joon Seok Park[1]

[1]Daewoong Pharmaceutical Company Ltd., Yongin-si, Korea, Republic of,[2]New Drug Development Center, Daegu-Gyeongbuk Medical Innovation Foundation, Daegu, Korea, Republic of

Checkpoint inhibitors have transformed cancer immunotherapy, yet their efficacy is often undermined by the immunosuppressive tumor microenvironment (TME). Arginase, a key enzyme secreted by myeloid-derived suppressor cells and tumor-associated macrophages, contributes to this suppression by depleting arginine, a critical nutrient for T-cell and NK cell activation. Elevated Arginase activity is associated with immune resistance and diminished response to immunotherapy, highlighting it as a promising target to reprogram the TME and restore antitumor immunity. Preclinical evaluation of DWP217 revealed its potent ability to inhibit Arginase activity, enabling T-cell proliferation and reversing immune cell dysfunction. Structural analyses uncovered a unique binding mechanism, supporting the rational design of an optimized compound series with enhanced potency. In combination with anti-PD-1 antibodies, DWP217 achieved significantly better tumor control and survival outcomes in syngeneic cancer models compared to anti-PD-1 monotherapy. Notably, DWP217 outperformed competing Arginase inhibitors that had advanced to clinical trials, underscoring its superior efficacy and potential as an immune-oncology therapeutic candidate. Immune profiling revealed that DWP217 enhances tumor-infiltrating lymphocyte activation and reprograms the TME toward a pro-inflammatory state. These findings indicate that DWP217 not only counteracts Arginase-mediated immune suppression but also reshapes the TME to support durable antitumor immunity. With its strong preclinical efficacy and favorable immune modulation profile, DWP217 is a promising therapeutic candidate for overcoming immuno-oncology resistance. Its further development holds the potential to significantly improve therapeutic outcomes in refractory solid tumors.

#3122 A novel solid tumor-tissue-penetrating platform technology: Overcoming tumor microenvironment barriers for an effective targeted delivery of therapeutic agents into solid tumors.

Serry Koh, Ji-young Lee, Young Pil Jung, Won-seok Choi, Min Gyu Soung

Cellicon Lab Inc., Daejeon, Korea, Republic of

The tumor microenvironment (TME)—comprising tumor vasculature, stromal cells, immune cells, and extracellular matrix (ECM)—presents significant challenges for effective anticancer therapy delivery. To address these challenges, we developed a novel solid tumor-tissue penetrating (STTP) platform featuring DST-516, a tumor-penetrating peptide designed to enhance tumor-specific delivery and deep penetration of therapeutic agents into solid tumors. Preclinical studies demonstrated that DST-516 outperformed the iRGD control in terms of tumor penetration. Confocal laser scanning microscopy (CLSM) revealed that co-administration of DST-516 with fluorescently labeled doxorubicin (10 mg/kg) and 70 kDa albumin (10 mg/kg) resulted in profound and extensive tissue penetration. Enhanced distribution was observed over a period of 1 to 24 hours in AsPC-1 xenograft mouse models. The efficacy of fluorescently labeled doxorubicin penetration was further validated in both 3D PANC-1 and 3D AsPC-1 spheroids. Co-administration of DST-516 with gemcitabine and paclitaxel resulted in a significantly greater reduction in pancreatic tumor volume compared to either drugs alone or in combination with iRGD, demonstrating enhanced therapeutic efficacy *in vivo*. The efficient delivery of 70 kDa albumin to pancreatic tumors via co-administration with DST-516 highlights its potential for transporting large molecules, laying a strong foundation for future applications in antibody-drug conjugates (ADCs) and other advanced cancer therapies through the STTP platform. Mechanistic studies demonstrated that DST-516 preferentially binds to neuropilin-1 (NRP-1) and integrins αvβ3/αvβ5 in AsPC-1 cells, with minimal binding in siNRP-1-transfected AsPC-1 cells, emphasizing DST-516's tumor specificity. This specificity suggests that DST-516 could minimize off-target toxicity while maximizing therapeutic efficacy. Comprehensive safety evaluations, including nine preclinical toxicology studies, confirmed DST-516’s tolerability, with no significant adverse effects observed in single- or repeated-dose intravenous toxicity or genetic toxicity assessments. These results support its translational feasibility and clinical development potential. In conclusion, our findings establish DST-516 and the STTP platform as a promising strategy to overcome TME-mediated resistance, enabling safe and efficient delivery of therapeutic agents to solid tumors. Future studies will expand its applications across various solid tumor types and further refine its mechanism of action. This platform represents a pivotal step toward advancing precision oncology and improving outcomes for patients with hard-to-treat cancers.

#3123 Fracturing the tumor-bone alliance in metastatic prostate cancer with Ra-223.

Radium-223 dichloride (Ra-223) is a calcium-mimetic alpha-emitting radiopharmaceutical homing to bone, approved for the treatment of bone metastases in castration-resistant prostate cancer (CRPC), significantly prolonging overall survival in patients with advanced disease. This study integrates preclinical and clinical studies to investigate the effects of Ra-223 on tumor volume, bone structure, transcriptomics alterations, and to identify biomarkers of therapeutic response to Ra-223. Using patient-derived xenografts (MDA PCa PDX), which mimic the hallmark characteristics of clinical bone-forming metastases, mice with tumor-bearing and non-tumor-bearing bones were treated with Ra-223 or vehicle. Tumor burden was monitored via magnetic resonance imaging (MRI), bone parameters were assessed through microCT and bone histomorphometry, and transcriptomics changes were evaluated using RNA sequencing in both, tumor and stroma. Ra-223 treatment significantly reduced tumor volume and altered bone architecture, promoting bone remodeling and increasing bone density. Histomorphometric analysis revealed suppressed osteoclast activity in both tumor-bearing and non-tumor-bearing bones treated with Ra-223, with a more pronounced effect in non-tumor-bearing sites. Transcriptomic profiling identified differential expression of immune, metabolic, and cell-cycle pathways, with TP53 and MYC as central regulators. Additionally, we analyzed human serum samples from patients with CRPC bone metastases. We profiled novel candidate protein markers of Ra-223 response on serial serum samples collected at baseline (prior to initiation of Ra-223 treatment), on-treatment (OT), and at end of treatment (EoT) from 25 patients enrolled in a single-center, open-label clinical study (NCT02135484). Subjects received six intravenous doses of Ra-223 (50 kBq/kg) every four weeks, unless they experienced disease progression or toxicity, or until withdrawal. Our analysis highlighted IL18, SPARC, MET, TFF3 and TNFSF11 as survival-associated proteins significantly deregulated in patients receiving Ra-223 therapy. In particular, multivariable analyses showcased that elevated levels of TFF3 were independently linked to lower overall survival and possible resistance to Ra-223, suggesting its potential as a predictive biomarker of treatment efficacy. In summary, our findings suggest that Ra-223 has a more extensive impact on the tumor-bone microenvironment than previously understood. The increases in bone density and associated transcriptomics alterations pave the way for future investigations into combination therapies that enhance Ra-223's benefits while addressing potential risks. Considering the clinical importance of TFF3, further validation in larger patient cohorts is essential to refine treatment strategies to improve outcomes for patients with CRPC bone metastases.

#3126 Tumor microenvironment composition is shaped by tumor cell line-derived xenograft subtype and tumor burden in BRGSF-HIS mice.

Florent Creusat, Siham Hedir, Alexis Gonon, Amelie Marguier, Yacine Cherifi, Fabiane Sonego, Gaelle Martin, **Kader Thiam**

genOway, Lyon, France

Emergence of immunotherapies for treating cancer has been an important step towards a more efficient, selective and safe approach for patients. However, only a fraction of patients can respond to treatments currently available, requiring the identification of additional therapeutic targets. The relevance of preclinical models in the identification of new therapeutic targets and assessment of immunotherapies has vastly improved with mice bearing a human immune system. BRGSF (Balb/C $Rag2^{-/-}$, $IL2R\gamma^{-/-}$, SIRPαNOD and $Flt3^{-/-}$) is a highly immunodeficient mouse featuring reduced murine myeloid cells. BRGSF mice reconstituted with human cord blood $CD34^+$ cells (BRGSF-HIS) develop functional lymphoid and myeloid compartments. This engraftment is stable for over a year (Labarthe *et al.*, 2019) and mice do not develop GvHD. Human myeloid compartment can be transiently boosted with exogenous human Flt3L injections. In contrary to other models, which overexpress human cytokines to develop human myeloid cells, Flt3L-treated BRGSF-HIS mice do not show side effects. BRGSF-HIS mice are permissive to mouse and human cancer cell lines engraftment and represent a valuable preclinical model to study cancer development and evaluate novel therapeutics. Here, we show that composition of tumor microenvironment (TME) is tumor burden-dependent. Indeed, BRGSF-HIS mice engrafted with triple negative cancer cell line MDA-MB-231 have a diverse TME, enriched in myeloid cells. The major cell type present in tumors of approximately 200mm^3 is $CD206^+$/$CD163^+$ M2-like macrophages, which express high levels of PD-L1 and other immunomodulatory proteins. At this tumor volume, TME is also composed of a small fraction of T cells. However, the frequency of conventional $CD4^+$T cells increase from <5% to 15% of human infiltrate when tumors reach approximately 500 mm^3. Interestingly, NK cells are detected at very low levels in tumors of 200 mm^3, but increase to 10% in the TME of tumors of 500 mm^3. The infiltration of human immune cells in the TME is also tumor type-dependent, as in a colon-derived adenocarcinoma SW480 tumor model, conventional $CD4^+$ T cells are the major cell type present in the TME (40%) of tumors of 200 mm^3. Interestingly, these tumors show an infiltrate of γδ T cells as well, ranging from 6% to 8%of human immune cells in tumors of 200 mm^3 and 800 mm^3, respectively. BRGSF-HIS mice hence represent a valuable tool to investigate immune cell infiltration in the TME, enabling a translatable assessment of mechanism of action of immunotherapies.

#3127 An mRNA-encoded masked IL-12 improves systemic tolerability while maintaining anti-tumor efficacy in preclinical studies.

Kanchana Ravichandran[1], Erwan LeScolan[2], Na Cai[2], Bruce Howng[2], Robert Lau[2], Lisa Clark[2], Joshua Millet[2], Pankaj Kumar[3], Sushma Gurumurthy[1], Raghava Sriramaneni[2], Sean McAllister[2], Vangipuran Rangan[2], Olga Vasiljeva[2], Madan Paidhungat[2], Dylan Daniel[2], Marcia Belvin[2], Lin Guey[1]

[1]Moderna, Cambridge, MA,[2]CytomX Therapeutics, San Francisco, CA,[3]Demeetra, Lexington, KY

IL-12 is a potent pro-inflammatory cytokine that has shown promising anti-tumor activity through its ability to activate both innate and adaptive immune cells. However, systemically administered IL-12 has limited clinical utility due to striking inflammatory toxicity and short half-life leading to a narrow therapeutic margin. Alternative strategies to reduce systemic exposure or restrict IL-12 activity to the tumor microenvironment and limit activity in circulation and non-tumor tissues have been explored. Using CytomX proprietary PROBODY® Therapeutics masking technology and Moderna mRNA technology, we describe a novel product concept of an mRNA encoded masked IL-12 molecule that is designed to have reduced activity systemically. Masked IL-12 is activated by elevated protease activity associated with the tumor microenvironment (TME), leading to preferential IL-12 activity in the tumor microenvironment. mRNA-encoded masked IL-12 protein showed 200X lower cell-based potency relative to an unmasked IL-12 counterpart and regained full activity upon protease-mediated cleavage of the mask *in vitro*. In an *in vivo* MC-38 tumor-bearing mouse model, systemically administered LNP encapsulated mRNA encoding masked IL-12 showed significantly improved tolerability (>30X) compared to unmasked IL-12. Consistently, masked IL-12 mRNA led to significantly lower serum IFNγ levels relative to unmasked IL-12 mRNA dosed at 10X lower dose. Most importantly, masked IL-12 mRNA dosed systemically resulted in complete remission of tumors in all dose levels and demonstrated protease-dependent intra-tumoral activation and efficacy. Taken together, these data show a novel and attractive engineering approach to develop an mRNA-encoded IL-12 therapeutic that significantly improves tolerability while maintaining potent anti-tumor activity.

#3128 Nonclinical efficacy and safety evaluation of IL-12 mRNA delivered by a novel lipid nanoparticle.

Qing He[1], Chunyan Dong[1], Dejiang Tan[1], Huimin Sun[1], Yiyang Zheng[1], Zhuang Li[1], Linyu Zhang[1], Sihan Liu[1], Yu Zhang[1], Jijun Yuan[2], Peng Gao[2], Liang Du[2], Huayuan Yan[2], Bo Ying[2]

[1]State Key Laboratory of Drug Regulatory Sciences, National Institutes for Food and Drug Control, Beijing, China,[2]Suzhou Abogen Biosciences, Suzhou, China

Interleukin-12 (IL-12) is considered to be a promising cytokine for enhancing anti-tumor immune response. However, systemic recombinant IL-12 had significant toxicity and limited efficacy in early clinical trials. Recently, many strategies to express IL-12 in the tumor tissue are being pursued preclinically and in clinical trials. Here, we report on ABO2011 (LNP-IL12 mRNA), developed by Abogen Bioscience, an innovative mRNA therapeutic cancer vaccine with novel lipid nanoparticles encoding IL-12.The LNP-IL12 mRNA significantly activates a robust T-cell-mediated adaptive immune response and exhibits strong anti-tumor potential. In the anti-tumor efficacy evaluation of B16F10, MC38 and EMT6 tumor-bearing mice, LNP-IL12 mRNA successfully eradicated tumors with a single administration. In the preliminary evaluation of safety, LNP-IL12 mRNA treatment did not significantly change body weight, HE staining of major organs did not significantly change, and serum cytokine levels were extremely low, indicating a good safety. Flow cytometry detected that LNP-IL12 mRNA induced large infiltration of total lymphocytes in B16F10, MC38 and EMT6 tumor-bearing mice, especially the proportion of cytotoxic $CD8^+$ T cells and NK cells increased significantly, while the proportion of immunosuppressive Treg cells decreased. In addition, the levels of pro-inflammatory factors such as IL-1β, IL-6, IFN-γ and TNF-α in tumors induced by LNP-IL12 mRNA were significantly increased by CBA method, but IL-10 was not detected. It was shown that LNP-IL12 mRNA mediated immunotherapy can safely and effectively induce a strong immune response. In conclusion, we conducted relevant evaluation studies with LNP-mIL12 mRNA as an example, trying to establish non-clinical efficacy evaluation criteria for mRNA therapeutics.

#3129 Fibroblast activation protein directed CAR T cells engineered *in situ* using targeted lipid nanoparticles inhibit progression of pancreatic ductal adenocarcinoma.

K. Bajbouj[1], Z. Xiao[1], L. A. Hopper[1], L. Huang[1], T. E. Papp[1], J. Ramani[1], A. Bot[2], Y. Bao[2], M. Butcher[2], H. Aghajanian[2], C. H. June[1], D. Weissman[1], H. Parhiz[1], S. M. Albelda[1], E. Pure[1];

[1]University of Pennsylvania, Philadelphia, PA, [2]Capstan Therapeutics, San Diego, CA

The growth of solid tumors is greatly influenced by stromal components including cancer-associated fibroblasts (CAFs) and desmoplastic matrix through both immune-dependent and immune-independent mechanisms. Fibroblast activation protein (FAP) is a stromal cell target that is selectively expressed at high levels on the cell surface of CAFs. We previously established an *ex vivo* retroviral-transduced CAR T cell approach to target FAP^+ CAFs that resulted in depletion of FAP^+ stromal cells, disruption of desmoplastic matrix, enhanced immune infiltration, and inhibition of tumor growth. In this study, we generated FAP-CAR T cells *in situ* using a novel platform to deliver modified FAP-CAR mRNA encased in anti-CD5 conjugated targeted lipid nanoparticles (tLNPs) and assessed the efficacy of this approach in a preclinical model of pancreatic ductal adenocarcinoma utilizing a cell line derived from a spontaneous pancreatic tumor isolated from a genetically engineered KPC mouse. We found that a single intravenous dose of anti-CD5 tLNP loaded with 30 µg of FAP-CAR mRNA resulted in transient FAP-CAR expression on >45%, >69% and >35% of CD3 T cells in spleen, blood and tumor tissues, respectively. Although CAR expression was more transient, the percentage of $FAP\text{-}CAR^+$ T cells generated using this approach was significantly greater than the percentage of $FAP\text{-}CAR^+$ cells detected following administration of $1X10^7$ *ex vivo* retrovirally transduced FAP-CAR T cells. Notably, this *in situ* mRNA CAR T-cell engineering resulted in significantly increased inhibition of tumor growth, as compared to adoptive transfer of *ex vivo* retroviral-engineered T cells (74% vs 48%) respectively. Given that this approach circumvents the need for autologous T cell isolation, *ex vivo* viral transduction and expansion (thereby reducing the potential risk of insertional mutagenesis, while also eliminating the need for pre-conditioning by lymphodepletion), our data indicate a promising therapeutic delivery platform for treating desmoplastic solid tumors using a more accessible and cost-efficient technology.

#3130 Differential gene expression regulation by the RXR agonist V-125 in MMTV-Neu mammary tumors.

A. Chowdhury[1], L. A. Reich[2], C. J. Occhiuto[2], K. T. Liby[1];
[1]Indiana University School of Medicine, Indianapolis, IN, [2]Michigan State University, East Lansing, MI

Retinoid X receptors (RXRs) are nuclear receptors that play a pivotal role in regulating gene expression by forming homodimers and heterodimers with other nuclear receptors. When activated, RXRs influence various cellular processes, including cell differentiation, proliferation, and apoptosis. This regulatory activity makes RXR agonists promising candidates in cancer research. However, the specific gene expression changes induced by RXR agonists can vary depending on the compound, reflecting their unique interactions within cellular environments and signaling networks. In this study, RNA sequencing was performed to compare the molecular pathways activated by the novel compound V-125 and FDA-approved drug bexarotene in mammary tumors of a mouse model of HER2+ breast cancer (MMTV-Neu mice). By analyzing the transcriptomic profiles, we identified that each treatment differentially regulated cancer-relevant gene categories, including focal adhesion, regulation of actin cytoskeleton, and extracellular matrix-receptor interaction. The most significantly altered genes by V-125, including *Lrrc26, Mgarp, Aldh1a3*, and *Colca2* are positively correlated with improved survival in breast cancer patients. While V-125 and bexarotene act on many common pathways, they induce distinct gene expression profiles. V-125 primarily targets focal adhesion and extracellular matrix-receptor interaction pathways, whereas bexarotene affects the regulation of actin cytoskeleton and NF-kappa B signaling pathways. We confirmed the significant differential expression ($p<0.05$) of key genes (*Nrg1, Nfasc, Chi3l1, Slit2*) at both the mRNA and protein levels using quantitative PCR (qPCR) and immunohistochemistry (IHC). Beyond cancer cells, RXR modulation influences the tumor microenvironment, including immune cells. Our transcriptomic analysis revealed that RXR agonist treatment affects pathways associated with macrophage activation and phagocytosis. This suggests the role of RXR in the polarization of macrophages, an important immune population related to breast cancer. To investigate this further, we utilized bone marrow-derived macrophages (BMDMs) to evaluate the impact of V-125 and bexarotene treatment on macrophage polarization toward a tumor-suppressive phenotype. Upon treatment, the polarization status of macrophages was assessed through gene expression analysis by qPCR. We observed that BMDMs treated with 300nM of either RXR agonist significantly ($p <0.05$) increased mRNA expression of IRF7 and TLR9, associated with a pro-inflammatory, anti-tumor phenotype. This comprehensive approach allowed us to determine the relative effectiveness of V-125 and bexarotene in modulating gene expression and polarizing macrophages toward a tumor-suppressive phenotype, providing valuable insights into their therapeutic potential and the underlying molecular mechanisms.

#3131 In vitro analysis of collagen deposition in lung cancer-associated fibroblasts using clinically validated biomarkers.

Annika Hettich, Morten Karsdal, Nicholas Willumsen

Nordic Bioscience, Herlev, Denmark

Background: Lung cancer remains the leading cause of cancer-related mortality worldwide, affecting both men and women. This high mortality rate is largely due to the frequent ineffectiveness of interventions and the late-stage diagnosis of the disease, which typically limits available treatment options. Within the tumor stroma of lung cancers, cancer-associated fibroblasts (CAFs) play a crucial role in tumor progression and metastasis by depositing extracellular matrix (ECM) components, such as collagens. To further understand lung cancer biology and support drug discovery, novel tools that replicate the tumor microenvironment are essential. In this study, we developed a pseudo-3D in vitro model incorporating healthy normal lung fibroblasts (lNFs) or lung cancer-associated fibroblasts (lCAFs), combined with clinically validated collagen-based biomarkers, as a translational platform for anti-fibrotic drug screening.
Methods: Primary human CAFs from lung adenocarcinoma (lCAFs) and normal lung fibroblasts (lNFs) were cultured for 12 days in ficoll-based media supplemented with ascorbic acid under unstimulated conditions and with TGF-β stimulation. Additionally, cells were treated with the ALK5/TGF-β1 receptor kinase inhibitor (ALK5i) and Fresolimumab, a human monoclonal antibody targeting all TGF-β isoforms. Collagen type I (PRO-C1), III (PRO-C3), and VI (PRO-C6) levels were measured in the cell supernatant on days 3, 6, 9, and 12 using competitive enzyme-linked immunosorbent assay.
Results: TGF-β1 stimulation increased type I, III, and VI collagen deposition in both lCAFs and lNFs. Notably, lCAFs showed higher type I collagen formation than lNFs, even after treatment. While untreated lCAFs and lNFs exhibited no type III collagen formation, TGF-β1 treatment significantly induced PRO-C3, with higher levels in lNFs than in lCAFs. PRO-C6 levels were initially comparable in untreated lCAFs and lNFs, yet TGF-β1 stimulation led to a significant increase in type VI collagen in lCAFs compared to a smaller increase in lNFs. Treatment with ALK5i and Fresolimumab reduced levels of PRO-C1, PRO-C3, and PRO-C6 in both lCAFs and lNFs.
Conclusion: The pseudo-3D in vitro model using lCAFs and lNFs successfully replicates key aspects of the lung tumor microenvironment, particularly the differential collagen deposition patterns. The model demonstrated that lCAFs exhibit distinct collagen formation responses to TGF-β1, especially in type I and VI collagens, compared to lNFs. Additionally, treatment with ALK5i and Fresolimumab effectively reduced collagen formation, underscoring the model's potential for preclinical anti-fibrotic drug screening. These findings support the model's application in studying CAF-driven ECM remodeling and assessing therapeutic responses in lung cancer.

#3132 Innovative development of IMB-201, an anti-HLA-G antibody-drug conjugate (ADC), for enhanced tumor immunotherapy.

Hyeonju Kang, Inyoung Lee, Joseph Kim, Yoojin Kim, Sungmuk Kang, Yongjun Kang, Hongjai Lee, Chungmin Lee, Chihye Park, Gyongsik Ha

IMBiologics Corp., Suwon-si, Korea, Republic of

Human leukocyte antigen-G (HLA-G), a non-classical MHC class I molecule, is expressed only in the placenta, where it functions as an immune suppressor to protect the fetus from maternal immune recognition. Recent studies have demonstrated that HLA-G is enriched in various malignant cells, providing evidence that HLA-G is strongly associated with tumor immune escape. HLA-G, a tumor-specific antigen, mediates immune suppression in tumor-infiltrating immune cells, including T cells, natural killer (NK) cells, and macrophages, by engaging inhibitory receptors such as Ig-like transcript 2 (ILT2) and 4 (ILT4). Therefore, the development of an HLA-G-targeting ADC can be a novel therapeutic strategy not only to induce direct tumor cell killing through payload delivery upon binding to HLA-G, but also to take advantage of the fact that HLA-G is minimally expressed on normal cells and predominantly restricted to tumor cells. This selective expression pattern makes HLA-G a promising target compared to other cancer antigens, in which off-target effects on normal tissues are expected to be minimal. Moreover, by disrupting the interaction between HLA-G and inhibitory receptors such as ILT2, this approach enhances anti-tumor immunity, followed by boosting immune activation and improving therapeutic outcomes. We developed an antibody-drug conjugate (ADC) targeting HLA-G (IMB-201) to selectively deliver cytotoxic drugs to HLA-G-expressing tumor cells, thereby overcoming immune suppression and promoting tumor regression. We generated a monoclonal antibody specific to HLA-G and conjugated it with a potent cytotoxic drug via a stable linker. The IMB-201 demonstrated high binding affinity and selectivity for HLA-G-positive tumor cells. *In vitro* serum and preliminary stability assays confirmed that the stability of IMB-201 is comparable to that of other developed ADCs. *In vitro* studies revealed significant dose-dependent cytotoxicity when treated to HLA-G-expressing cell lines, with minimal off-target effects on HLA-G-negative cells. *In vivo* studies employing mouse models demonstrated significant tumor regression and prolonged survival. Collectively, the IMB-201 could be a promising therapeutic approach for the treatment of HLA-G-positive solid tumors, such as gastric and pancreatic cancers. As HLA-G is a tumor-specific antigen, it has the potential to widen the therapeutic index (TI) compared to other conventional therapies. This strategy selectively targets tumor cells, delivering cytotoxic agents and enhancing immune response, thereby overcoming immune evasion mechanisms.

#3133 PF-08046032: a CD25-directed vedotin ADC leveraging a well characterized safety and pharmacokinetic profile for enhanced regulatory T cell depletion in the tumor microenvironment.

Christopher Carosino, Sherif Abdelhamed, Priyanka Gupta, Xinqun Zhang, Bryan Grogan, Weiping Zeng, Lauren Bou, Devra Olson, Paromita Raha, Andrea R. Lim, Brian P. O'Connor, Ryan A. Heiser, Matthew R. Levengood

Pfizer, Inc., Bothell, WA

PF-08046032 is a novel vedotin antibody-drug conjugate (ADC) engineered to target and deplete immunosuppressive regulatory T cells (Tregs) within the tumor microenvironment (TME) through direct cytotoxicity. PF-08046032 directs delivery of the cytotoxic MMAE (monomethyl auristatin E) vedotin payload to cells expressing CD25, the alpha chain of the IL-2 receptor, which is highly expressed on intratumoral Tregs and lymphoma cells. The MMAE-based vedotin drug linker platform, utilized in four approved ADCs for hematologic and solid tumors, has a well-characterized mechanism of action (MoA), exposure, and target-independent toxicity profile. PF-08046032 leverages this platform, exerting anti-tumor activity through the multifaceted MMAE-driven MoA, including direct cytotoxicity, bystander killing, and immunogenic cell death. Additionally, PF-08046032 is differentiated from other vedotin ADCs and anti-CD25 depleting agents through affinity-tuned binding, which enables selective targeting of $CD25^{hi}$ intratumoral Tregs while sparing peripheral Tregs. Here, we present preclinical data demonstrating safety, pharmacokinetics, and anti-tumor activity of PF-08046032 which is highly consistent with the vedotin ADC platform, while additionally harnessing a Treg-directed anti-tumor approach. PF-08046032 selectively kills Tregs compared to CD8 T cells, with preferential activity on Tregs with the highest CD25 expression and shows dose-dependent antitumor activity in CD25-expressing lymphoma xenograft models. In human CD25-expressing mice bearing MC38 colorectal carcinoma tumors, PF-08046032 significantly suppressed intratumoral Treg levels with minimal activity on peripheral Tregs and no effect on intratumoral CD8+ T cells. A mouse surrogate of PF-08046032 demonstrated that targeted depletion of immunosuppressive tumoral Tregs resulted in robust antitumor activity as both a single agent and in combination with anti-PD1 checkpoint inhibitor blockade. Pharmacokinetic and toxicity studies in non-human primates demonstrated safety and PK profiles consistent with the vedotin platform despite targeting CD25. Leveraging the cumulative knowledge of the vedotin platform, PF-08046032 enables a novel additional mechanism of action for vedotin ADCs at potentially efficacious and safe doses. These data support further investigation of PF-08046032 in clinical trials for advanced malignancies.

#3134 Preclinical anti-glioblastoma pharmacology of HX301, a novel CSF-1R inhibitor.

T. Yang[1], H. Ke[1], J. Wang[2], S. Xiong[2], L. Zhang[1], F. Zhang[1], **H. Q. Li**[1];
[1]Hanx Bio, Hangzhou, China, [2]Crown Bioscience, Taicang, China

Background. GBM is the most malignant and frequently occurring glioma (>60% of all brain tumors in adults) with poor prognosis (12-18 months survival time after diagnosis and 5-year survival of ~5%) and an unmet medical need. Glioma-associated macrophages/microglia (GAMs) are the prominent and suppressive immune cells in the tumor microenvironment (TME), promoting the growth, migration, invasion and stemness of tumor cell . GAMs also secret VEGF to promote angiogenesis and TGF-β to suppress immunity. Notably, the numbers of surrounding GAM inversely correlate with the prognosis. CSF1R, together with its two ligands, CSF1 (M-CSF) and IL-34, governs the proliferation, polarization, differentiation and functions of the myeloid lineage cells, including macrophage/microglia in GBM. Blocking CSF1/CSF1R signaling inhibits microglia/macrophage proliferation and delayed tumor growth by depleting GAMs and diminishing their tumor-promoting activities. HX301 (Narazaciclib or ON123300) is a clinical-stage tyrosine kinase inhibitor (TKI, NCT#05731934) with great potency against CSF1R (IC_{50} 0.285nM) and has demonstrated significant inhibition on macrophage proliferation *in vitro/in vivo* as well as capability of penetrating brain-blood-barrier (BBB). We hypothesized it has anti-GBM activity.
Methods. A single dose of HX301 (30 mg/kg) was orally administrated in NOD/Scid mice, followed by plasma and brain tissues collection at designated timepoints and the drug concentration determination by LC-MS. Anti-GBM pharmacology of the drug was assessed in the following preclinical models: 1) subcutaneous U87-MG xenograft; 2) orthotopic GL261-Red-Fluc syngeneic mouse GBM model; and 3) orthotopic BN2289-Luc PDX model, respectively. HX301, Temozolomide (TMZ), or their combination were oral-administrated daily. tumor-focused-irradiation was also performed using a X-RAD320 (Precision X-Ray, 15-Gy two days after randomization).
Results. The mouse PK study showed that HX301 efficiently penetrate BBB resulting in adequate exposure in brain for activity. In the three GBM pharmacology modeling, HX301 alone significantly inhibited the tumor growth, of which the anti-tumor activity seen in the orthotopic GL261-Red-Fluc and BN2289-Luc models also confirmed HX301 penetration BBB to exert its anti-tumor effects, possibly acting on the macrophages or microglia in the TME. Moreover, although HX301 and radiation combo failed to show any synergistic effects in orthotopic GL261-Red-Fluc model, HX301 in combination with TMZ exhibited significantly stronger anti-tumor activities over either HX301 alone or TMZ alone in the subcutaneous U87-MG model, suggesting a synergistic effect between the two.
Conclusions. HX301 demonstrated great ability to penetrate BBB and robust anti-tumor efficacy, as well as enhanced activity when combined with TMZ, in GBM models, which warrants a further clinical investigation.

#3135 First-in-class NR2F6 antagonist TES-ONC-07 enhances anti-cancer host immunity reducing tumor growth in a “cold” cancer model.

Francesco A. Greco[1], Daniela Passeri[1], Gianmario Ciaccioli[1], Cipolloni Marco[1], Carolina Colliva[1], Cristina Geroni[1], Paride Liscio[1], Emiliano Rosatelli[1], Giorgia Manni[2], Francesca Fallarino[2], Giuseppe Damiano[3], Vincenzo Russo[3], Roberto Pellicciari[1]

[1]Tes Pharma Srl, Corciano, Italy,[2]University of Perugia, Perugia, Italy,[3]Ospedale San Raffaele, Milano, Italy

Anti-cancer immunotherapy has been a groundbreaking approach in the oncology field. However, currently approved immune checkpoint inhibitors (ICI) suffer from several drawbacks, such as low patient response rate and acquired resistance. The reasons why certain patients do not respond to ICI have not been fully elucidated. Recently, the high expression of the orphan Nuclear Receptor Subfamily-2 Group-F Member-6 (NR2F6) has been suggested as a biomarker for ICI sensitivity in melanoma patients (Kim H. et al. Science, 2023). NR2F6 expression correlates with low IFNγ signature and response to anti-PD-1. In T cells, NR2F6 acts as a transcriptional repressor of specific cytokines (IL-2, IFNγ), pivotal for anti-tumor response. Thus, NR2F6 is a pivotal factor that limits immune infiltration and activation in the tumor microenvironment. So far, the evaluation of NR2F6 as a potential drug target has been limited by the lack of small molecule ligands. A Tes Pharma drug discovery project has led to the identification of TES-ONC-07, an orally available first-in-class NR2F6 antagonist. TES.ONC-07 binds NR2F6 recombinant protein in the nanomolar range. TES-ONC-07 binding to NR2F6 leads to the detachment of the nuclear receptor from the promoter of target genes such as IL-2. Ex vivo, TES-ONC-07 stimulation increases the production of specific cytokines, including IL-2 and IFNγ, when added to CD4+ and CD8+ T cells. In a melanoma B16-F1 mouse model, TES-ONC-07 increases infiltration of several myeloid and lymphoid cell subsets, resulting in a significantly reduced cancer growth. Finally, we demonstrated that orally administered TES-ONC-07 has antitumor activity. In conclusion, we have identified the first small molecule NR2F6 antagonist endowed with characteristics that allowed in vivo proof of concept. TES-ONC-07 administration leads to increased immune infiltration in a notably “cold” cancer model and this effect remarkably slows down cancer growth. Overall, our data suggests that NR2F6 is a valuable novel drug target. Potentially, treatment with TES-ONC-07 may increase sensitivity to ICI, also in those patients with limited response. Further studies are ongoing to test combination therapies as well as complete the preclinical development of TES-ONC-07.

#3136 EOS-215, a first-in-class TREM2 antagonist, designed to reprogram the tumor microenvironment and overcome resistance.

Thibaut Janss, Romain Pirson, Virginie Rabolli, Iain Welsby, Clotilde Hoyos, Quentin Dubray, Laura Saerens, Jean-Philippe Deglasse, David Carbonez, Lennart Raman, Francesco Strozzi, Julie Chesne, Joao Matos Marchante, Reece Marillier, Yvonne McGrath, **Catherine Hoofd**

iTeos Therapeutics, Charleroi, Belgium

TREM2 (triggering receptor expressed on myeloid cells 2) is a central regulator of macrophage functions involved in tissue damage and resolution of inflammation in multiple pathologies. TREM2 macrophages have recently emerged to play a critical role in oncology, shaping a tolerogenic tumor microenvironment, favoring resistance to multiple therapeutic approaches (including anti-PD-1) and promoting metastasis, across solid tumor indications. EOS-215 a first-in-class human TREM2 antagonist, has been specifically designed to reprogram $TREM2^{+}$ macrophages and block their pleiotropic pro-tumoral functions. This antibody demonstrates a sub-nanomolar affinity to human, cynomolgus and mouse TREM2. *In Silico* modeling has predicted that EOS-215 could compete with multiple TREM2 ligands such as phosphatidylserine (PS) and low density lipoprotein (LDL), and thereby prevent the TREM2 multimerization required for downstream signaling. Those predictions were confirmed in *in vitro* competition and signaling assays. Importantly EOS-215 was specifically selected among a panel of antibodies to potently inhibit efferocytosis, a key mechanism driving macrophage pro-tumoral functions, LAM (lipid associated macrophage) formation and involved in the metastatic niche formation. *In vitro*, EOS-215 profoundly impacted the transcriptomic program of various models of In monocyte derived macrophages. Hallmark gene set enrichment analysis (GSEA) revealed a significant enrichment in genes related to metabolism and regulation of the immune response, supporting the ability of EOS-215 to reprogram macrophages. This was further confirmed by increased secretion of pro-inflammatory markers from macrophages in response to EOS-215. In vivo efficacy of EOS-215 was first tested in the orthotopic 4T1 triple negative breast cancer model. This model shows limited response to anti-PD-1 and spontaneously leads to the development of lung metastasis. In this model, EOS215 decreased metastasis burden in monotherapy and this effect is reinforced when combined with anti-PD-1 treatment. In another anti-PD-1 resistant model, CT26, EOS-215 combined with anti-PD-1 significantly delayed tumor growth. In conclusion, EOS-215 is a potent TREM2 antagonist with a sub-nM potency proven preclinically to block pro-tumoral function in macrophages, consequently leading to in vivo efficacy. EOS-215 is now ready to enter clinical trials in 2025.

#3137 The combination of anti-PD1 and a mouse analog of PYX-201, an antibody-drug conjugate targeting the extra-domain B splice variant of fibronectin (EDB+FN), shows greater anti-tumor efficacy than either treatment alone.

Anthony Burt Rodriguez, Amanda Facklam, Matthew Iovino, Chuan Shen, Justin Trickett, Sara Lewandowski, Frank Wang, Marsha Crochiere, Nicolas Severe, Jan Pinkas

Pyxis Oncology, Boston, MA

Antibody-drug conjugates (ADC) are transforming cancer therapy, with some showing potential for enhanced efficacy with immunotherapy (Hoimes et al., 2023; Powles et al., 2024). PYX-201 is a first-in-concept, non-cellular ADC targeting EDB+FN, an extracellular matrix protein that is highly expressed in the stroma of various solid tumors but minimally present in normal adult tissues, making it an ideal drug delivery target. Currently, PYX-201 is being evaluated as a monotherapy in a phase 1 clinical trial for various solid tumors (NCT05720117). Preclinical studies have shown that PYX-201 exhibits broad anti-tumor activity across an array of patient-derived xenograft mouse models (Severe et al., 2024). PYX-201 operates through multiple mechanisms, including modulating the tumor immune compartment and increasing sensitivity to immunotherapy (Hooper et al., 2022). Combining PYX-201 with immunotherapy could be a potent strategy for tackling difficult-to-treat cancers. This study aims to demonstrate that combining a mouse analog of PYX-201 with anti-PD1 is more effective than either treatment alone in a syngeneic mouse breast tumor model. The mouse analog of PYX-201 was generated using the variable regions of the heavy and light chains of an anti-human EDB+FN monoclonal antibody (L19), fused to mouse IgG2a constant regions, and conjugated to an optimized Auristatin0101 payload via an mcValCitPABC linker, with an average drug-to-antibody ratio of 4 (Hooper et al., 2022). For efficacy studies, immunocompetent mice bearing subcutaneous EMT6 breast tumors were treated with the mouse analog of PYX-201 (3 mg/kg) and anti-PD1 (10 mg/kg), either alone or in combination. Tumor volume and body weight were measured bi-weekly, with tumors collected for pharmacodynamic analysis and immune profiling by flow cytometry and imaging. Treatment with either anti-PD1 or the mouse analog of PYX-201 resulted in significant tumor growth inhibition (TGI) and some complete responders (CR) compared to the vehicle control group (anti-PD1: 53.76% TGI, 3/15 CR; mouse analog of PYX-201: 65.87% TGI, 3/15 CR). Notably, the combination of the mouse analog of PYX-201 and anti-PD1 resulted in significantly greater tumor regression and clearance than either treatment alone (93.21% TGI, 8/15 CR). Flow cytometry and image analysis revealed an increased number of infiltrating lymphocytes post-treatment with the mouse analog of PYX-201. Further studies are underway to characterize changes in the activation status and tumor localization of these lymphocytes after treatment. Overall, these results provide compelling evidence that combining PYX-201 with anti-PD1 is a highly effective and promising strategy for improving outcomes in patients with difficult-to-treat cancers.

#3138 EGR1 is a master regulator of tumor growth and macrophage polarization in inflammatory breast cancer.

Verena Martinez-Rodriguez[1], Van Ngu Trinh[2], Suguru Ogata[1], Manuel Van Gijsel-Bonnello[1], Andrew C. Montgomery[1], Naoto T. Ueno[1], Xiaoping Wang[1]

[1]Cancer Biology, University of Hawaii Cancer Center, Honolulu, HI,[2]The University of Texas MD Anderson Cancer Center, Houston, TX

Background: Inflammatory breast cancer (IBC) is one of the most aggressive forms of breast cancer, accounting for 2-4% of cases but 8-10% of breast cancer-related deaths in the United States. Patients with IBC face poor prognoses and limited treatment options, highlighting the urgent need to understand the mechanisms driving this disease. The transcription factor early growth response 1 (EGR1) is highly dysregulated in various cancers, including IBC, where its expression is significantly elevated compared to stage-matched non-IBC samples. Lower EGR1 expression correlates with improved survival outcomes. Our previous research has identified EGR1 as a key mediator of the EGFR-regulated immunosuppressive tumor microenvironment (TME), a critical driver of IBC's aggressiveness. The molecular mechanisms through which EGR1 modulates the IBC TME remain poorly understood. This study aims to fill this significant knowledge gap by exploring EGR1's role in IBC and testing the hypothesis that targeting EGR1 is a novel therapeutic strategy for IBC.

Methods: We depleted EGR1 expression in IBC cells using CRISPR/Cas9 knockout (KO) or shRNA knockdown (KD) and examined the effect on cell proliferation, migration, and invasion *in vitro* and tumor growth *in vivo*. We depleted EGR1 in THP-1 monocytes to test the impact on M2 polarization and subsequent effect on IBC cell migration. Coculture experiments were performed to investigate the crosstalk between IBC cells and M2 macrophages. RNA-sequencing (RNA-seq), real-time PCR, and Western blot analyses were performed to determine the molecular mechanisms by which EGR1 regulates the IBC TME.

Results: EGR1 KO significantly reduced proliferation, colony formation, and migration of IBC cells *in vitro. In vivo* tumor xenograft models confirmed that EGR1 KD reduced tumor burden, decreased M2 macrophages, and increased M1 macrophages, indicating EGR1's role in modulating the TME. Depleting EGR1 in macrophages reduced M2 polarization and their migratory and phagocytic abilities, suggesting that EGR1 impacts both IBC cells and macrophages. *In vitro* coculture experiments showed that EGR1 KO in IBC cells reduced M2 macrophage recruitment, while EGR1 KO in macrophages attenuated IBC cell migration. RNA-seq analysis of IBC Ctrl and EGR1 KO cells showed gene downregulation in cell signaling, cancer progression, and metabolism. In EGR1 Ctrl and KO M2 macrophages, RNA-seq indicated downregulation of immunosuppressive macrophage signature genes.

Conclusion: Our findings establish EGR1's dual role in promoting cancer cell proliferation and shaping an immunosuppressive TME in IBC. Targeting EGR1 impairs M2 macrophage polarization and fosters an anti-inflammatory TME, positioning EGR1-targeted therapy as a novel IBC treatment strategy. These results warrant further investigation to elucidate the underlying molecular mechanisms and validate its therapeutic potential.

#3139 The novel peptide drug conjugate AVA6103 is a FAP-enabled pre|CISION® medicine which targets exatecan, a topoisomerase I inhibitor, to the tumor microenvironment following FAP cleavage.

C. Rink, T. Clough, E. Watts, F. Orafidiya, M. Houee, C. Tong, V. Juskaite, M. Morrow, D. Jones, F. Wilson;
Avacta Life Sciences, London, United Kingdom

AVA6103 is a novel peptide drug conjugate (PDC) based on proprietary pre|CISION® technology which incorporates a dipeptide that is specifically cleaved by Fibroblast Activation Protein α (FAP). FAP is a post-proline protease that is overexpressed on the surface of cancer associated fibroblasts (CAFs) in many solid tumors, and facilitates delivery of pre|CISION® medicines specifically to the tumor microenvironment (TME). AVA6103 consists of exatecan, a potent Topoisomerase I warhead, covalently linked to a dipeptide containing a cleaving sequence (D-Ala-L-Pro), which is susceptible to hydrolysis by FAP but is resistant to hydrolysis by other mammalian proteases. Exatecan has been investigated both as a single agent and as a warhead in ADC therapeutics in the clinic. However, clinical utility of this family of warheads is limited by dose-limiting toxicities, including severe neutropenia. The exquisite selectivity of the pre|CISION® substrate to FAP results in release of exatecan warhead in the TME, greatly increasing the therapeutic window and hence reducing systemic exposure and associated toxicities. AVA6103 is a pre|CISION-enabled exatecan programme, with a candidate in IND-enabling studies. A series of compounds have been engineered with modifications in the capping-group and linker portions. Using structure-based drug design, clear structure-activity relationships have been established for affinity to, and susceptibility of linker cleavage by FAP and subsequent warhead release. Concentric partitioning algorithms show differential FAP expression in stromal regions closest to cancer cells vs. those more distal to cancer cells, in multiple indications. Multiplex-immunofluorescence (mIF) data also shows the spatial organization of blood vessels, FAP-positive CAFs, and adjacent FAP-negative cancer cells provide an ideal architecture for the delivery, cleavage, and warhead uptake of a FAP-enabled PDC. In a cancer cell line/fibroblast cell co-culture, AVA6103 demonstrates FAP-dependent release of exatecan and bystander cancer cell kill. *In vivo* studies demonstrate targeting and accumulation of warhead in the TME, resulting in tumor growth inhibition and complete tumor regressions. Tolerability profiles of AVA6103, allied with tumor growth inhibition efficacy, shows a greatly increased therapeutic window compared to conventional exatecan, with pharmacodynamic biomarkers demonstrating on-target activity of the warhead. The enhanced therapeutic index and efficacy data shown here supports the rationale to progress AVA6103 towards clinical development and supports wider utility of the pre|CISION® platform to target warheads to the tumor while reducing systemic dose-limiting toxicities.

#3140 Preclinical development of YL242, a non-internalized antibody-drug conjugate (ADC) targeting soluble VEGF for treatment of solid tumors.

Tongtong Xue, **Wei Lian**, Qing Zong, Chun Deng, Qigang Liu, Peng Zou, Jiaqiang Cai

MediLink Therapeutics (Suzhou) Co., Ltd., Suzhou, China

Traditional ADC technologies require overexpressed targets, high internalization and efficient intracellular processing. To this end, a non-internalized antibody-drug conjugate (ADC) targeting soluble VEGF was developed using MediLink's TMALIN® platform. VEGF is overexpressed in virtually all human tumors and contributes to key aspects of tumorigenesis and angiogenesis. YL242 incorporates an anti-VEGF antibody, protease-cleavable tripeptide linker and novel DNA topoisomerase I inhibitor. It introduces a novel cleavage mechanism that occurs in the tumor microenvironment while stable during systemic circulation. YL242 is designed to leverage anticancer activity through both anti-angiogenesis by the VEGF antibody and the cytotoxicity of the extracellularly released payload. The linker of YL242 can be enzymatically cleaved by enzymes in TME (tumor microenvironment) to release payload C24, subsequently inducing cytotoxic effects to kill cancer cells. Significant dose-dependent antitumor effects, including complete tumor regressions were observed in tumor xenograft mouse models. The stability of YL242 has been demonstrated by incubation with various plasmas under physiological conditions. This high stability was further evidenced by the pharmacokinetic profiles in non-human primate (NHP) studies, where both the ADC and TAb curves are overlapped. YL242 demonstrated promising safety profiles in pivotal non-human primate (NHP) toxicity studies with no drug-related adverse effects observed. In summary, VEGF-targeted ADC YL242 synergistically combines both antitumor activity of cytotoxic payload and anti-angiogenesis effect of antibody and demonstrated both antitumor efficacy and safety. Consequently, YL242 holds promise for further development in the treatment of cancer patients.

#3141 Development and comprehensive preclinical evaluation of dual-drug polymeric micelles ONP-001 for PDAC and HCC.

Qiu-Xu Teng[1], Guodong Zhang[1], Lu Dai[2], Defeng Deng[1], Ping Pan[1], Diana S-L Chow[2], Guorong Ma[3], Peiying Yang[1], **Chun Li**[1]

[1]UT MD Anderson Cancer Center, Houston, TX,[2]University of Houston, Houston, TX,[3]OmniNano Pharmaceuticals, Houston, TX

Introduction: Pancreatic ductal adenocarcinoma (PDAC) and hepatocellular carcinoma (HCC) remain the leading causes of cancer-related mortality, with poor outcomes. This study comprehensively evaluated the mechanisms of polymeric micelles co-encapsulating cyclopamine (CPA) and paclitaxel (PTX) (M-CPA/PTX, ONP-001) and the effectiveness against HCC and PDAC. The dual-drug delivery system targets embryonic signaling pathways, such as Hedgehog (Hh), which drives tumor progression and resistance.
Methods: CPA and PTX were encapsulated in micelles (~55 nm in size) to improve bioavailability and tumor concentrations. Preclinical experiments included *in vitro* assays for cytotoxicity, tumorsphere, and colony formation in both cancer cell lines. *In vivo* models included orthotopic Kras* cell implanted PDAC and spontaneous HCC in transgenic LAP-tTA/TRE-MYC mice. The antitumor efficacy was examined by intravenously injection of ONP-001 at 2.5, 5.0, and 7.5 mg/drug equivalent/kg thrice weekly for 4 weeks, as well as combination regimens with irreversible electroporation (IRE) and an immune checkpoint inhibitor. Survival, tumor burden, immune modulation, and cytokine profiles were analyzed using Kaplan-Meier survival curves, bioluminescence imaging, and multiplex cytokine assays.
Results: In the PDAC model, ONP-001 significantly extended median survival at 2.5 mg equivalent drug/kg ($p<0.01$), 5.0 mg/kg ($p<0.0001$), and 7.5 mg/kg ($p<0.05$) compared untreated control. ONP-001 administered at 7.5 mg/kg displayed shorter median survival than 5.0 mg/kg suggesting that the optimal regimen tested was 5 mg/kg. ONP-001 reprogrammed tumor stroma, and reduced cancer stem cell (CSC)-associated tumorsphere formation. Combination of ONP-001 with IRE and anti-PD-1 further enhanced survival and immune infiltration, overcoming PDAC's immunosuppressive microenvironment. In HCC, ONP-001 significantly inhibited tumor growth and colony formation. Tumor cytokine profiling revealed significant reductions in markers associated with CSC maintenance (e.g., IL-15, IL-33) and tumor progression, highlighting an anti-inflammatory effect on the tumor microenvironment. Studies in the transgenic HCC model also confirmed significantly greater antitumor efficacy for ONP-001, with no observed hepatotoxicity, compared to sorafenib treatment.
Conclusion: ONP-001 was an effective therapeutic strategy for PDAC and HCC, targeting CSCs, modulating the stroma, and enhancing immunotherapy, at 5.0 mg/kg, TIW, with enhanced benefits when in combination regimens. Ongoing studies will further characterize the pharmacokinetics, tumor uptake and biodistribution of both drugs. The data supports further development of ONP-001 for potential future clinical development.

#3142 Patient-derived models of breast cancer for drug screening and precision medicine approaches.

Rui Li[1], Xiao Hu[2], Ning Ge[3], Michael Kerin[1], Laura Barkley[1]

[1]Lambe Institute, University of Galway, Galway, Ireland,[2]State Key Lab of New Drug and Pharmaceutical Process, Shanghai Institute of Pharmaceutical Industry, China State Institute of Pharmaceutical Industry, Shanghai, China,[3]Pharmacology, Northwestern University Feinberg School of Medicine, Chicago, IL

Introduction: The breast tumor microenvironment (TME) consists of a complex and heterogeneous network of cancer cells, cancer-associated fibroblasts (CAFs), immune cells, and an acellular extracellular matrix (ECM). These components critically impact treatment responses, emphasizing the utilization of patient-derived models that closely mimic the TME. Such models provide valuable insights into chemotherapy responses and facilitate the development of personalized treatment strategies. Natural products represent a vast and diverse source for anti-tumor drug discovery due to their structural diversity and wide range of biological activities. This study aims to utilize patient-derived models to screen a library of natural products to identify lead compounds with potential for personalized breast cancer therapy.

Methods: A primary screen was performed using a patient-derived co-culture system comprising breast cancer cells and matched CAFs. A library of 61 natural products and 6 standard chemotherapy drugs was evaluated for their impact on cell viability, with IC_{50} values calculated to assess efficacy. Positive hits were further investigated in a secondary screen using 3D patient-derived organoid (PDO) models derived from four breast cancer subtypes. These PDOs included patient-derived cancer cells, matched CAFs, and autologous tumor-infiltrating lymphocytes (TILs), representing the tumor immune microenvironment. The anti-tumor effects of these compounds on PDO viability, growth, TIL recruitment, TIL activity and induction of apoptosis were assessed.

Results: The patient-derived co-culture and PDO models retained characteristics of their respective primary breast cancers and showed varied responses to different chemotherapeutics. Among standard drugs, doxorubicin and camptothecin showed uniform IC_{50} values across all PDOs, while paclitaxel primarily inhibited proliferation rather than inducing significant cell death. Conversely, 5-fluorouracil and etoposide displayed limited efficacy. In the natural product screen, Emodin (an anthraquinone) and Platycodin D (PD, a triterpenoid steroid) demonstrated potent anti-tumor activity. Both compounds caused a dose-dependent reduction in PDO size and a significant increase in cell death. Apoptosis assays revealed enhanced tumor cell and CAF apoptosis following treatment. Additionally, Emodin and PD increased TIL cytotoxicity, evidenced by elevated Granzyme B expression in $CD4^+$ and $CD8^+$ T cells.

Conclusion: This study highlights the utility of patient-derived models in precision medicine and drug screening, providing a valuable platform for identifying effective therapeutic agents for breast cancer. Emodin and PD emerge as promising candidates with broad efficacy across multiple breast cancer subtypes, highlighting their potential for future development in breast cancer therapies.

#3143 Leveraging chemo-immunotherapy to remodel the tumor microenvironment and enhance treatment efficacy in osteosarcoma lung metastases.

Raneem R. Aldaqqa[1], Fatemah S. Sunbul[2], Victoria A. Garcia[1], Asma M. Al-terawi[1], Joshua J. Reineke[3], Sandro R. P. da Rocha[1]

[1]Pharmaceutics, Virginia Commonwealth University - VCU, Richmond, VA,[2]Department of Respiratory Therapy,, Mohammed Al-Mana College for Medical Sciences, Dammam, Saudi Arabia,[3]Pharmaceutical Sciences, South Dakota State University, Brookings, SD

Osteosarcoma (OS), the most common primary bone cancer across all ages, predominantly metastasizing to lungs. At diagnosis, 20% of OS patients present gross OS lung metastases (OSLM), while most others harbor undetectable micrometastases. Despite current treatments, including systemic chemotherapy and experimental therapeutics like immune checkpoint inhibitors, the 5-year survival rate for OSLM continues to be low (ca. 20-30%), making it the leading cause of death in OS patients. Thus, there is an urgent need for innovative therapies to shift OSLM tumor microenvironment (TME) towards a more immunogenic state to overcome tumor tolerance. Gemcitabine (GMT), has shown limited efficacy in relapsed OSLM when administered systemically. Pulmonary administration (PA) of GMT demonstrated promise in reducing tumor burden but does not eradicate it. To address this gap, we propose a novel strategy combining inhaled GMT with colony-stimulating factor-1 receptor inhibitors (CSF-1Ris); pexidartinib (PLX-3397), that target tumor-associated macrophages (TAMs), both delivered locally to lungs via PA. GMT's pulmonary efficacy is partially linked to its ability to upregulate Fas, a death ligand on tumor cells, promoting Fas-mediated apoptosis, and CSF-1Ris are expected to shift TAMs towards a more inflammatory, M1-like phenotype. Our studies began with evaluating GMT's immunomodulatory effects on Fas expression *in vitro* using OSLM cells. Moving to 3D multicellular tumor spheroid (MCT) model composed of OSLM cells, macrophages, and fibroblasts, we confirmed GMT's ability to increase Fas expression, simulating the results we obtained in OSLM *in vivo* model. Concurrently, we tested the ability of PLX to shift macrophages from tumor-promoting M2-like phenotype to tumor-suppressing M1-like phenotype. RAW 264.7 macrophages polarized to M2-like state with IL-4 were treated with PLX, resulting in a significant reduction of M2-like macrophages. Similar effects were observed in the 3D MCT model, which recapitulates again our *in vivo* studies. *In vivo*, Balb/c mice with OSLM were treated via PA with GMT (5 mg/kg weekly for 2 weeks) and PLX (2 mg/kg every other day for 3 weeks). Tumor burden, tracked with bioluminescence imaging (BLI), has significantly reduced for combination therapy. GMT increased Fas expression in tumor cells, while PLX shifted TAM toward an anti-tumorigenic state, reducing M2 TAMs and enhancing M1/M2 ratio. The treatment was well-tolerated without affecting body weight or overall health.

In conclusion, we showed that chemo-immunotherapy combination via PA can effectively remodel the TME in an immunocompetent OSLM mouse model. We also developed a 3D spheroid model with the relevant immune-cells that mimic key aspects for the *in vivo* model. These studies help us identify clinically translatable combination therapies for OSLM as both GMT and PLX are approved clinically.

#3144 Selective HDAC10 inhibitor enhances innate antitumor immunity.

Nithya Gajendran[1], David Quiceno-Torress[1], Xintang Li[1], Bryan Weselman[1], Manasa Suresh[1], Sonia Sebaoui[1], Fereshteh Mahmoudi[2], Marie Durr[1], Satish Kumar Reddy Noonepalle[1], Wolfgang Sippl[2], Alejandro Villagra[1]

[1]Oncology, Georgetown Lombardi Comprehensive Cancer Ctr., Washington, DC,[2]Medicinal chemistry, Institute of Pharmacy, Martin-Luther- Universitaet Halle, Wittenberg, Germany

Most anticancer therapies aim to target specific mechanisms that regulate or potentially inhibit the proliferation and survival of cancer cells. Macrophages play a crucial role in the tumor microenvironment (TME), exhibiting both pro and antitumoral functions depending on the polarization state. Our lab focuses on transforming the immune suppressive TME into an antitumoral environment, explicitly enhancing the proinflammatory M1 macrophage phenotype using HDAC inhibitors. Many research studies have shown the aberrant expression of HDAC10 in cancer and various pathologies. However, the deacetylation targets and biological functions of HDAC10 remain poorly characterized due to a lack of specific and potent HDAC10 inhibitors with cellular activity. HDAC10 has a unique structure and substrate preference. Understanding its mechanisms of action is crucial for developing effective therapies. In our study to identify the potential HDAC10-specific inhibitor, we screened 13 HDAC10 inhibitors for their ability to suppress the M2 macrophage phenotype. We also identified six potent inhibitors that suppress the M2 phenotype and tested for cytotoxicity and HDAC inhibition. Interestingly, FM60 with 0.9 nM IC50 against HDAC10 in cells showed negligible cytotoxicity and more than 60 % HDAC inhibition. Inhibition of HDAC10 in primary mouse bone marrow-derived macrophages results in upregulating proinflammatory M1 markers-iNOS and TNFa while concurrently downregulating the expression of anti-inflammatory M2 markers Arginase1 and Fizz1. Flow cytometry analysis demonstrated reduced CD206 + and increased CD80 + macrophages in BMDMs treated with FM60, indicating potential antitumor effects. M1-like macrophages are antitumoral due to their intrinsic phagocytosis and antigen presentation capability. To investigate the phagocytic potential of FM60, BMDMs from GFP mice were left unpolarized (M0) or polarized to M1, pretreated with HDAC10i FM60, and co-cultured with cell trace far red stained SM1 murine melanoma cells. Images captured at every 20-minute interval demonstrated a significant increase in phagocytosis by M1 macrophages treated with FM60. Principal Component Analysis (PCA) showed the closest association between BMDMs from HDAC10 KO mice and FM60-treated in M1 macrophage phenotype, additionally, RNA seq analysis indicated that treatment with FM60 significantly regulates polyamine biosynthesis, crucial for tumorigenesis. To evaluate the antitumor immunity in syngeneic murine melanoma, FM60 was given intraperitoneally at varying doses. 50 mg/kg body weight of FM60 significantly reduced the tumor growth, enhancing its antitumor effects. These findings provide the rationale for using HDAC10is as an immunotherapeutic anticancer agent.

CHEMISTRY: High-Throughput Screening Assays and Libraries
Poster Session

#3149 Desorption electrospray ionization mass spectrometry (DESI-MS) high-throughput screening of small-molecule inhibitors for human sulfotransferase 2B1b & biophysical and crystallographic characterization of target-hit interaction.

Beinan Yang[1], Nicolas M. Morato[2], Samadhi Kulathunga[2], Timothy L. Ratliff[3], Graham Cooks[2], Andrew D. Mesecar[1]

[1]Biochemistry, Purdue University, West Lafayette, IN,[2]Chemistry, Purdue University, West Lafayette, IN,[3]Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN

Upon malignancy and metastasis to distant organs such as brain, lung and bone marrow, the 5-year survival rate of castration-resistance prostate cancer (CRPC) is only around 30%. Therefore, there is an urgent need for identifying new CRPC drug targets and developing new CRPC treatments. A potential new drug target for CRPC is human sulfotransferase isozyme SULT2B1b. It catalyzes the transfer of the sulfate group from 3'-phosphoadenosine 5'-phosphosulfate (PAPS) to cholesterol to produce cholesterol sulfate (CS). Increased expression of SULT2B1b has been shown to correlate to prostate cancer cell proliferation with decreased level of TNF-mediated apoptosis. Knockdown of SULT2B1b leads to elevation of TNF expression and NF-κB activation. SULT2B1b knockdown also enhances TNF-mediated apoptosis in both TNF-sensitive (LNCaP)and TNF-resistant (C4-2) cells. We demonstrate herein that catalytic knockout mutants, H125A and K70A, of SULT2B1b abolish CS production in cells mimicking genetic knockdown studies. This result suggests that small molecule inhibitors of SULT2B1b activity could serve as potential CRPC therapeutics. Towards this goal, we established a novel high-throughput (50nL, <1s per sample) label-free DESI-MS platform for the screening of small-molecule compounds with excellence Z' scores ranging from0.73 to 0.86. Using DESI-MS, we first determined Kcat and KM values for catalysis of cholesterol by SULT2B1b to be 0.05 ± 0.002 min^{-1} and 19.8 ± 2.2 μM respectively. We then screened 4500compounds from three chemical libraries (ChemBridge Kinase Inhibitor, LOPAC 1280 &AnalytiCon MEGx Natural Products) and identified 3 bona fide hit compounds (#099, #170 and#954) that had IC50 values ranging from 1.2 to 1.6 μM. We also showed via DESI-MS that these three compounds, each containing multiple hydroxyl groups, could not be sulfated. NanoDSF was used to show that the hit compounds stabilize the SULT2B1b melting temperature by 1.7°C to3.0°C. Binding interactions of the hit molecules were also examined using microscale thermophoresis (MST) and dissociation constants (KD) of 13.5 μM (#099), 6.9 μM (#170) and 7.2μM (#954) were determined. X-ray structures of SULT2B1b in complex with #099 and #170 were determined to 2.8 Å and 2.9 Å resolution respectively. Both compounds are found bound within the cholesterol substrate binding site. One important structural observation is the N-terminus helix (residues 1 - 28) is displaced due to the binding of the inhibitors. In summary, we used DESI-MS to identify three compounds that potently inhibit SULT2B1b through interactions at the cholesterol binding site. These results should now allow for the structure-based design and development of more potent lead compounds of SULT2B1b which ultimately may be useful forCRPC treatment.

#3150 Utilizing the HiBiT system to identify CARM1 degraders for targeted cancer therapy.

Megan Bacabac[1], Fabao Liu[1], Eui-Jun Kim[1], Isaac Hayes[1], Yidan Wang[1], Weiping Tang[2], Tim S. Bugni[2], Wei Xu[1]

[1]Oncology, University of Wisconsin-Madison, Madison, WI,[2]Pharmaceutical Sciences, University of Wisconsin-Madison, Madison, WI

Coactivator-associated arginine methyltransferase 1 (CARM1) is a member of the protein arginine methyltransferase (PRMT) family that asymmetrically dimethylates proteins on arginine residues. Methylation of BAF155 by CARM1 in triple-negative breast cancer (TNBC) drives cancer metastasis. Amplification and overexpression of CARM1 has been observed in a variety of cancers, including breast cancer, and its overexpression correlates with poor prognosis. Potent small molecule inhibitors for CARM1 have been developed but the effects of inhibiting CARM1 differ from the effects of knocking out (KO) CARM1 in cancer cells. CARM1 KO, but not CARM1 inhibition, decreases cancer cell proliferation. This implies that CARM1 also has non-enzymatic roles in driving cancer progression which necessitates the development of small molecule degraders of CARM1 to inhibit both structural roles and enzymatic activity. We have developed CARM1-specific proteolysis targeting chimeras (PROTACs), which contain a CARM1 ligand (TP-064), a rigid chemical linker, and an E3 ligase ligand (von-Hippel Lindau) to target CARM1 for proteasomal degradation. We characterized the degradation activity of the best compound, 3b, which has a DC_{50} of 8.1 nM and a D_{max} of 97%. While PROTAC 3b is potent and selective, many challenges remain in using PROTACs in clinical settings. There are still no PROTACs that have received FDA-approval. A possible way to overcome the potential toxicity and side effects of chemically synthesized drugs is to utilize naturally occurring products. We generated a breast cancer cell line containing HiBiT-tagged CARM1 to perform high-throughput unbiased screening of 1408 natural products. Two natural product fractions, named 5_9 and 10A, decreased luciferase signal and CARM1 protein levels by Western blot. Treatment with either natural product did not impact the protein levels of another PRMT family member, PRMT6. Ongoing studies will determine the biological consequences of 5_9 and 10A on breast cancer cell lines and organoids. CARM1 PROTACs and natural products may be developed as therapeutic agents for targeting CARM1-driven cancers more effectively than currently available inhibitors.

#3151 Designing and utilizing a c-Rel specific bioassay in drug repurposing screen for HNSCC.

Kristin A. Altwegg[1], Kathryn E. King[2], Natalia J. Martinez[1], Ty C. Voss[1], Dvir Blivis[1], Wendy C. Weinberg[2], Mark J. Henderson[1]

[1]NIH-NCATS (National Center for Advancing Translational Sciences), Rockville, MD,[2]Food and Drug Administration, White Oak, MD

Head and neck squamous cell carcinoma (HNSCC) is the 7th most common cancer worldwide, with incidence anticipated to increase by 30% by 2030. HNSCC occurs most often in men in their 50-60s, although the incidence among women and younger individuals is rising. The current standard-of-care practices are surgical resection and chemoradiotherapy. HNSCC tumors exhibit frequent mutation of TP53 (72% of tumors). Two additional members of the TP53 gene family, TP63 and TP73, are frequently altered in HNSCC. TP63 encodes two major isoforms, ΔNp63 and TAp63 (containing an alternate or p53-like transactivation domain, respectively). Specifically, ΔNp63α is overexpressed in ~80% of HNSCC tumors. Our lab has reported that ΔNp63α interacts with activated c-Rel (a nuclear factor-κB family member) in HNSCC, and this interaction is associated with uncontrolled proliferation, inflammation, and metastasis. Consistent with a role in growth regulation, ΔNp63α:c-Rel complexes bind a promoter motif and repress the cyclin-dependent kinase inhibitor p21WAF1 in both human HNSCCs and normal keratinocytes overexpressing ΔNp63α. A robust nuclear co-localization in the proliferating compartment of primary HNSCC reflects the relationship between ΔNp63α and activated c-Rel. Stimulation of HNSCC cells with TNFα results in the activation and nuclear localization of c-Rel, which binds to ΔNp63α. This binding displaces and inactivates the tumor suppressor TAp73 from ΔNp63:TAp73 complexes. By western blot, we confirmed that TNFα stimulation enhances nuclear c-Rel localization in human HNSCC cell lines. We then designed and optimized a high-throughput screening bioassay to evaluate compounds inhibiting c-Rel nuclear localization under TNFα stimulation. A 1536-well immunofluorescence assay was developed using high-content image analysis to quantify nuclear translocation. The specificity of the c-Rel antibody was validated using CRISPR/Cas9-generated c-Rel knockout cell lines. The optimized bioassay was used to screen the NCATS pharmaceutical collection of approved drugs. Of the 2,807 compounds screened, we identified 168 inhibitors (6% hit rate). Interestingly, 17 compounds promoted/activated c-Rel nuclear translocation. These “hits” were then validated in dose-response to confirm activity. Other NCATS compound libraries will be screened to discover new candidate inhibitor compounds. Top candidates will undergo further investigation for drug synergy with current standard-of-care therapeutics in vitro, ex vivo, and in vivo to explore the possibility of repurposing drugs for HNSCC therapeutics.

#3152 Identification and characterization of inhibitors SHOC2-MRAS-PP1C complex assembly.

Alexei Brooun[1], Patrick Fagan[1], Simon Bergqvist[2], Oleksii Hrabovsky[3], Fang Fang[4], Yecenia Peraza[1], Yin Wu[4], Dongming Quan[4], Meiying Cui[5], Liang Huang[5], Yujie Chen[5], Huihui Zhu[5], Ping Chen[1], Adriana Irimia[1], Peter Chua[1], Mykola Protopopov[3], Yurii Moroz[6], Olga Tarkhanova[3], Jean-Michel Vernier[1], Robert Shoemaker[1]

[1]ERASCA, Inc., San Diego, CA,[2]Biofizik, Inc., San Diego, CA,[3]Chemspace LLC, Kiev, Ukraine,[4]Viva Biotech Ltd., Shanghai, China,[5]Suzhou AlphaMa Biotechnology Co., Ltd, Suzhou, China,[6]Enamine LTD, Kyiv, Ukraine

Inhibition of SHOC2 function by either genetic ablation or protein degradation potently sensitizes RAS-driven cells to MEK inhibition and impairs RTK-mediated adaptive reactivation of MAPK signaling induced by a MEK inhibitor (MEKi). The SHOC2-MRAS-PP1C (SMP) complex is responsible for full activation of RAF via dephosphorylation of the phosphoserine in conserved region 2 (CR2-pS). Based on the SMP complex's critical role in RAF activation and SHOC2 synthetic lethal interaction with MEKi, the SMP complex represents an attractive target for the development of novel therapeutic agents that could prevent adaptive resistance to MEKi. We have conducted a systematic DNA encoding library (DEL) screening campaign against the purified intact SMP complex and all three individual components using the HitGen OpenDEL kit. A series of SHOC2 selective hits were identified and profiled using direct binding and biochemical assays. The lead compounds bind to full-length SHOC2 protein with K_Ds in the low nM range, inhibit SMP complex formation, and block dephosphorylation of BRAF CR2-pS peptide. Hydrogen/deuterium exchange mass spectroscopy (HDX-MS) analysis of SHOC2 in complex with a lead compound identified a putative binding site, consistent with biochemical studies and supporting the MRAS competitive nature of the lead compounds. To our knowledge, these compounds represent first-in-class examples of direct modulators of the SMP complex, via SHOC2 engagement, that have the potential for optimization as either PPI modulators or selective degraders.

#3153 High-throughput identification of radiosensitizers and synergistic drug combinations with potent therapeutic efficacy against diffuse midline glioma.

Syed M. Faisal[1], Monika Yadav[1], Garrett R. Gibson[1], Adora T. Klinestiver[1], Ryan Sorenson[1], Anuradha Roy[2], Carl Koschmann[3], Scott J. Weir[4], Stefan H. Bossmann[4], Viveka N. Yadav[5]

[1]Children's Mercy Research Institute, Kansas City, MO,[2]High-throughput Screening Laboratory, University of Kansas, Lawrence, KS,[3]University of MIchigan Medical School, Ann Arbor, MI,[4]University of Kansas Medical Center, Kansas City, KS,[5]Department of Pediatrics, Children's Mercy Research Institute, Kansas City, MO

Diffuse midline gliomas (DMGs), including diffuse intrinsic pontine glioma (DIPG), are the most aggressive pediatric brain tumors with a median survival of less than one year. Over 85% of DMGs harbor the H3K27M mutation in histone genes H3F3A (H3.3) and H3C2 (H3.1), which inhibits EZH2, the catalytic subunit of the Polycomb Repressive Complex 2 (PRC2), leading to global loss of H3K27 trimethylation (H3K27me3). This epigenetic disruption drives oncogenesis by reprogramming gene expression and activating oncogenic pathways. Current treatments, including chemotherapy and radiotherapy (IR), offer marginal benefits, with 95% of patients dying within 1.5 years of diagnosis. ONC201 has shown clinical benefits in H3K27M-mutant DMGs, extending median survival to 21.7 months by disrupting metabolic and epigenetic pathways and reversing H3K27me3 loss. Novel therapeutic strategies targeting H3K27M oncohistone are urgently needed. We performed high-throughput screening (HTS) of 1,520 FDA-approved compounds to identify drugs that selectively target H3K27M-mutant primary DMG cell lines, but not CRISPR-corrected H3K27M-KO lines, derived from distinct neuroanatomical location: the thalamus (BT-245) and the pons (DIPGXIIIP). From this screening, we identified 86 promising drugs, further narrowed down to five lead compounds: floxuridine, gemcitabine, cytarabine, pyrimethamine, and cladribine (HTS-identified lead candidates, HTS-ILCs). These HTS-ILCs exhibited potent cytotoxicity against other patient-derived H3K27M-mutant DMG lines (DIPG007, SF8628) and murine PPK cells (DNp53/PDGFRA/H3.3K27M) from genetically engineered mouse models (GEMMs). HTS-ILCs were further tested for radiosensitizing potential, with floxuridine, gemcitabine, cytarabine, and pyrimethamine showing enhanced efficacy when combined with IR. Western blot analysis confirmed H3K27me3 restoration, indicating epigenetic modulation and reduced DMG growth. Combining IR, HTS-ILCs, and ONCs (201/206/212) showed synergistic effects and reversed epigenetic dysregulation. Gemcitabine exhibited strong anti-invasive properties, followed by floxuridine against H3K27M mutant DIPGXIIIP and SF8628 cells. Conditioned medium from HTS-ILCs-treated PPK cells showed enhanced HMGB1 secretion, suggesting activation of an immune-stimulatory response. Ongoing *in vivo* testing includes orthotopic implantation of PPK cells in immune-competent murine models and IUE-generated GEMMs of H3K27M DMGs. Spatial transcriptomics and phosphoproteomic microarray analysis are being used to elucidate the molecular mechanisms. Our findings suggest that combining HTS-ILCs with IR, alone or with ONC therapies, offers a promising strategy for treating H3K27M-mutant gliomas, potentially leading to more effective, personalized therapies for children with DMGs.

#3154 Targeting of the Elongator tRNA-modifier complex through high-throughput screening revealed series of compounds with novel mechanism of action.

Mariantonietta Rubino[1], Kerstin-Maike Schmitz[1], Andrea Lauri[1], Debora Zian[1], Nazareno Menegatti[1], Samuel Bradberry[1], Francesca Rapino[2], Pierre Close[2], **Daniele Carettoni**[1], Cinzia Nucci[1], Angela Molteni[1], Jean-Francois Rolland[1]

[1]AXXAM SpA, Bresso, Italy,[2]THERAtRAME SA, Liege, Belgium

Numerous human diseases, such as cancers and neurodegenerative disorders, have been associated with the dysregulation of tRNA-modifying enzymes' activity. These post-transcriptional modifications can affect tRNA structure stability, codon-anticodon base pairing during ribosomal decoding, translation efficiency, and proper protein folding during protein synthesis, impacting both cell cycle and metabolism. It is therefore not surprising that several tRNA-modifying enzymes have recently emerged as attractive therapeutic targets in drug discovery. Nevertheless, these enzymes often form large complexes with multiple subunits, and assessing their activity *in vitro* using reconstituted protein complexes and tRNA substrates is particularly challenging.The aim of the present study was to identify inhibitors of a cancer-implicated tRNA-modifying enzyme. For this purpose, we have developed a TR-FRET-based protein-RNA interaction assay suitable for high-throughput screening (HTS) in 384 MTP format. The protein-RNA interaction was assessed using a tagged recombinant catalytic subunit and a biotinylated RNA oligo derived from a specific tRNA. The optimization through buffer component screening and the validation with tool inhibitors yielded a thorough biochemical characterization of the *in vitro* protein-RNA binding. A HTS campaign with a proprietary library of ~100,000 compounds was performed in search of protein-RNA interaction inhibitors. A secondary assay was used to identify those hit compounds interfering with the primary assay's readout system. The primary screening hit rate was 1 % (cut-off: 49% inhibition) and 84% of those hits were confirmed as putative protein-RNA interaction inhibitors with IC_{50} values in the nM-µM range and no interference effects.A few of these primary hits have progressed to the hit-to-lead stage, and the preliminary results obtained thus far are highly promising.This study illustrates a hit discovery program targeting the interaction between the catalytic subunit of a tRNA-modifying enzyme and a tRNA-derived RNA, aimed at identifying specific inhibitors. Targeting tRNA modification systems represents an attractive strategy for treating human cancers.

#3155 High-throughput drug repositioning identifies dinaciclib as a potent osteosarcoma inhibitor.

Mithun Sarangdhar[1], **Jonah Snyder**[2], Eric O'Brien[1], Brett VanCauwenbergh[1], Mitali Basu[1], Joseph Pressey[1], John Perentesis[1]

[1]Department of Pediatrics, CBDI, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, Cincinnati, OH,[2]CBDI, Cincinnati Children's Hospital Medical Center, Cincinnati, OH

Background: Osteosarcoma (OS) is the most common primary malignant bone tumor, predominantly affecting adolescents and young adults. Despite multimodal treatment combining chemotherapy and surgical resection, survival rates for metastatic OS remain below 20%, underscoring the urgent need for novel therapies. Recent studies implicate chromothripsis, a phenomenon of chromosomal shattering and reassembly, in OS pathogenesis, contributing to its aggressive behavior and treatment resistance. However, therapeutic options for OS have remained largely stagnant over the past two decades. Advancing our understanding of OS biology and identifying new therapeutic approaches are essential to improving outcomes for patients with metastatic and relapsed disease.
Methods and Findings: We conducted a high-throughput screen of 3,800 compounds across eight OS cell lines. Two-thirds of the drug library consists of FDA approved drugs and one-third consists of drugs in early phase clinical trials. Each compound was tested in five concentrations (1 nM to 10,000 nM), generating over 200,000 data points to identify active single agents. Dinaciclib, a CDK1/2/5/9 inhibitor, emerged as one of the top-performing agents, ranking in the top 0.5% based on cytotoxicity across all cell lines. Notably, clinically relevant agents Gemcitabine and Docetaxel, components of active retrieval regimens for relapsed OS, also ranked in the top 0.5%. To investigate drug synergy, combinations of Gemcitabine and Docetaxel were tested at varying molar ratios (1:10, 10:1, 1:5, 5:1, and 1:1) across the eight cell lines. The 1:10 molar ratio demonstrated the highest cytotoxicity, consistent with the clinically established 1:9 ratio. Subsequently, an iterative screen assessed the synergy of third agents with the Gemcitabine+Docetaxel regimen in the MG-63 OS cell line. Dinaciclib exhibited additive effects when layered onto this regimen, further supporting its therapeutic potential.
Conclusions: This study identifies Dinaciclib as a potent inhibitor of osteosarcoma, with additive cytotoxicity when combined with the clinically relevant Gemcitabine+Docetaxel regimen. These findings, coupled with prior evidence of Dinaciclib's efficacy in reducing metastatic burden in OS patient-derived xenograft models, highlight its potential as part of a triple combination therapy. This research underscores the value of high-throughput drug repurposing in identifying innovative treatment strategies for osteosarcoma and supports further preclinical and clinical evaluation of Dinaciclib to improve outcomes for patients with metastatic or treatment-resistant disease.

#3156 A surface plasmon resonance-based screening platform to identify potential PD-1/PD-L1 inhibitors from a FDA-approved drugs library for cancer immunotherapy.

H. Li, A. Cai, N. P. Seeram, **C. Liu**;
University of Rhode Island, South Kingstown, RI

The PD-1/PD-L1 axis plays a pivotal role in immune checkpoint regulation in cancer, making its inhibition a key strategy in cancer immunotherapy. However, the development of small molecule inhibitors targeting PD-1/PD-L1 interaction has been hindered by the lack of robust high-throughput screening platforms. In this study, we developed a high-throughput screening platform based on surface plasmon resonance (SPR) technology, utilizing a 384-well plate format. This platform integrates a dual-step coupling method, employing both amine and bio-streptavidin coupling to optimize PD-1 orientation on the sensor chip.We screened a library of 2,764 FDA-approved drugs using this SPR platform with a 1:1 ratio of drug to PD-L1, alongside two positive control PD-L1 inhibitors. Three compounds, RB, MB, and VP, were identified as hits, showing PD-1/PD-L1 blockade rates of 13.1%, 9.6%, and 6.7%, respectively, compared to the positive controls BMS-1166 (33%) and BMS-202 (8.4%). Structural validation through saturation transfer difference nuclear magnetic resonance (STD-NMR) spectroscopy confirmed the binding of RB to PD-L1, with a unique STD peak at 7.6 ppm, further supported by a WaterLOGSY control experiment indicating a negative nuclear overhauser effect to water. The dissociation constants KD of RB were determined using SPR, revealing moderate binding affinities to PD-L1.Cytotoxicity assays conducted on Jurkat T cells and A375 melanoma cells demonstrated that RB exhibited no toxicity across a concentration range from 100 μM to 0.01 μM. Functional assays using a co-culture model of T cells and cancer cells, designed to replicate the tumor microenvironment, showed that RB treatment modulated IL-2 secretion and induced apoptosis in A375 cancer cells. Proteomic analysis of sorted Jurkat T cells from the co-culture model via bottom-up proteomics revealed key proteins and signaling pathways regulated by RB.Overall, these findings suggest that RB exerts significant PD-1/PD-L1 inhibitory activity and may hold promise as a repurposed drug candidate for cancer immunotherapy.

Keywords: PD-1/PD-L1, FDA-approved drugs, surface plasmon resonance, STD-NMR, co-culture model, proteomics

#3157 Novel synthetic lethality-based cellular assays for cancer drug discovery.

G. Maresca[1], F. Scagnoli[1], F. Sassone[1], A. Poli[1], P. Bonetti[1], L. Curti[1], S. Goldoni[2], H. Batoulis[3], E. Nevedomskaya[4], J.-F. Rolland[1], E. Pook[3], L. Redaelli[1], **T. Grammatopoulos**[1];

[1]AXXAM SpA, Bresso, Italy, [2]Bayer AG R&D Pharmaceuticals, Cambridge, MA, [3]Bayer AG R&D Pharmaceuticals, Wuppertal, Germany, [4]Bayer AG R&D Pharmaceuticals, Berlin, Germany

In the present study we illustrate how, using the concept of synthetic lethality (SL), we developed cellular assays suitable for the screening of new drugs targeting cancer-specific weaknesses. SL is a promising strategy in cancer therapy that exploits the genetic vulnerabilities of cancer cells. This approach targets pairs of genes where the mutation or changes of one gene does not affect cell viability, but the simultaneous occurrence of these events in both leads to cell death. This concept is particularly valuable in cancer treatment, as it allows for the selective targeting of cancer cells while sparing normal cells. In this study we coupled powerful molecular approaches such as CRISPR/Cas9 or RNA interference (siRNA and shRNA) with cell viability tests (CellTiter-Glo®), to generate cellular assays suitable for assessing SL of two different genes of interest (GOIs) in proof-of-concept studies and perform drug screening to identify novel inhibitors able to mimic loss or mutations of the GOIs, inducing specific cell death of tumor cells. First, we induced SL by silencing VPS4A in cells already exhibiting loss or reduced function of VPS4B, ultimately triggering selective tumor cell death while sparing normal cells. Indeed, the homozygous loss of VPS4B is seen in up to 4% of colorectal, ovarian, and pancreatic cancers. The SL was then assessed by using siRNA to silence VPS4A and VPS4B in various cancer cell lines expressing different levels of the 2 GOIs and evaluating cell viability. Conversely, to generate stable cellular assays, CRISPR/Cas9 technology was applied to develop both VPS4B knockout (KO) and heterozygous (HET) cell lines, validated through Sanger sequencing and protein expression analysis. These genetically modified lines were critical for understanding the molecular mechanisms driving SL, as they were further engineered to obtain an inducible VPS4A silencing (shRNA technology), allowing for controlled VPS4A depletion. These experiments demonstrated that VPS4A silencing in VPS4B KO cells significantly reduced cell viability, confirming the synthetic lethal relationship between the two GOIs. In conclusion, our survival assay approach could be applied to validate the SL between 2 GOIs, identify a suitable genetic context for applying customized therapeutic options, and new drugs to treat cancer. Proof of principle studies could be conducted in transient using siRNA to silence GOIs in various cancer cell lines expressing different levels of GOIs; while stable modulation of the expression of GOI might be obtained using *ad hoc* engineered cell lines, thus allowing long-term studies and screening campaigns. Cellular assays able to elucidate SL mechanisms may have a significant impact on the cancer drug discovery identifying therapies that specifically target cancer cells with known genetic alterations, while minimizing the impact on normal cells and therefore reducing potential side effects.

#3158 CARP: a high-throughput platform for rapid VHH discovery of potent CAR-T therapy.

Weihong Wang[1], Huiyuan Tang[1], John Lee[1], Xinhao Wang[1], Leo Ng[1], Yong Wang[1], Toya N. Baral[1], Jia Yu[2], Jiaguo Li[2], Wenfeng Xu[1]

[1]Chantibody Therapeutics Inc., Menlo Park, CA,[2]Shanghai Cell Therapy Group Co., Shanghai, China

Background: The conversion of suitable antibodies into functional CAR-T therapy presents challenges. Traditional methods for antibody discovery and screening face significant bottlenecks, including the difficulty of high-throughput identification of high-quality antibodies with diverse epitope and affinity coverage, also carry a high risk of missing functionally relevant candidates or falsely identify unsuitable candidates.

Methods: Here, we introduce **CARP** (**C**AR-T **A**I-powered **R**apid high-throughput screening **P**latform), a novel solution designed to rapidly identify VHHs with clinical potential in CAR structures. Our screening platform was applied for the development of CAR T-cell therapy targeting Cadherin 17 (CDH17). Following immunization of alpacas and llamas, hundreds of CDH17 VHH hits were analyzed using an AI-powered platform for lineage determination (epitope coverage), humanization, and immunogenicity profiling. A library of >400 CDH17 VHHs was screened in serial proliferation tumor cell line co-culture assays simulating long-term tumor-CAR-T interactions to evaluate their target-specific expansion capacity in CAR-T format.

Results: After screening and validation of individual VHH candidates, CDH17 CAR hits consistently outperformed VHHs via traditional methods in functional assays, demonstrating superior activity and robustness. Moreover, CARP successfully identified multiple VHHs with identical target binding domain that demonstrated superior target-dependent expansion compared to clinical CDH17 CAR benchmarks and traditionally selected VHHs.

Conclusion: Our CAR VHH platform not only accelerates the discovery process by enabling high-throughput screening to identify highly target-dependent and proliferative VHH leads, but also eliminates the need for additional rounds of immunization and immunogenicity assessments once lead VHHs are identified. CARP offers a powerful, efficient approach for uncovering VHHs that enhance CAR-T cell functionality, providing significant promise for advancing CAR-T therapy development.

#3159 The 5-base genome, a simultaneous detection of genomic and methylation signatures using a concise, integrated multiomic library prep.

Evgenii Chekalin, William Jordan, Oscar Murillo, Danielle Goldberg, James Baye, Joshua Beytebiere, Eric Brustad, Kayla Busby, Bridget Dorsey, Sophie Fertel, Stephen Gross, Rebekah Karadeema, Huy Lam, Valerie Montel, June Pais, **Suzanne Rohrback**, Angelica Schalembier, David Tse, Kat Tzeng, Ali Crawford, Lisa Watson, Allison Yunghans, Fiona Kaper

Illumina, Inc., San Diego, CA

Multiomic (multiple omic) approaches provide an integrated tool set to power biological discovery due to their ability to generate comprehensive information about the molecular underpinnings of distinct phenotypes. Such integrated analyses have shown broad utility across a range of applications, such as cancer classification and rare disease prognosis. For example, a recent population-scale study on breast cancer by Staaf et al showed that the combination of WGS and DNA methylation can be useful to detect BRCA1/BRCA2-deficient tumors with greater sensitivity than DNA sequencing alone. However, multiomic studies that employ single-ome technologies are often time-consuming, costly, and require considerable sample input. A streamlined workflow which provides both genome and methylome annotations stands to greatly accelerate discovery and translational research. Here we present a novel methyl-conversion technology, capable of simultaneous genome variant detection and DNA methylation profiling. This methodology introduces a simplified workflow, requires less than seven hours turnaround time, as little as 50ng of genomic DNA input, and comes with comprehensive analysis pipelines, the combination of which deliver accurate dual-omic annotations for discovery. Here were present a comparative analysis of our 5-base genome technology against existing methodologies, including Whole Genome Sequencing, Enzymatic Sequencing (EM-Seq) and Illumina Methylation EPIC arrays.

#3160 Silicon membrane technology enables novel live-cell assays for screening impermeable compounds prior to medchem optimization.

Zhihui Song, Sophia Hirsch, Andrew Laroque, Jacquelyn Hanson, Alec Barclay, Armon Sharei, Darby Kreienberg, Eleni Rogers, Monique Richards, Crystal Tsui

Portal Biotechnologies, Inc., Watertown, MA

Cell permeability poses a significant challenge to understanding target biology and exploring structure/function interactions of potential drug candidates. As a result, many experiments are performed in biochemical or lysate-based systems, which often fail to replicate the conditions of a live cell, leading to expensive and time-consuming downstream failures. Portal Biotechnologies has created an innovative intracellular delivery platform that leverages silicon membrane-based mechanoporation technology to directly deliver otherwise non-permeable cargos, such as small molecules, peptides, PROTACs, DELs, macrocycles, and probes, into the cytosol. Our research shows that mechanoporation causes minimal disruption to cellular function compared to other techniques like electroporation, which tend to impose stricter cargo limitations and inflict more cellular damage. This platform has also shown early success in delivering probe molecules for innovative intracellular assays, including LgBiT/HiBiT systems for protein degradation studies. Furthermore, we have demonstrated efficient co-delivery of diverse cargos like oligonucleotides, antibodies, and nucleic acids, achieving delivery rates exceeding 80% while maintaining cell viability above 80%.The platform has been validated across a variety of cell types, including widely used cancer cell lines and primary cells such as human immune cells and stem cells. The straightforward mechanical delivery approach enables scalability and seamless integration with liquid-handling systems for high-throughput applications. This capability allows for the automated screening of molecules previously unsuitable for live-cell assays, thereby enhancing the efficiency of drug discovery at multiple stages. By enabling live-cell assays, the Portal platform aims to offer novel biological insights, reduce target-related risks, and lower the likelihood of failures during lead optimization.

#3161 High throughput drug screening to uncover molecular vulnerabilities in pancreatic ductal adenocarcinoma.

Nikta Feizi[1], Eugenia Flores-Figueroa[2], Karen Ng[2], Zhen-Mei Liu[2], Farnoosh Abbas Aghababazadeh[2], Gun Ho Jang[3], Daniela Bevacqua[2], Stephanie Ramotar[2], Shawn Hutchinson[2], Anna Dodd[2], Julie Wilson[3], Robert Grant[1], Ronan Mclaughlin[2], Erica Tsang[1], Jennifer Knox[1], Steven Gallinger[1], Benjamin Haibe-Kains[1], Faiyaz Notta[1]

[1]University of Toronto, Toronto, ON, Canada,[2]University Health Network, Toronto, ON, Canada,[3]Ontario Institute for Cancer Research, Toronto, ON, Canada

Introduction: High-throughput drug screening enables rapid testing of numerous drugs on tumor samples and has achieved breakthroughs in treatment selection for fatal diseases such as acute myeloid leukemia. This study leverages high-throughput screening to identify molecular vulnerabilities in pancreatic ductal adenocarcinoma (PDAC), a highly lethal cancer with a 5-year survival rate of just 13%.

Methods: Using PDAC patient-derived organoids (PDOs), we developed a platform to screen approximately 3,000 compounds at a single dose and 600 compounds across six doses on 120 PDOs. Additionally, we designed a tailored focused screening of 22 drugs at 20 doses, prioritizing Health Canada-approved drugs identified as promising in earlier screenings. To ensure robust data analysis, we developed an optimized bioinformatics pipeline incorporating a three-tier evaluation: Area Under the Curve (AUC), Drug Sensitivity Score (DSS), and maximum efficacy (Emax). Results from each PDO were systematically compared against the entire cohort, ensuring that sensitivity profiles reflect reliable outcomes. Additionally, we integrated drug response data with genomics and transcriptomics obtained through whole-genome and whole-exome sequencing of PDOs.

Results: We identified highly potent compounds capable of suppressing tumor growth in over 55% of PDOs, prioritizing clinically approved drugs to facilitate rapid translation to patient care. Drug sensitivity patterns from single-dose screenings were corroborated through six-dose validation and a focused screening platform. By integrating drug response data with multi-omics analyses, we uncovered patient-specific drug response profiles linked to molecular vulnerabilities. Notably, we validated a gene-drug association involving anagrelide, a selective agent that induces cytotoxicity in cancer cells with elevated phosphodiesterase PDE3A levels, highlighting the robustness of our approach. Preliminary findings demonstrate a strong concordance between PDO-derived and patient drug responses, establishing a foundation for actionable clinical insights in the ADOPT trial to guide personalized treatment strategies.

Conclusion: In conclusion, our high-throughput drug screening platform, integrated with multi-omics analysis and robust bioinformatics, enables the identification of patient-specific molecular vulnerabilities in PDAC. This approach advances the potential for precision oncology, providing a foundation for tailored therapeutic strategies in this highly lethal cancer.

#3162 New hit compounds for p53 identified with a CETSA based high throughput screen.

Tomas Friman, Merve Kacal, Laurence Arnold, Stina Lundgren, Daniel Martinez Molina

Pelago Bioscience AB, Solna, Sweden

The p53 tumor suppressor protein is of central importance in tumor biology because of its role as guardian against neoplastic growth. The importance of p53 is highlighted by the frequency of mutations that have been identified in cancers. Most of these mutations are inactivating the original functions of the protein but some mutations also provide p53 with new functions that act pro-tumorigenic. Therefore, therapeutic strategies and initiatives that either restore the original function of p53 or limit gained functions have been applied. Numerous compounds have been reported in the literature to modulate p53 function. Still, to date, no project has proven successful in the clinical setting, which highlights the difficulty of finding compounds to manipulate p53. Reasons for the undruggable nature of p53 comprise the absence of accessible deep pockets and its lack of enzymatic activity. To understand the nature of the interaction between a set of reference compounds and p53, we subjected these molecules to a high throughput (HT) assay based on the Cellular Thermal Shift Assay (CETSA). Three different breast cancer cell lines with different p53 mutational status were used for this study: SK-BR-3 (p53R175H), BT-474 (p53E285K), and MCF-7 (p53WT). We generated ten-point concentration - response curves for all compounds in each of the three cell lines. In addition, knowing the complex nature of both p53 and its central role in the cell, we ran the assay both in lysate and intact cells. Target engagement could be established for some of the compounds in intact cells but was lacking in lysate. There was also a cell type specific variation in effects of the compounds. As an example, Butein exhibited single digit micromolar potency in intact SK-BR-3 cells, whereas there was very little effect in MCF-7 cells, which could be attributed to the difference in p53 mutational status between these cells. To learn more about the reference compounds and to investigate if their effects could be attributed to other cellular protein interactions, we subjected them to a proteome wide CETSA profiling, using mass spectrometry as a read out. The target engagement profile of the tested compounds was as diverse as their chemical structures, with very little overlap. Next, we again turned to the CETSA HT platform to screen a library of low molecular weight compounds aiming to identify new hit compounds for mutant p53. The screen was successful in identifying compounds that induced a thermal shift of mutant p53 in intact SK-BR-3 cells. These hits were then confirmed by QPCR based efficacy assays which showed effects on p53 regulated transcription. Here we highlight the applicability of CETSA in investigating the relevance of annotated tool compounds and how the properties of CETSA make it well-suited for screening for new hit matter, also when aiming for notoriously hard to drug targets.

#3163 Discovery of highly selective ligands for the Bcl-2 family of proteins using DNA-encoded chemical libraries.

Ying Zhang, Sana Bazzaz, Corey Bienstock, Paolo A. Centrella, Marie-Aude Guie, John P. Guilinger, Anthony D. Keefe, Matthew A. Clark

X-Chem Pharmaceuticals, Waltham, MA

DNA-encoded chemical library (DEL) technology enables the efficient screening of large collections of encoded compounds and has emerged as a powerful tool for hit identification. De Novo design and synthesis of non-traditional encoded libraries such as a reversible covalent compound library and beyond Lipinski's rule of five (bRo5) macrocyclic (MC) libraries have significantly expanded the chemical space available for DEL screening, and further enhances the feasibility of discovering highly selective ligands for challenging oncology targets. We will present examples of affinity-based ligand discovery targeting protein-protein interactions within the Bcl-2 family of proteins, specifically focusing on MCL1 and BFL1. We highlight the multiplexed DEL selection strategy employed and elucidate the molecular details around the uniqueness of the ligand interactions.

#3164 Micro-Tag^{TM} cell target engagement platform - From discovery to optimization.

Ivan Babic, **Elmar Nurmemmedov**

CellarisBio, San Diego, CA

Smartly designed drug discovery programs can amplify the success rate and accelerate the progress from hit discovery to optimization. Drug discovery for challenging or “undruggable” drug targets such as transcription factors necessitates the proteomic complexities of the cellular milieu for proper folding and function. Therefore, conventional drug discovery methods are not sufficient for most of these proteins. The incorporation of recent cell target engagement methodologies has helped improve drug discovery efforts. However, currently available high throughput cell target engagement methods are limited to measurement of end-point signal, poor utility across multiple challenging target families and insufficient resolution for kinetic and mechanistic readouts. Here we present MICRO-TAG^{TM} cell target engagement platform for challenging drug targets. We provide data demonstrating utility of MICRO-TAG platform for rapid discovery of novel interacting drug molecules to several challenging drug targets. The platform enables cross experimentation with the same cell reporter system for comprehensive hit identification, validation, lead identification and optimization employing several experimental strategies.

#3165 Leveraging chemoinformatics and high-throughput screening for the identification of novel ubiquitin specific protease 7 (USP7) inhibitors.

R. Oliveira[1], C. Franco[2], M. Mano[3], A. Leal[4], K. Liby[4], J. Salvador[1];

[1]Faculty of Pharmacy - University of Coimbra, Centre for Innovative Biomedicine and Biotechnology & Center for Neuroscience and Cell Biology - University of Coimbra, Coimbra, Portugal, [2]Center for Neuroscience and Cell Biology - University of Coimbra, Coimbra, Portugal, [3]Centre for Innovative Biomedicine and Biotechnology & Center for Neuroscience and Cell Biology - University of Coimbra, Coimbra, Portugal, Coimbra, Portugal, [4]IU School of Medicine, Indianapolis, IN

Ubiquitin-Specific Protease 7 (USP7) is a member of one of the most largely studied families of deubiquitylating enzymes, proteases that play a key role in controlling the dynamics of ubiquitination within the cellular ubiquitome. USP7 plays a pivotal role in modulating the levels of multiple proteins, including tumor suppressors, transcription factors, epigenetic modulators, DNA repair proteins, and regulators of the immune response. This suggests USP7 as a promising druggable target that offers interesting new avenues for cancer therapy. Wherefore, the main goal of this study was the identification of promising small molecules that inhibit USP7 enzymatic activity. The work was conducted according to an integrated workflow combining Computer-Aided Drug Discovery (CADD) and High-Throughput Screening (HTS) of chemical libraries to discover and characterize selective USP7 inhibitors with new chemotypes and adequate pharmacological properties as potential drug candidates to be used for anticancer therapy. Such protocol screened a large set of databases, disclosing 9 novel USP7 hit compounds with *in vitro* USP7 inhibitory activities against both USP7 full-length and USP7 catalytic domain, displaying IC_{50} values between 4.5 μM to 33 μM. The dose-response curves of these compounds tested against cancer cell lines showed promising selective cytotoxicity in breast and lung cancer cells, with IC_{50} values ranging from low nanomolar to micromolar. These results highlight the utility of using CADD and HTS in the early steps of drug discovery and pave the way for the identification of novel USP7 inhibitors that might represent a steppingstone for cancer treatment.

#3166 High-throughput screening and triage assays for the identification of PPI disruptors in cancer cells.

A. Dos Santos, R. De Gioia, A. Segnali, D. Zian, C. Nucci, M. Catalani, A. Molteni;
Axxam, Bresso, Italy

Epigenetic and transcriptional dysregulations play pivotal roles in cancer development, progression aggressiveness, and recurrence of malignancies. In collaboration with a pioneering stealth company sprouted from the academic world, we leveraged an innovative drug discovery platform designed to target the disruption of the target protein-protein interaction (PPI). Using a luminescence complementation assay, we identified small molecules capable of selectively disrupting the target PPI within cells (native conformation, *i.e.* target assay) as well as disrupting the interacted proteins in cellular extracts. Over 4.10^5 compounds were screened using the target assay, successfully adapted to a 384-well plate format, in the search of a specific compound disrupting the native conformation of the PPI. An overall statistical hit rate of 0.4% (cut-off ranging between 46%-57% inhibition, depending on the collection tested) was obtained at the completion of the compounds' libraries screening tested at one concentration (20 µM). Up to 1% of screened compounds were selected for further validation via dose response assessment on both the target and the counter-screening assays (i.e. unrelated protein-protein interaction related to cancer progression). Among the 5,000 compounds promoted, 184 compounds were identified as putative selective disruptors of the target, while 107 were selected for further assessments due to a > 0.7 log shift in IC_{50}. Similarity search using Tanimoto coefficient from confirmed hits was performed to select additional analogs compounds from the original pool. A total of 1,279 confirmed hits and their analogs were promoted to potency evaluations on the target and three counter-screening assays. These assays included dynamic interactions in cellular assays and protein disturbance in cell lysates, confirmed the activity on the target assay of more than 60% of the compounds. Notably, 27 hits were confirmed as specific in the native conformation assays, while 88 compounds demonstrated specificity in lysate-based assays. Among these, seven compounds were validated as selective and specific disruptors, and one compound showing a >1 log shift in IC_{50} between target PPI and unrelated cancer PPI. A subset of compounds has undergone further validation through co-immunoprecipitation and target-specific in vitro growth arrest models, showing encouraging results. Following a well-defined screening cascade that integrates bioactivity in cancer-specific cell lines with cytotoxicity assays in non-transformed cells, the compounds will be further triaged to select the best qualified hits. Targeting PPI directly or indirectly has been a challenging and long-standing goal in cancer research. By integrating diverse expertise and resources, from academia and industry, this drug development program has not only been accelerated but it was enhanced by the robustness of the findings.

#3167 Longer and brighter live cell bioluminescence prosubstrates.

C. Gao[1], B. Binkowski[2], H. Wang[1], W. Zhou[1];
[1]Promega Corporation, San Luis Obispo, CA, [2]Promega Corporation, Madison, WI

Bioluminescence prosubstrates are chemically protected bioluminescence substrates which, upon introduction to cells, can gradually and slowly release free substrate for generating luminescent signals in cellular assays. Prosubstrates can generate steady signals that last for several hours or days, enabling live-cell, kineticassays. Noticeable examples of bioluminescence prosubstrates include Nano-Glo Endurazine and Vivazine Live Cell Substrates. Although these prosubstrates have been serving the scientific community for years, they still have drawbacks, including reduced brightness, sensitivity, and signal duration. Herein, we describe a new generation of live cell bioluminescence prosubstrates that can overcome the drawbacks of current prosubstrates.

#3168 High-throughput hybridoma monoclonality characterization using the Celigo™ Image Cytometer.

M.-S. Lin[1], **C. Franco Nitta**[2], M. Pierce[2], B. Lin[2], L. L. Chan[2], J. Ni[1];
[1]BioLegend, San Diego, CA, [2]Revvity, Lawrence, MA

Hybridomas are hybrid cells produced by fusing an antibody producing B cell with a myeloma cell to produce a specific monoclonal antibody. In the process of generating stable clones, developers are often required to perform several rounds of subcloning by plating cultures with a density of a single cell per well. The wells with a single colony are then selected to produce the target antibodies. Traditionally, this lengthy process was heavily relied on researchers with extensive training and experience; however, even experienced researchers may suffer from human error of selecting clones that are not truly monoclonal, thus potentially delaying antibody development and increasing costs. In this work, we demonstrate a high-throughput solution that has successfully established monoclonality of our hybridoma by employing the Celigo™ Image Cytometer (Revvity Health Sciences, Inc., Lawrence, MA) with the robotic arm accessory to screen potential candidates for downstream antibody production under a GMP environment. The Celigo™ is a plate-based, whole well, high-throughput image cytometry system with brightfield and fluorescence imaging capabilities. In combination with the robotic arm, automation can be implemented to further streamline the monoclonality workflow, and subsequently reduce subcloning personnel time by 25-50%, while also minimizing human handling errors by at least 10-fold. Following imaging acquisition, an in-house monoclonality analytical software was utilized to provide concrete documentation for every clone selected for production. Lastly, we demonstrated that time for hybridoma development in clone confirmation screening as well as subcloning could be further improved by incorporating ClonePix technology.

#3169 Dependency-agnostic drug discovery: A dual-screening strategy to uncover novel cancer vulnerabilities.

Olasunkanmi Olaoye[1], Colleen Harrington[2], Kenneth N. Ross[1], Allen T. Basanthakumar[1], Jamie O. Brett[3], Shakchhi Joshi[1], Jonathan H. Shrimp[4], Min Shen[4], Lucy Merickel[1], Audrey Taillon[1], Silvi Salhotra[1], Bo Kyung A. Seong[1], Ji Seul Han[3], Yara R. Zabala[1], Ashleigh Meyer[1], Qi Liu[1], Luc de Waal[2], Jun Qi[1], Matthew D. Hall[4], Marcia C. Haigis[3], Jennifer Roth[2], Kimberly Stegmaier[1]

[1]DFCI/Harvard Medical School, Boston, MA,[2]Broad Institute, Boston, MA,[3]Department of Cell Biology, Harvard Medical School, Boston, MA,[4]National Center for Advancing Translational Sciences, Rockville, MD

The current landscape of small-molecule drug discovery prioritizes genetic dependencies considered as viable protein targets. While this approach has driven significant therapeutic advancements, it has also constrained the exploration of non-dependency targets harboring tractable vulnerabilities. Moreover, many genetic dependencies remain undruggable, precluding their therapeutic exploitation and leaving critical gaps in addressing cancers with unmet clinical needs. To overcome these limitations, we developed a tandem screening approach that integrates large-scale chemical and genetic screens to identify novel vulnerabilities independent of traditional dependency paradigms. Using PRISM, a multiplexed drug-screening platform, we identify compounds with selective toxicity against specific cancer lineages, revealing novel biology readily amenable to small-molecule drug discovery. Subsequent genome-wide CRISPR screens elucidate the mechanistic underpinnings of these compounds, offering actionable insights into new therapeutic opportunities. We applied this approach to Ewing sarcoma, an aggressive bone tumor characterized by the fusion oncoprotein EWS-FLI1, a known dependency that drives epigenetic reprogramming and disease progression. Despite its critical role in disease initiation and maintenance, therapeutic targeting of EWS-FLI1 has remained elusive, underscoring the urgent need for alternative strategies. From our PRISM screen of 4,518 compounds across 935 cancer cell lines, including 17 Ewing sarcoma lines, we identified several compounds with selective toxicity against Ewing sarcoma. Chemical clustering and mechanism-of-action analysis revealed diverse chemical motifs and biological targets, none of which were directly linked to Ewing sarcoma dependencies. A CRISPR rescue screen with three top compounds identified a shared vulnerability: UGT3A2, a UDP-glucose transferase specifically expressed in Ewing sarcoma under the transcriptional control of EWS-FLI1.Our mechanistic studies revealed that UGT3A2-mediated glycosylation of these compounds depletes intracellular UDP-glucose, disrupting glycolysis and triggering ER stress via the PERK-EIF2A pathway, culminating in cell death. This unique vulnerability of UGT3A2, while not a dependency itself, represents a tractable target for therapeutic exploitation in Ewing sarcoma. Building on these findings, we have developed a library of lead compounds exploiting the vulnerability imposed by UGT3A2 in Ewing sarcoma and are currently advancing them in later-stage preclinical optimization. This study underscores the potential of our tandem screening approach to uncover vulnerabilities in cancers with undruggable targets and unmet clinical needs. Beyond Ewing sarcoma, this platform offers a promising strategy to expand the therapeutic landscape for difficult-to-treat malignancies.

#3170 DMSO 2.0 - An advanced DMSO product for 2D and 3D cell culture of PROTACs and hydrophobic drugs.

Ketan Patel

St. John's University, Queens, NY

Dimethyl sulfoxide (DMSO) is the most commonly used aprotic solvent for solubilizing poorly water-soluble molecules in cell culture assays. It is an inert, biocompatible solvent with high solubilization capacity. In the last decade, there has been a big parade shift in cancer drug discovery with the development of next-generation cancer therapeutics, especially oncogenic protein-specific small molecules and targeted protein degraders, also known as Proteolysis Targeting Chimera (PROTACs). Such novel drugs are efficiently degrading/inhibiting the key oncoproteins that remained “undruggable” for many years before 2010 e.g., KRAS, PARP, BRAF, etc. Though very efficient, the majority of them fall in beyond Lipinski rule 5 space (bRo5) due to extreme hydrophobicity. Due to poor solubility and rapid precipitation tendency, such molecules pose great challenges during *in vitro* cell culture and preclinical testing. In our lab, we have observed that stock solution of anticancer molecules (BRD4 PROTAC, EGFR PROTAC, BRD4/MDM2 PROTAC, Sorafenib, Adagrasib, Trametinib, Vemurafenib, Lenvatinib) prepared in DMSO showed immediate to sustained precipitation of drug in DMEM/RPMI media with 5-10% serum. It resulted in significant variation and inaccuracy in cytotoxicity assays. Precipitation of the molecule within the tip (while mixing it from stock solution to media) led to inaccuracy in concentration. Thus, designing and developing an advanced DMSO formulation for testing such novel anticancer molecules is imperative. After screening over 15 hydrophilic adjuvants and their combinations, DMSO 2.0 was developed and tested using the above anticancer molecules. 50 mM stock solution of molecules was prepared in DMSO and DMSO 2.0, followed by addition into cell culture media. Precipitation was monitored by microscopy and high-performance liquid chromatography (HPLC) method. DMSO 2.0 led to the easy mixing of stock solutions with the media by preventing the precipitation of molecules within the tip. Most importantly, DMSO 2.0 led to marked inhibition/slowing down the precipitation of molecules in media compared to DMSO. Precipitation was inhibited at as high as 50 µM and all the subsequent dilutions. DMSO 2.0 showed no apparent cytotoxicity at a concentration below 0.5% v/v in lung cancer cells. Overall, DMSO 2.0 could be a promising solvent for cancer drug discovery, and its drug-specific composition will provide crucial insight into early formulation development strategy for preclinical testing.

CLINICAL RESEARCH: Adoptive Cell Therapy 1
Poster Session

#3173 JL-lightning CAR-T, a next generation non-viral CAR-T without *in-vitro* culturing procedure, shows high clinical efficacy, good safety with low treatment dosage.

Shuya Wang[1], Yan Sun[1], Jinxing Lou[2], Hongfan Zhu[2], Zhicai Lin[1], Dan Sun[1], Jiaguo Li[1], Lijie Rong[1], Jun Guo[1], Jinjing Zhang[1], Yi Liu[1], Wenfeng Xu[3], Qijun Qian[1]

[1]Shanghai Cell Therapy Group Co., Ltd, Shanghai, China,[2]Shanghai Mengchao Cancer Hospital, Shanghai, China,[3]Chantibody Therapeutics Inc., Menlo Park, CA

Background: CAR-T with high in vivo proliferation and long persistency could benefit hematologic malignancy patients with low relapse and long survival. Previous studies reveal that CAR-T stemness (T-stem) and exhaustion level are major determinants of CAR-T quality that contribute to clinical outcome. However, conventional manufacturing process with 9-14 days *in vitro* culture sacrifices T-stem and prolong the vein-to-vein process. Researchers have tried to shorten this process, but many failed due to T-cell activation insufficiency, transfection toxicity, and poor quality control, especially in non-viral transfection.

Methods: Two versions of non-viral JL-Lightning-CAR-T fast manufacturing process have been developed to shorten *in vitro* culture process, V-30h and V-6h. Of note, there is no culture after transfection to enhance CAR-T-stem and *in vivo* expansion. JL-transposon has been developed and proved with high transfection efficiency and low toxicity on both activated and resting T cells. We generated a tri-targeting CAR-T (BZE2204) using VHHs against CD19, CD22 and BCMA, then evaluated its safety and efficacy with both V-30h and V-6h *in vitro* and *in vivo* using Raji orthotropic model. One investigator-initiated trial (IIT) is designed to assess the safety and preliminary efficacy of BZE2204 CAR-T in relapsed/refractory Non-Hopkins Lymphoma (r/r NHL) patients.

Results and Conclusion: *In vitro* experiments showed both versions of BZE2204 exerted strong cytotoxicity on CD19-, CD22- and BCMA-positive tumor cells with high CAR-T cell expansion rates, superior stemness and low exhaustion phenotype compared with conventional CAR-T. V-6h, which has the shortest process, displayed the highest T-stem and proliferation among all groups. *In vivo* models showed V-30h BZE2204 inhibited tumor growth and significantly prolonged mice lifespan under super low dosage (1E5 CAR-T/mouse). Three r/r NHL patients with high tumor burden were enrolled and infused with the dosage of 40-fold lower than conventional CAR-T. The data showed that CAR-T BZE2204 had promising clinical response with manageable safety profile, two achieved complete remission (CR) within 1 month, and the third patient with a single tumor over 7000mm^2 in-size, achieved partial remission (PR) with >80% of tumor shrinkage. Pharmacokinetics data showed high CAR-T proliferation with Cmax of 5066 CAR-T cells/ul and AUC_{0-28} of 46,486 cells*d. Our results show JL-Lightning CAR-T achieves high anti-tumor efficacy and good safety in large tumor-burden r/r NHL patients with super low dosage, likely due to short non-viral manufacturing process, high stemness and proliferation, and VHH-based multi-targeting design in CAR-T product. It offers a more effective, affordable and short vein-to-vein process option for hematologic malignancies CAR-T treatment.

#3174 BiTE® molecule vs CAR-T targeting FLT3 in AML: How positive co-stimulation tips the scale.

Lisa Rohrbacher[1], Daniel Nixdorf[1], Helena Stadler[1], Bettina Brauchle[1], Florian Markl[1], Adrian Gottschlich[1], Gordon Hoffmann[1], Nora Philipp[1], Gerulf Hanel[1], Martin Kirmaier[1], Anetta Marcinek[1], Maryam Kazerani[1], Alica-Joana Emhardt[1], Giulia Magno[1], Rebecca L. Goldstein[2], Sebastian Theurich[1], Tobias Straub[3], Sebastian Kobold[1], Tara Arvedson[4], Veit L. Bucklein[1], Marion Subklewe[1]

[1]LMU University Hospital, LMU Munich, Munich, Germany,[2]AMGEN Inc., South San Francisco, CA,[3]Core Facility Bioinformatics, Biomedical Center, LMU Munich, Munich, Germany,[4]AMGEN Inc, South San Francisco, CA

T cell-based immunotherapy has revolutionized the treatment of B-cell malignancies, yet applying it to acute myeloid leukemia (AML) is challenging due to difficulties in identifying suitable target antigens without on-target off-leukemia toxicity. Prior studies identified FLT3 as a promising target antigen with restricted expression in the healthy hematopoietic compartment[1]. Here, we evaluate a FLT3-directed BiTE® molecule and 2nd generation FLT3-specific CAR T cells in a preclinical AML model. We hypothesize that positive costimulatory molecules on AML cells enhance BiTE® molecule effectiveness, while CAR T cells may be less dependent due to their built-in costimulatory domain. Cytotoxicity was assessed in cocultures over time using MPFC. The impact of positive costimulation was tested using our established Ba/F3 model system lacking any human costimulatory molecules. On-target off-leukemia toxicity was evaluated in cytotoxicity and CFU assays of pAML cells and healthy bone marrow (hBM). T-cell exhaustion was examined in a longterm culture system with continuous antigen exposure. Lastly, xenograft AML models and RNA sequencing explored differences between the two platforms *in vivo*. BiTE® molecule and CAR effectively mediated cytotoxicity against various AML cell lines and pAML cells. Overexpression of the costimulatory CD86 on the target cells significantly increased BiTE® molecule-mediated cytotoxicity cells, while CAR-mediated lysis was unaltered. In both scenarios, low E:T-dependent toxicity was observed against hBM. Mixing experiments showed efficient pAML cell lysis with minimal impact on hBM. CFU assays indicated no effect on hematopoiesis of healthy $CD34^+$ stem cells. 28-day cocultures led to T-cell exhaustion in both settings, marked by reduced proliferation, cytokine secretion, metabolic fitness, and cytotoxicity. CAR T cells demonstrated superior antileukemic activity, with enhanced proliferation and splenic homing in an AML xenograft model. RNA sequencing revealed more exhaustion-related markers in BiTE® molecule-redirected T cells, while CAR T cells showed upregulated glycolysis and fatty acid metabolism. Repeating our *in vivo* xenograft experiment with CD86-overexpressing AML cells supported our hypothesis that costimulation might be a key factor providing a head start to CAR T cells by increasing T-cell proliferation and persistence *in vivo*. Our *in vitro* data show similar cytotoxicity and specificity, while xenograft mouse models suggest CAR T cells offer a significant survival advantage over BiTE® molecules. Our data support the hypothesis that positive costimulation integrated within the CAR constructs boosts T-cell activation, homing, and efficacy, thereby delaying T-cell exhaustion *in vivo*. Future studies are needed to further dissect differences between BiTE® molecule vs CAR T cell-based immunotherapy and identify suitable patient groups. [1]Brauchle et al 2020

#3175 Exploring the potential of CEA-CAR-NK cells in colorectal cancer.

Alice D'Andrea[1], Marco Cortese[2], Enzo Medico[1]

[1]Candiolo Cancer Institute, FPO IRCCS, University of Torino, Torino, Italy,[2]Oncology, Candiolo Cancer Institute IRCCS, Candiolo, Italy

Chimeric Antigen Receptor (CAR) therapy targeting carcinoembryonic antigen (CEA/CEACAM5) is a promising strategy for colorectal cancer (CRC). CAR-T cells, however, carry significant side effects, and the fact that CEA is also expressed at low levels in normal tissues makes CAR-NK cells a safer alternative, offering reduced toxicity while maintaining effective anti-tumor activity. Despite this potential, CAR-NK systems targeting CEA remain underexplored. In this study, we generated and evaluated clones of the NK-92 cell line expressing two CAR constructs with distinct affinity for CEA: BW431/26 (moderate affinity) and hMN-14 (high affinity). The BW431/26-based CAR, with its lower affinity, may offer a safer profile by reducing potential on-target, off-tumor effects. On the other hand, the hMN-14-based CAR demonstrated superior cytotoxicity in *in vitro* studies due to its higher affinity. Sorted populations and clones of CAR-NK cells transduced with these constructs were evaluated for killing activity both *in vitro* and *in vivo*. *In vitro*, the high affinity hMN-14 CAR exhibited enhanced killing capacity compared to the BW431/26 CAR. However, *in vivo* experiments on CRC xenografts in NOD/Scid mice showed comparable tumor growth inhibition between the two constructs. These findings suggest that higher scFv affinity does not necessarily translate to improved *in vivo* efficacy of CEA-CAR-NK cells, emphasizing the multiplicity of factors influencing their activity—such as persistence and activation—and highlighting the need for further modifications to optimize their functionality.

#3176 CD19/CD22 bispecific CAR-T cells are effective in CD19 loss B-cell tumor models.

Jiao Jiao

Gan & Lee Pharmaceuticals, Beijing, China

Background: Chimeric antigen receptor T (CAR-T) cell therapy targeting CD19 can significantly improve the long-term survival rate of patients with relapsed or refractory leukemia. However, CD19 absence or loss leads to resistance of the B-lymphoblastic leukemia cells to CD19 CAR-T cells and the patients will relapse. To solve the problem, we developed bispecific CAR-T cells that target CD19 and CD22 and evaluated their antitumor effects.
Methods: The CD19/CD22 bispecific CAR-T cells were generated through the transduction of lentiviruses that simultaneously carry the genes for both CD19 CAR and CD22 CAR, including an anti-CD19 scFv, an anti-CD22 scFv, a CD8 hinge region, a CD8 transmembrane region, a 41BB intracellular region and a CD3ζ intracellular region. In vitro tumor killing assay on NALM6 and Ramos cells and in vivo efficacy studies on Ramos cell line-derived xenografts (CDX) were performed.
Results: In in vitro studies, the CD19/CD22 CAR-T cells killed wild-type (WT) NALM6 and WT Ramos cells effectively like CD19 CAR-T; the CD19/CD22 CAR-T cells but not CD19 CAR-T cells killed NALM6 cells with loss of CD19 protein but expression of CD22 protein (CD19-CD22+) and CD19-CD22+ Ramos cells effectively. In in vivo studies, the CD19/CD22 CAR-T cells significantly prolonged the survival of mice bearing CD19-CD22+ Romas cells than CD19 CAR-T.
Conclusion: The CD19/CD22 bispecific CAR-T cells effectively kill B-cell tumors with CD19 loss both in vitro and in vivo, which will have a superior therapeutic effect on patients with relapse due to loss of CD19 protein.

#3177 Advancing CAR T-cell therapy in AML: Enhancing specificity and bone marrow homing via chemokine receptor engineering.

Lis Winter[1], Katharina Konnerth[1], Anne-Sophie Neumann[1], Luisa Schmid[1], Stefanos Michaelides[2], Yingshuai Wang[1], Louisa von Baumgarten[3], Sebastian Kobold[2], Veit L. Bucklein[1], Marion Subklewe[1]

[1]Department of Medicine III, University Hospital, LMU Munich, Munich, Germany,[2]Division of Clinical Pharmacology, Department of Medicine IV, University Hospital, LMU Munich, Munich, Germany,[3]Department of Neurosurgery, University Hospital, LMU Munich, Munich, Germany

To date, the success of CD19-directed CAR T cells in B-cell malignancies has not been replicated in other hematological or solid malignancies. Key hurdles include the absence of suitable target antigens and limited tumor site homing. CAR T-cell efficacy can be enhanced by engineering T cells to express receptors specific to chemokines released by cancer or cancer-associated cells[1]. Thus, we aimed to identify receptors that promote directed migration to the bone marrow niche, thereby enhancing CAR T-cell efficacy in AML. Köhnke et al.[2] identified upregulated expression of CCR2 and CXCR2 on the surface of AML cells via mass spectrometry, which we confirmed on primary AML cells using MPFC. Next, we used a retroviral-based transduction to engineer αCD33-28ζ-CAR T cells to co-express CCR2 or CXCR2. We analyzed $CCR2^{high}$- or $CXCR2^{high}$-CD33 CAR T-cell mediated cytotoxicity against the AML cell lines MV4-11 and MOLM-13 by MPFC. Next, we evaluated the specific migration towards the ligands CCL2 and CXCL8, conditioned AML cell line medium as well as towards bone marrow serum from primary AML samples using transwell assays and 3D migration chambers. The engineered $CCR2^{high}$- and $CXCR2^{high}$- CD33 CAR T cells showed no significant phenotypic differences compared to CD33 CAR T cells, as shown by activation or exhaustion marker expression or T-cell subset formation. To our surprise, we observed a reduced target cell killing together with reduced inflammatory cytokine secretion at high E:T ratios (1:20 & 1:30) with the $CCR2^{high}$- or $CXCR2^{high}$- CD33 CAR T compared to CD33 CAR T cells. These effects were more prominent in MOLM-13 than MV4-11 cells and we are currently investigating the underlying mechanism. Next, we tested for the migratory capacity towards the specific ligands CCL2 and CXCL8. Enhanced migration, cell velocity and speed of $CCR2^{high}$- and $CXCR2^{high}$-CD33 CAR T cells were observed compared to CD33 CAR T cells. As expected by the surfacome data of primary AML cells, we identified CCL2 and CXCL8 to be highly abundant in the bone marrow serum of AML patients. Accordingly, transwell assays using bone marrow serum of primary AML patients demonstrated a higher targeted migration of $CCR2^{high}$- and $CXCR2^{high}$ CD33 CAR T cells compared to CD33 CAR T-cell controls. Taken together, we demonstrated that $CCR2^{high}$- and $CXCR2^{high}$- CD33 CAR T cells show enhanced specific migration towards their ligands but also towards AML bone marrow serum. Surprisingly, we detected a reduction in specific lysis after transduction of the chemokine receptors into CD33 CAR T cells. Further studies are needed to understand the influence of the chemokine receptors on killing capacity. Next, we aim to validate these findings in a model system permitting *in vivo* live-cell imaging.

#3178 Discovery and characterization of small molecules to enhance NK cell cytotoxicity against solid tumors.

Indrani Das, Olubukola Abiona, Riufu Liu, David N. Wald

Case Western Reserve University School of Medicine, Cleveland, OH

Adoptive cell therapies (ACT), such as CAR-T and NK therapy, have transformed hematologic cancer treatment but show limited efficacy against solid tumors. NK cell therapies in particular have an excellent safety profile due to their specific, innate recognition of cancer cells, but fail to elicit adequate and sustained tumor clearance *in vivo*. To address this hurdle, we developed a high-throughput phenotypic small molecule screen to identify novel compounds that can enhance NK cell cytotoxicity against tumor cells.
We screened 300,000 compounds for their ability to enhance NK cytotoxicity against ovarian cancer cells (OVCAR-3). Our primary screen and subsequent hit validation identified 11 lead compounds that increase NK cell killing of OVCAR-3 cells (>10% increase over vehicle-treated control). We performed secondary screening using a flow cytometry-based assay on 5 of these 11 compounds to date, confirming that 3 significantly enhance NK cytotoxicity against OVCAR-3. After completing the secondary screening of the remaining 6 compounds, we will identify the most promising lead compound(s) through a series of secondary and orthogonal assays to characterize the biological activity and toxicity profile of validated hits. We will then pursue medicinal chemistry efforts to increase potency of our best lead compound, coupled with mechanistic studies for how the compound promotes NK cytotoxic activity. Ultimately, we hope to translate our findings into NK cell therapy clinical trials to achieve greater efficacy against solid cancers.

#3179 A comprehensive serial killing workflow for assessment of CAR T-cells.

Xiaoyu Zhang, Jyothi Thyagabhavan Mony, Natalia Romero

DGG, Agilent Technologies, Inc., La Jolla, CA

Adoptive cell therapy with chimeric antigen receptor T cells (CAR-T cells) has been highly successful in individuals with hematological malignancies. However, its efficacy against most solid tumors remains elusive due to short-term persistence and inadequate expansion of CAR T-cells within the tumor microenvironment. Traditional in vitro cytolysis assays often fail to reflect the true antitumor potential of the CAR T cells, as they typically involve brief co-culture periods and assess CAR T-cell performance only from a single perspective. To address these limitations, we developed a long-term multiplexed workflow that can robustly and comprehensively assess CAR T cell products. In our study, the EpCAM CAR T-cells were repeatedly challenged with an EpCAM expressing breast cancer cell line, T47D cells, over seven consecutive rounds. During each challenge, the EpCAM T-cells were directly added to the T47 D cells cultured on an E-Plate VIEW 96 (E-Plate) for 24 hours, at the effector to target ratio (E:T) of 0.5 :1. The CAR T-cell cytotoxicity against T47D cells was continuously measured over three days using an xCELLigence RTCA eSight system (eSight). After each co-culture round, the CAR T-cell metabolism, immunophenotype and percentage were evaluated using Agilent XF Pro analyzer and NovoCyte flow cytometer respectively. Following assessment, the challenged CAR T-cells were transferred to a new tumor cell-containing E-Plate to repeat the assay sequence. Our results indicate that: 1) although the percentage of CAR T-cells progressively increased from 25% to 80% by the fifth challenge round, a significant decline was observed in the sixth round; 2) CAR T-cells exhibited a gradual reduction in proliferation and cytotoxicity against tumor cells, along with an increase in the PD1+Tim3+ population across repeated challenges; and 3) CAR T-cells demonstrated a distinct metabolic profile, characterized by progressively decreased maximal respiration, spare respiratory capacity (SRC), and ATP production rate throughout the successive challenges. In conclusion, this multiplexed workflow enables comprehensive evaluation of CAR T-cell proliferation, killing potency, exhaustion phenotype, and metabolic profile over repeated tumor cell challenges, providing a more accurate prediction of their in vivo therapeutic efficacy.

#3181 Single cell characterization and anti-tumor efficacy of single & multi-armored CAR Ts against CLDN18.2.

Megha Sah, Liang He, Gundula Povysil, Cassandra Kontur, Ashley Chui, Stephen Pu, Annie Dyatel, Malavika Sabu, Alice HK Kwon, Xinchen Wang, **David Phizicky**

Waypoint Bio, Inc., New York, NY

Adoptive cell therapies such as CAR T have struggled to translate to solid tumors due to challenges posed by the solid tumor microenvironment (TME) and the low-throughput of *in vivo* testing. Pooled CAR T screens are typically restricted to single readouts (e.g. proliferation) and cannot measure the cell-cell and cell-TME interactions that are critical for CAR T success in solid tumors. We performed *in vivo* spatial pooled screening to profile >250 different CAR T designs to identify efficacious constructs based on spatial-dependent CAR T properties and CAR T-TME interactions. Mouse xenograft models of pancreatic cancer were each injected with hundreds of unique CAR T constructs, including variations in CAR designs and armors. For each library, we prepared 30-40 FFPE slides, harvested from different mice across time points and treated with CAR T cells from different donors. Each slide was stained for 20-30 protein markers, and we also performed *in situ* genotyping to determine CAR T construct identities in the same microscope images. We obtained image-based phenotypes of ~20M total single cells and used custom computer vision pipelines to define single cell spatial phenotypes for each CAR T design, including cytotoxicity, exhaustion, local-neighborhood phenotypes, tumor infiltration, on-target/off-tumor toxicity, proliferation, and activity in immunosuppressive tumor regions. We evaluated selected screen hits in single-construct studies, and trained a random forest model with cross-validation to identify the combination of single cell spatial phenotypes for CAR T designs that were most predictive of tumor shrinkage in the efficacy studies. Overall, we identified multiple single- and double-armored constructs that had superior spatial single cell-level phenotypes (e.g. improved infiltration, increased persistence, decreased PD1/LAG3, etc.) compared to both unarmored 2nd gen CLDN18.2 CAR Ts and TGFβRIIDN-armored CLDN18.2 CARs. We then confirmed superior anti-tumor efficacy of these CAR modifications and armors in multiple xenograft models, at multiple doses ranging from $0.5x10^6$ to $2x10^6$ cells. Combinations of these top armors will be further tested in WP-001, a CAR T construct for solid tumors expressing CLDN18.2.

#3182 Profiling of B7-H3 CAR T cells generated from patients with pancreatic ductal adenocarcinoma.

Giulia Cattaneo[1], Liti Zhang[1], Marco Ventin[1], Shahrzad Arya[1], Enrica Quattrocchi[1], Arsen Osipov[2], Andrew Hendifar[2], Russel W. Jenkins[3], Xinhui Wang[4], Cristina R. Ferrone[1]

[1]Department of Surgery, Cedars-Sinai Medical Center, Los Angeles, CA,[2]Department of Medicine (Medical Oncology), Cedars-Sinai Medical Center, Los Angeles, CA,[3]Department of Medicine, Mass General Cancer Center, Massachusetts General Hospital, Boston, MA,[4]Department of Surgery, Massachusetts General Hospital, Boston, MA

Background: Chimeric antigen receptor (CAR) T cells targeting B7-H3 represent a promising treatment option for pancreatic ductal adenocarcinoma (PDAC), but their application in patients with advanced-stage disease is challenging. CAR T cell fitness is key for therapeutic success, and it correlates with the quality of T cells obtained via leukapheresis. T cell quality can be affected by several factors, including prior therapies and global T cell suppression driven by high tumor burden. In this study we aim to identify immune determinants of CAR T cell fitness in PDAC.

Methods: Peripheral blood mononuclear cells (PBMC) were isolated from pre-operative blood of 9 PDAC patients and analyzed by flow cytometry. CAR T were generated from patients' PBMC by retroviral transduction with a second generation B7-H3-CAR. Results are described as median values and interquartile range.

Results: Of the 9 PDAC patients, 5 were treatment naïve (TN) and 4 had previously received neoadjuvant (NA) chemotherapy. Pathologic tumor size and CA 19-9 level were higher in NA patients than in TN patients (4.7cm [6.4-3.2] vs. 3.3cm [4.5-2.3] and 464 [700-110] vs. 54 [186-13], respectively). TN patients' PBMC presented with a higher T cell count, as compared to the NA group (CD4: 1251 cells/ul [2356-274] vs. 675 cells/ul [1175-512]; CD8: 434 cells/ul [3124-255] vs. 225 cells/ul [1090-140]). The number of circulating Treg was similar between the two groups, while the level of circulating myeloid derived suppressor cells was higher in NA patients as compared to TN patients (875 cells/ul [1317-452] vs. 285 [1147-59]). T cells isolated from TN patients demonstrated a superior proliferation ability upon either acute or chronic *in vitro* activation with anti-CD3 and anti-CD28 antibodies, and were characterized by a higher presence of early memory T cell subsets, as compared to NA patients (percentage of CD45RA+CD45RO-: 17% [31-10] vs. 14% [17-12] for CD4 , and 44% [72-36] vs. 31 [33-28] for CD8). B7-H3 CAR T generated from either TN or NA patients demonstrated a good transduction efficiency (80% [84-73] vs. 73% [82-70]). However, NA-B7-H3 CAR T had a reduced *in vitro* expansion rate than TN-B7-H3 CAR T (18-fold [30-10] vs. 15-fold [21-8]). When cocultured with the human PDAC2 cell line, TN-B7-H3 CAR T demonstrated a significantly higher antitumor activity as compared to NA-B7-H3 CAR T (percentage of PDAC cell killing: 70% [82-65] vs. 50% [63-42], p=0.028). At the end of the coculture, NA-B7-H3 CAR T displayed a more differentiated phenotype, indicated by a higher presence of effector memory CD8 T.

Conclusions: Our findings support the hypothesis that PDAC patients with a greater tumor burden present with a higher degree of T cell dysfunction and that this might hamper the fitness of the related CAR T product. This study provides the basis to further investigate mediators of CAR T cell biology to advance the therapeutic potential of CAR T cell therapy with PDAC.

#3183 GPRC5D and BCMA bi-specific CAR-T: Optimized CAR design to mitigate antigen escape and elicit deep and durable response in heterogeneous multiple myeloma.

Jincai Zhou, Xinran Luo, Kai Wu, Feifei Shi, Bixia Lei, Yanhong Xu, Joy Zhou, **Xiaowen He**

Oricell Therapeutics Co., Ltd., Shanghai, China

Introduction: BCMA CAR-T cell therapies have demonstrated superior efficacy, including in patients with extramedullary disease and high-risk cytogenetics, compared to BCMA-directed TCE or ADC. The longitudinal single cell analysis revealed that pre-existing T cell exhaustion and presence of highly proliferative plasma cells with Ag downregulation predisposed to early relapse post BCMA CAR-T. Moreover, shedding BCMA and suppressive TME also pose significant challenges for sustained clinical response. To tackle these obstacles, BCMA and GPRC5D bi-specific CAR-Ts were designed. GPRC5D is a promising therapeutic target for multiple myeloma (MM), as it - expresses exclusively on MM cells but not in normal tissues (except for hair follicles) and is independent of BCMA expression. Clinical studies confirmed the co-existence of single or double Ag positive MM subsets within the same patient, along with a rare occurrence of double-negative multiple myeloma plasma cells.
Methods: Aiming to broadly and deeply eradicate MM subsets and achieve long-term remission, we've developed bi-specific CAR-Ts exclusively targeting BCMA and GPRC5D. Our design incorporates novel VHH binders with optimized CAR design to enhance sensitivity and efficacy toward heterogenous MM cells in the presence of soluble BCMA, mitigate Ag escape, restore T cell functionality and improve expansion. We've conducted the pre-clinical investigations to validate the activity, functionality and druggability of the bi-specific CAR-Ts.
Results: Binding to GPRC5D and BCMA resulted in bi-specific CAR-T exhibiting improved immune cell activation, superior anti-tumor activity, and functionality over mono-CAR-T or benchmark, and enhanced target-dependent expansion under re-stress. Moreover, the bi-specific CAR-T retained its functionality against BCMA.KO or GPRC5D.KO cells, whereas the mono-CAR-T could not. Importantly, the optimized bi-specific CAR designs incorporating the novel BCMA VHH binder(s) showed robust cytotoxicity against MM cells with low Ag expression in the presence of high concentrations of soluble BCMA, suggesting their potential to effectively counteract the inhibitory effects of soluble BCMA in the serum of MM patients. Compared to mono-specific CAR-Ts, the bi-specific CAR-T showed robust efficacy in tumor eradication at low dose(s) in NSG mice xenografted with heterogeneous MM cell lines.
Conclusions: The pre-clinical data of GPRC5D and BCMA bi-specific CAR-T exhibited superior anti-tumor efficacy and persistence, mitigated Ag escape and preserved potency with shedding BCMA. Our findings provide support for the clinical investigation of the bi-specific CAR-T as a therapeutic approach to broadly and deeply deplete heterogenetic MM cell clones and subsets, potentially leading to durable responses in both newly diagnosed and R/R MM patients.

#3184 Development of novel anti-mesothelin CAR-T cells for the treatment of solid tumors.

Sayyed Hamid Zarkesh Esfahani[1], Kun Luo[1], Michael Wagner[2], Ngoc Tran[1], Brittany Steimle[1], Rimas J. Orentas[1], Peirong Hu[1], Dina Schneider[1]

[1]Lentigen Technology Inc., a Miltenyi Biotec Company, Gaithersburg, MD,[2]Miltenyi Biotec B.V. & Co. KG, Bergisch Gladbach, Germany

Introduction: Mesothelin (MSLN) is overexpressed in many human solid tumors and absent from most healthy tissues. Despite multiple clinical trials, little success has been achieved by MSLN CARs. Shed MSLN accumulates in patient sera and tumor draining fluids, potentially blocking MSLN CAR function (1,2). Alpaca-derived VHHs are an attractive option for CAR design that offer exquisite epitope targeting and the potential to circumvent the challenges of cleaved and shed MSLN.

Methods: Eight alpaca-derived VHHs targeting the MSLN membrane-proximal region were incorporated into a second-generation CD28-CD3ζ CAR framework. A previously developed scFv-based MSLN CAR with either CD28 or 4-1BB co-stimulation was used as comparison. MSLN CAR-T cells from healthy donors were tested *in vitro* for CAR surface expression, overnight killing and real-time consecutive tumor re-challenge. Cytokine production by CAR-T cells was measured after overnight co-culture with $MSLN^+$ tumor cells. *In vivo* CAR-T cell function was evaluated in an AsPC1 pancreatic tumor NSG mouse xenograft model. Persistence of CAR-T cells *in vivo* was investigated by measuring T cells in peripheral blood (PB) and at tumor site. Additionally, shed MSLN in plasma samples was quantified by ELISA. We also tested the effect of soluble MSLN on the potency of CAR-T cells as analyzed by spiking MSLN into *in vitro* killing assays, modeling *in vivo* conditions.

Results: VHH CAR D0492 and scFv CAR D0405 were selected for their high surface expression, *in vitro* cytotoxicity and expansion. *In vitro*, scFv-based CARs with a CD28 co-stimulatory domain demonstrated higher anti-tumor activity, in comparison to 4-1BB. CAR-T cell production of TNFα, IL2 and IFNγ in response to $MSLN^+$ A431 tumor cells was consistently stronger in CD28 CARs. The VHH CAR showed moderate cytokine release without target stimulation, assumed to be via self-association on the T cell surface. *In vivo,* tumor-bearing mice treated with MSLN CAR-T cells each delayed tumor progression without adverse effects on body weight. In contrast to *in vitro* studies, the scFv-based 4-1BB CAR D0181 showed the highest expansion and persistence in PB. IHC staining of tumor samples demonstrated the presence of T cells within tumors in mice treated with anti-MSLN CARs. Shed MSLN plasma concentration *in vivo* at the end of study take down (TD) correlated with tumor size. Importantly, spiking with equivalent or greater MSLN concentrations did not impede CAR-T cell activity in an *in vitro* cytotoxicity assay.

Conclusions: A series of novel MSLN CARs demonstrated potent *in vitro* and *in vivo* anti-tumor activity, were well-tolerated and insensitive to inhibition by soluble MSLN. Second generation scFv-based CARs with 4-1BB co-stimulation demonstrated greater CAR expansion *in vivo*. VHH CARs demonstrated equivalent *in vivo* tumor control to scFv, highlighting the importance in both formats to targeting MSLN membrane-proximal domains.

#3185 Optimizing Stim-R^{TM}, a synthetic stimulatory agent, for feeder-free tumor-infiltrating lymphocyte manufacturing.

Riley P. Allen, Jason Duecker, Mikayla Min, Samantha Chan, Christina Ta, Benjamin Harris, Emily Fu-Sum, Stefan Siebert, Purnima Sundar, Yogin Patel, Shobha Potluri, Suman Vodnala, Gary Lee, Alexander Cheung, Aileen Li

Lyell Immunopharma, South San Francisco, CA

The choice of stimulation agent (e.g. irradiated feeder cells) utilized to expand cells for adoptive cell therapy may limit both scalability and potency of the product. Synthetic cell stimulating agents are tunable, consistent, scalable, and can be adapted to a range of cell therapies. Previously, we reported the development of Stim-R^{TM} for use in melanoma tumor infiltrating lymphocyte (TIL) manufacturing. To broaden the potential application of the technology, we describe optimization of Stim-R in the TIL manufacturing process in additional cancer types. To achieve robust TIL expansion from multiple types of cancer, screens for additional feeder activation cues were conducted by assessing expression of T-cell stimulating ligands on the feeder cell surface, assessing the secretome of feeder cells, and assessing expression of stimulable surface receptors on the initial TIL populations. These data were utilized to develop a new, optimized Stim-R process, which incorporated both new surface cues on the Stim-R platform and soluble signals in the TIL culture media. The optimized Stim-R process was utilized to replace feeder cells in the second expansion step of the TIL manufacturing process. TIL products manufactured with the optimized Stim-R process or feeder cells were evaluated for total cell yield, the expression of stemness markers using flow cytometry, and retention of putative tumor-reactive clones, assessed as the highest frequency clones from the starting tumor material using T-cell receptor sequencing. We developed a new formulation of Stim-R, Stim-R$_{V2}$, which engages CD2, CD3, CD28, CD137 (41BB), and ICOS, and a set of feeder-secreted proteins (FSPs), which are supplemented in the TIL culture media. An optimized Stim-R process that incorporates both Stim-R$_{V2}$ and the FSPs resulted in increased TIL expansion from all melanoma and NSCLC tumors evaluated compared to products generated using feeder cells. TIL products generated with the optimized Stim-R process demonstrated similar CD8 T-cell stemlike phenotypes to feeder-produced TIL and retained a similar proportion of the tumor reactive cells compared to a feeder-based production process. Stim-R can serve as a synthetic replacement for feeder cells in TIL manufacturing. We have optimized soluble and tethered signals incorporated into the Stim-R process to increase TIL expansion in multiple types of tumors. TIL produced with the optimized Stim-R process were phenotypically comparable to TIL produced with a feeder-based process and retained a similar proportion of the putative tumor reactive clones. The Stim-R technology has potential to overcome scalability limitations in TIL manufacturing and may make TIL therapy accessible for more patients. Furthermore, we demonstrate the versatility of the Stim-R platform as a stimulating agent that can be tuned with activation signals based on cell population and desired phenotype.

#3186 Functional analysis of chimeric ILT receptor natural killer (CIR™NK) cells that target tumor cells expressing HLA-G *in vitro* and *in vivo*.

MyLinh Duong, Jihyun Park, Joseph Senesac, Raphael Ognar, Simon Wain-Hobson, **Henri Bayle**

NKILT Therapeutics, Houston, TX

Background: Human leukocyte antigen (HLA)-G exerts immunosuppression by binding to ILT2 and ILT4 on myeloid and lymphoid cells. While HLA-G expression is repressed in normal tissues except the placenta and cornea, more than 50% of cancers express HLA-G to evade immune surveillance. We developed Chimeric ILT Receptors (CIRs) that link the extracellular domains of ILT2 or ILT4 receptor with novel intracellular costimulatory domains (4-1BB.DAP10 ± TLR2) to drive HLA-G specific targeting and activation of Natural Killer (NK) cells.

Methods: $CD56^+$ NK cells were activated and transduced with γ-retroviruses directing multi-cistronic expression of CIR, soluble IL-15, and a ΔCD19 marker. Coculture assays were performed with GFPFluc-expressing tumor cell lines and NK cells transduced with RFP and monitored using the IncuCyte. In vivo, Molm13 tumor-bearing NSG mice were injected i.v. with a single dose of 7.5E6 mock or CIR-NK cells and tumor and NK cell bioluminescence were tracked via GFPFluc and ONLRluc, respectively. Cytokines from cocultures and mouse plasma were analyzed with a 26-panel multiplex kit.

Results: CIR-NK cells demonstrated target-specific elimination of HLA-G^+ multiple myeloma and AML cancer cells while sparing HLA-G^- cancer cells. ILT4.4-1BB.DAP10.TLR2 CIR-NK cells eliminated 2 fold more HLA-G^+MM1S tumor cells than mock-transduced NK cells (GFP intensity: mock = 4.21E5 ± 5.14E4 vs. ILT4.4-1BB.DAP10.TLR2 = 2.15E5 ± 2.26E4) but no killing was observed in coculture against HLA-G^- Molm14 AML cells. In repeated target coculture where tumor cells were added up to 4 times every 2 days, ILT4.4-1BB.DAP10-2A.TLR2 CIR-NK cells eliminated more than 60% of Molm13 AML cells (GFP intensity: 4-1BB.ζ = 3.96E7 ± 5.37E6 vs. 4-1BB.DAP10.2A-TLR2 = 1.45E7 ± 3.34E6) and expanded more than 2 fold relative to CIR-NK cells containing 4-1BB.ζ (RFP intensity: 4-1BB.ζ = 1.49E5 ± 5.72E3 vs. 4-1BB.DAP10.2A-TLR2 = 3.26E5 ± 5.1E4). Comparison of chemokine and cytokine production with and without Molm13 target revealed that that IL-33 (42 fold), CD40L (45 fold), IP-10 (26 fold), and IL-12 p70 (73 fold) were among the many analytes highly upregulated by ILT4.4-1BB.DAP10 CIR-NK cells that arm NK cells against the cancer. In vivo, a single dose of ILT4.4-1BB.DAP10 CIR-NK cells induced 60% greater clearance of Molm13 tumor burden in NSG mice in 10 days relative to ILT4.4-1BB.ζ counterparts and 3 fold greater in NK expansion on day 14. Proinflammatory cytokine and chemokines secreted into mouse plasma were remarkably higher as early as 7 days post CIR-NK injection (IFN-γ = 4134 ± 127pg/ml; GM-CSF = 594 ± 56pg/ml; granzyme B = 1529 ± 233pg/ml).

Conclusions: We demonstrated that engineered CIR-NK cells, coupled with potent intracellular costimulatory domains, can convert HLA-G expression in cancer cells from an inhibitor of immune surveillance into a practical target for anti-cancer therapy.

#3187 Assessing large-scale CAR-T cell cytotoxicity ex vivo using 2-D and 3-D multimodal imaging techniques for industrial standards.

Catherine McManus, John Foulke, Meghan Sikes, Luping Chen, Hyeyoun Chang, **Fang Tian**, Zhizhan Gu

ATCC, Gaithersburg, MD

CAR-T cell therapy is a revolutionary and highly effective treatment for hematologic malignancies, with rapid advancements particularly in applications to solid tumors. The development and refinement of this innovative therapy rely on efficient ex vivo assays to evaluate CAR-T cell cytotoxicity. Furthermore, advancement in the treatment of solid tumors using CAR-T cell therapy requires the development of ex vivo assays specifically using solid tumor models. Here, we report the development of luciferase reporter cancer cell lines that endogenously express high levels of key CAR-T target antigens such as CD19, CD20, BCMA, or HER2. Using targeted and mock-engineered CAR-T cells, we evaluated cytotoxicity against these reporter cells via a bioluminescence assay and phase contrast/fluorescence live imaging assays. Our multimodal imaging approach demonstrated significantly higher cancer cell killing by targeted CAR-T cells compared to mock CAR-T cells. To enhance our live imaging capabilities and enable assays for CAR-T cell infiltration into 3-D tumor models, we engineered GFP-Luc2 dual reporter cancer cell lines. Using 3-D confocal live imaging, we observed reduced spheroid size and decreased luciferase signal in Raji-GFP-Luc2 spheroids co-cultured with CD19 CAR-T cells versus mock CAR-T controls, indicating superior cancer cell killing when using targeted CAR-T cells. Upon embedding Raji-GFP-Luc2 spheroids in 3-D matrices to mimic a more physiologically relevant tumor microenvironment, we captured CAR-T cell infiltration into spheroids by time-lapse 3-D imaging. Our results highlight the utility of combining luciferase bioluminescence and live fluorescence imaging to assay CAR-T cell cytotoxicity and infiltration in 2-D and 3-D co-culture models. The luciferase assay provides sensitive, quantitative measurements, while live fluorescence imaging reveals the spatial and temporal dynamics of CAR-T cell-cancer cell interactions. These scalable assays hold significant potential for large-scale industrial applications in CAR-T cell therapy development.

#3188 Functional interrogation of human T cells using the accessible Beacon Discovery™ optofluidic system.

Patrick N. Ingram[1], Qiong Gao[1], Leqian Liu[2], Julie Perreau[2], Ritika Kukreja[2], Or Gadish[1], Brandon R. Bruhn[1], Minha Park[2], Edward Han[3], Alireza Salmanzadeh[3]

[1]Applications R&D, Bruker Cellular Analysis, Emeryville, CA,[2]Biology R&D, Bruker Cellular Analysis, Emeryville, CA,[3]Marketing & Business Development, Bruker Cellular Analysis, Emeryville, CA

Adoptive cell therapies (ACTs), such as chimeric antigen receptor therapy (CAR-T) and T-cell receptor therapy (TCR-T), involve the extraction, *ex vivo* study, genetic engineering, and reimplantation of live T cells. These therapies have proved invaluable in our ongoing battle against cancer, with *over 1,500* active clinical trials. Despite their promise, cell-based therapies are uniquely challenging to discover, validate, and translate, requiring deeper characterization compared to small molecules or other therapies. Researchers' success at each stage depends on accessible tools that enable the measure of viability, variability, persistence, and functionality of thousands of single cells. To this end, we have implemented Bruker's Opto® T Cell Profiling workflow on the new Beacon Discovery system and investigated on-instrument the resulting cytotoxicity, cytokine secretion, and surface marker expression for single human MART-1 T cells interacting with T cell activating beads (TABs) and antigen-presenting live cells (APCs).

The Beacon™ optofluidic single-cell analysis system provides multi-dimensional characterization and recovery of live cells using Opto-Electronic Positioning (OEP) to sort live cells into NanoPens. With applications in immune cell profiling (such as T cell profiling), antibody discovery, and cell line development, these platforms are utilized by top pharma companies and backed by 30+ published studies. These same capabilities have been enabled in the more accessible Beacon Discovery system. The Beacon Discovery has integrated fluidic handling, single cell sorting, culture and cell incubation, fluorescent microscopy, and immunoassay capabilities, all in a benchtop automated, user-friendly platform. In parallel experiments on the Beacon Discovery, single human T cells were paired with TABs or APCs, where they were cultured and assayed over 2 days. When paired with APCs, target cell cytotoxicity measurements were performed via continuous perfusion of a caspase-3 substrate and time-lapse fluorescent imaging, enabling differentiation of fast-killing and slow-killing T cells. We also assessed cytokine secretion upon activation by co-loading 3 customizable cytokine capture beads in each NanoPen. Comparing T cells paired with TABs or APCs, we observed differing levels of expression for TNF-α, IL-2, and IFN-γ. We also utilized the Beacon Discovery to detect the presence of surface markers (CD4/CD8) on the T cells during co-culture with TABs or APCs. These functional measures, combined with cell recovery for sequencing, are ideal for accelerating ACT development. In summary, the Beacon Discovery optofluidic system is an approachable, easy-to-use instrument that offers an intuitive user interface and powerful data analysis and visualization software, empowering labs of all sizes to revolutionize their single-cell functional analysis.

#3190 Enhancing chimeric antigen receptor (CAR)-T cell therapy for solid tumors through photobiomodulation.

Jude S. Franklin

Biomedical Engineering, CWRU, Cleveland, OH

Chimeric Antigen Receptor (CAR)-T cell therapy has demonstrated remarkable success in treating hematological malignancies, yet its efficacy in solid tumors remains limited, with response rates as low as ~9% and limited by high relapse rates (~50% within one year). Furthermore, CAR-T therapies have demonstrated challenges for reduced efficacy, largely attributed to poor penetration and poor infiltration of CAR-T cells into the tumor microenvironment (TME), combined with immune suppressive factors such as T cell exhaustion, metabolic fatigue, and anti-inflammatory cytokines. To address these barriers, we investigate the potential of photobiomodulation (PBM), a non-invasive light-based treatment to enhance CAR-T cell function in both solid tumors and hematological malignancies. PBM, which stimulates cellular activity, could improve CAR-T cell survival, metabolic fitness, and persistence, and thus, therapeutic efficacy. Using optimized wavelengths, we evaluated CAR-T cell function in vitro, focusing on cellular metabolism and expansion. Metabolic analysis using the Seahorse XF platform revealed a marked upregulation in oxygen consumption rates (OCR) indicative of enhanced glycolytic activity ($p<0.001$) in CAR-T cells exposed to PBM. Furthermore, we observed a significant increase in T cell counts over a 14-day period, validated by CFSE labeling and flow cytometry with AO/PI and hemacytometer counting, in addition to evaluation of cytotoxicity and differentiation of PBM-treated CAR-T cells compared to control CAR-T cells. These findings suggest PBM preconditioning significantly enhances CAR-T cell energy production, proliferation, metabolic activity, and persistence, potentially overcoming challenges related to TME penetration, immune suppression, and exhaustion in solid tumors. Additionally, the PBM treatment could help address issues of persistence and proliferation of CAR-T cells in both solid tumors and hematological malignancies, improving their overall therapeutic potential and optimizing treatment protocols for clinical application. This combinational approach of CAR-T cell therapy and PBM represents a promising strategy to refine and optimize CAR-T functional longevity in both hematological and solid malignancies for clinical translation.
As my lab experience focuses on immunology and the development of CAR-T therapies for pre-clinical use, this project will be in collaboration with the Jenkins/Moffitt Lab for their expertise in PBM.
An invention disclosure was made to CWRU for the use of PBM for adoptive cell therapy. It is expected that a provisional application will be filed in the future prior to public disclosure. CWRU is the full owner of this intellectual property.

#3192 GT316: a next-generation TIL therapy identified through genome-wide CRISPR screening with promising efficacy in advanced solid tumors.

Jingwei Sun[1], Yao Sheng[1], Jingman Wang[1], Jiahui Jin[1], Zhao Xu[1], JIng Yu[1], Jing Guo[2], Zhongping Cheng[2], **Pin Wang**[3], Yarong Liu[1]

[1]Grit Biotechnology, Shanghai, China,[2]Shanghai Tenth People's Hospital, Shanghai, China,[3]USC - University of Southern California, Los Angeles, CA

Adoptive cell therapy using tumor-infiltrating lymphocytes (TILs) has demonstrated therapeutic efficacy in late-stage melanoma patients. However, expanding its applicability to other solid tumors and improving clinical outcomes remain significant challenges. To address these limitations, we developed *ImmuTFinder*, a genome-wide CRISPR/Cas9 screening platform designed to identify key immunoregulatory targets that enhance TIL functionality and broaden their therapeutic potential. Functional validation of over 120 top candidate targets was performed in TCR-T cells using a high-throughput 96-well array. Promising targets were further tested for combinatorial effects in TILs through in vitro assays and in vivo models. A dual knockout of GT304 and GT312, termed GT316, emerged as the most effective combination, significantly improving TIL proliferation, cytokine production, tumor eradication in CDX and PDX mouse models, and long-term persistence with reduced dependency on IL-2. Specific and highly efficient sgRNAs for these targets were selected, and a scalable manufacturing process for GT316 TILs, named *KOReTIL*, was developed. A first-in-human trial of GT316 demonstrated good tolerability and encouraging preliminary antitumor activity in patients with advanced solid tumors. Notably, a patient with treatment-refractory cervical cancer achieved a confirmed complete response (CR) four weeks post-infusion, with the response persisting for 50 weeks to date (RECIST 1.1). Another patient with ovarian cancer, previously treated with nine lines of systemic therapy, achieved a confirmed partial response (PR) at six weeks post-infusion, with a response lasting over 50 weeks (RECIST 1.1). Data collection on additional responses is ongoing. In summary, these findings highlight the utility of the *ImmuTFinder* platform for discovering novel immunoregulatory targets and demonstrate the potential of GT316 as a next-generation TIL therapy for advanced solid tumors.

#3193 Overcoming glioblastoma heterogeneity and plasticity through the development of novel chimeric antigen receptor (CAR)-T cells targeting PTPRZ1.

Aditya A. Mohan, Barbara Lipes, Charla Gentry, Rushil Yerrabelli, Daniel Wilkinson, Kisha Patel, Emily Blandford, Andrew Hardigan, Peter Fecci, Michael Gunn, Anoop Patel

Duke University Medical Center, Durham, NC

Glioblastoma (GBM) is an aggressive and heterogeneous brain tumor characterized by extensive plasticity, which contributes to resistance against conventional therapies. To address this challenge, we generated a unique single nuclei RNA sequencing atlas, integrating GBM, normal brain tissue, and developmental brain datasets. Utilizing single-cell RNA sequencing (scRNA-seq) analysis methods, we comprehensively characterized GBM heterogeneity and plasticity, focusing on identifying homogeneous cell surface antigens suitable for chimeric antigen receptor (CAR) T-cell targeting. scRNA-seq analysis revealed PTPRZ1 as a promising candidate antigen, uniformly expressed across tumor cells, offering a compelling therapeutic target for CAR-T cell therapy. Following antigen identification, we initiated mouse immunization campaigns to stimulate antibody production, coupled with phage display technology to generate a diverse library of single-chain variable fragments (scFvs). A rigorous cell-based positive and negative selection protocol was employed to isolate scFvs that specifically bind to PTPRZ1 while avoiding binding to closely related proteins from the same family, thereby minimizing off-tumor effects. Protein language models were used and experimental site-directed mutagenesis was performed to affinity mature and humanize selected scFv clones. Once PTPRZ1-specific scFvs were identified, they were incorporated into novel CAR constructs designed to overcome the low surface antigen density challenge commonly observed with GBM antigens. These CARs incorporated several signaling domains and structural modifications to enhance sensitivity and efficacy in low antigen-density settings. Our approach integrates cutting-edge single-cell sequencing, phage display technologies, and CAR-T cell design principles to address the heterogeneity of GBM and develop precision-engineered CAR-T cells targeting PTPRZ1. This study presents a step forward in overcoming GBM's plasticity, offering a potential therapeutic strategy with translational potential.

#3194 Opposing roles of product CD27 and TIGIT expression in outcome to CAR-T cell therapy in R/R LBCL.

Justin Budka[1], Subing Cao[1], Chad Williams[1], Gabriela Balderrama-Gutierrez[1], Soumya Poddar[1], Mike Mattie[1], Jenny J. Kim[1], Saran Vardhanabhuti[1], Yohei Arihara[2], Yusuke Kamihara[2], Shogo Miura[2], Jerome Ritz[2], Davide Bedognetti[1], **Simone Filosto**[1]

[1]Kite Pharma, Inc., Santa Monica, CA,[2]Dana-Farber Cancer Institute, Boston, MA

Background: CAR-T cell therapy provides transformative outcomes for patients with relapsed/refractory (R/R) large B cell lymphoma (LBCL). However, a large fraction of patients remains at risk for relapse, underlying the need to uncover mechanisms of resistance and predictive biomarkers. We leveraged ZUMA-1, -6 and -7 studies of R/R LBCL to discover product features associated with outcome to CAR-T cell therapy [Axicabtagene Ciloleucel (axi-cel)]. We explored ligand-receptor interactions between product cells and the tumor microenvironment, identifying CD27-CD70 and TIGIT-PVR axes as putative mediators of durable response and disease progression, respectively.

Methods: Cytometry by time of flight (CyTOF) with 34 markers pertinent to T cell phenotyping and activation was performed on CAR-T cell products from ZUMA-1 (3rd line(L) LBCL; n = 57), ZUMA-6 (CAR-T cells + Atezolizumab; 3rd L LBCL; n = 14), and ZUMA-7 (2nd L LBCL; n = 45). Individual marker intensity and unsupervised clustering (by flowSOM algorithm) analysis were performed to identify features associated with outcome and a P-value < 0.05 was considered significant by descriptive statistics. The CyTOF analysis was combined with transcriptomic Nanostring IO360™ from ZUMA-7 pre-infusion tumors (N=35) for ligand-receptor interaction studies. scRNAseq analysis was performed (CellRanger v7.0 and Scanpy) on a set of ZUMA-1 products (n=36).

Results: Cross-study analysis of individual CyTOF markers presented increased expression of activation and exhaustion proteins CD29, OX40 and TIGIT in patients who experienced disease progression (lack of response or relapse after response), while co-stimulatory CD27 and NKG2D associated with ongoing response (P < 0.05). Unsupervised clustering analysis demonstrated that product CD8 stem central memory (T-SCM) cells, expressing CCR7, CD45RA, CD95, NKG2D, and CD27 associated with ongoing response (P < 0.01), while activated memory or senescent CD4+ cells associated with disease progression (P < 0.05). All patients with > 25% CD8 T_{SCM} (% of T cells) responded to axi-cel (100% ORR), with TIGIT expression representing the only marker significantly associated with Relapse Vs Ongoing response status in these patients (P < 0.05). The analysis of receptor expression on product cells Vs ligand expression in the tumor uncovered associations of the CD27-CD70 and TIGIT-PVR axes with durable response and disease progression, respectively. scRNAseq of ZUMA-1 products corroborated the above observations, with elevated TIGIT expression in two cell clusters enriched in non-responding patients.

Conclusions: Using orthogonal methods on three clinical studies, we identified product features consistently associated with CAR T-cell efficacy in r/r LBCL, informing design of next-generation products and combinatorial approaches to improve outcome, including product enrichment of CD27+ CD8 T_{SCM} and TIGIT inhibition.

#3195 Advancing CAR T clinical development with high-parameter CyTOF technology.

Ling Wang, Shakir Hasan, Stephen Li, Michael Cohen, Deeqa Mahamed, Christina Loh

Standard BioTools, Markham, ON, Canada

Adoptive immunotherapy using chimeric antigen receptor (CAR) T cells is considered a recent revolutionary treatment in cancer therapy. CAR T therapy has achieved great success in hematological B cell malignancies. However, it has faced significant challenges in solid tumors due to various factors, such as complex tumor microenvironments, restricted trafficking, impersistent antitumor activity and toxicities. A better understanding of CAR T biology will accelerate development of CAR T therapies with improved antitumor efficacy, durability and decreased toxicities. High-parameter flow cytometry has been a powerful tool to functionally characterize CAR T cells at multiple stages of clinical development, from product characterization during manufacturing to longitudinal evaluation of the infused product in patients. However, fluorescence-based cytometry faces significant challenges with signal overlap and autofluorescence, limiting sensitivity and the number of targets that can be detected in CAR T cells. Consequently, rare cell populations are poorly resolved and functional readouts of CAR T cells are unreliable. CyTOF technology overcomes these limitations with low signal overlap and no autofluorescence. Further, CyTOF technology enables a streamlined and flexible workflow in clinical research using freezing antibody cocktails and stained cell samples. Here, we present a 40-plus-marker CyTOF panel to simultaneously analyze phenotypic and functional protein expression in CAR T cells from *in vitro* co-culture with tumor cells. CD19 CAR T cells were expanded *in vitro* and co-cultured with Nalm6 cells at different E:T ratios for 2-5 days. A high-parameter CyTOF panel including over 40 surface, cytoplasmic and nuclear markers was used to stain CAR T cells. Samples co-cultured at different time points were stained, barcoded, frozen and simultaneously acquired on a CyTOF XT system at a later date. The cytotoxicity, activation, proliferation, differentiation and exhaustion of CAR T cells were evaluated. Comprehensive profiling revealed that CAR T cells became activated, proliferated and produced cytokines in *in vitro* co-culture with tumor cells and showed reduced cytotoxicity and exhaustive phenotype after an extended period of expansion. Overall, we demonstrate that the high-parameter CyTOF panel enables deep functional characterization of CAR T cells by simultaneous detection of surface, cytoplasmic and nuclear markers, supporting the continuous clinical development of CAR T products.

#3196 CRTAM defines effector functionality and robust anti-tumor response of cytotoxic CD8+T cells.

Zheng Liu[1], An Nguyen[1], Amy Olex[2], Mikail Bala[2], Jose Trevino[3], Bhaumik Patel[4], Jolene Windle[1], Xiang-Yang Wang[1], **Syed Ammer Shah**[5]

[1]Human and Molecular Genetics, Virginia Commonwealth University - VCU, Richmond, VA,[2]Bioinformatics Core, Virginia Commonwealth University - VCU, Richmond, VA,[3]Surgery, Massey Cancer Center, Virginia Commonwealth University - VCU, Richmond, VA,[4]Internal Medicine Massey Cancer Center, Virginia Commonwealth University - VCU, Richmond, VA,[5]Surgery, Massey Cancer Center, Central Virginia VA Healthcare System, Virginia Commonwealth University - VCU, Richmond, VA

The effectiveness of current cancer immunotherapies, such as immune checkpoint blockade (ICB), adoptive T cell therapy (ACT), and chimeric antigen receptor (CAR) T-cell therapy, is limited in solid tumors due to the scarcity of tumor-specific immunogenic targets, impaired tumor antigen processing, and immune cell dysfunction. Cytotoxic $CD8^+$ T lymphocytes (CTLs) are the primary effectors in antitumor immunity, yet their dysfunctional or exhausted states present significant challenges to successful immunotherapy. Recent study of pre-infusion CAR T cells in non-Hodgkin lymphoma (NHL) have identified polyfunctional T cell subsets that exhibit engagement of diverse immune programs, characterized by the production of various cytokines and chemokines (IFN-γ, GMZB, and MIP1a) which corroborated with enhanced patient survival. In our previous clinical study involving ACT in melanoma patients (NCT00665470), we observed engraftment of $CD8^+$ T cell clones without objective antitumor responses (non-responders), while spontaneous complete responses were noted in two patients prior to ACT (responders). A comparative analysis of $CD8^+$ T cell clones derived from responders versus non-responders identified Cytotoxic and Regulatory T cell Molecule (CRTAM) as a differentially expressed gene in activated $CD8^+$ T cell clones from responders. We propose CRTAM as a predictive marker for a potent and durable $CD8^+$ T cell-mediated antitumor response and to explore its potential role in enhancing the antitumor efficacy of ACT and CAR T cell therapy in solid tumors. We have thus far established the role of CRTAM in defining enhanced effector functions of murine cytotoxic $CD8^+$ T cells by examining antigen specific P - Mel $CRTAM^{Hi}$ Vs $CRTAM^{Lo}$ $CD8^+$ T cell subsets with $CRTAM^{Hi}$ T cells showing enhanced cytotoxic profile (perforin/ GMZB), cytokine production (IFN- γ), antitumor cytotoxicity, immunophenotype and gene profile using both in vitro and in vivo models. RNA sequencing analysis reveals that $CRTAM^{Hi}$ P-Mel T cells exhibit a unique gene expression profile associated with cytokine activity, signal transduction, cell migration, and cytotoxicity. Furthermore, increased overall survival in patients with solid tumors exhibiting T cell infiltration and increased CRTAM expression was demonstrated by query of publicly available databases, such as The Cancer Genome Atlas (TCGA). Therefore, CRTAM identifies a unique subset of CTL with enhanced effector functions, with deployment of diverse immune programs leading to improved antitumor activity. T cells engineering to knockout and express CRTAM is currently underway to evaluate the feasibility of enhancing antitumor responses in, in vivo murine models of ACT. Engineering $CD8^+$ T cells for CRTAM may generate more effective and durable T cell products for ACT and CAR T cell therapy in solid tumors.

#3197 Macrophage-ferritin-drug conjugates: a novel approach to overcome glioblastoma drug resistance and induce long-term tumor immunity.

Maciej Białasek[1], Miaomiao Sun[2], Bartłomiej Taciak[1], Tomasz Rygiel[3], Michael Weller[2], Tobias Weiss[2], **Magdalena Krol**[1]

[1]Center of Cellular Immunotherapies, Cellis AG | Warsaw University of Life Sciences, Zurich, Switzerland,[2]University Hospital Zurich and University of Zurich, Zurich, Switzerland,[3]Cellis AG, Zurich, Switzerland

Glioblastoma (GBM) remains a major clinical challenge due to its resistance to conventional therapies and immunosuppressive tumor microenvironment. To address these challenges, we developed Macrophage-Ferritin-Drug Conjugates (MDCs), leveraging the unique ability of macrophages to infiltrate gliomas and transfer therapeutic ferritin-drug complexes directly to cancer cells. In orthotopic glioma models (GL-261 and CT-2A), MDC-735, consisting of macrophages loaded with ferritin conjugated to inhibitor of tubulin polymerization, demonstrated significant tumor reduction and improved survival compared to controls, including unloaded macrophages or cell-free ferritin-drug conjugates. MDC-735 also outperformed current standard treatments such as temozolomide, radiation, and second-line agents like lomustine, which fail to achieve long-term survival. Remarkably, rechallenge studies showed that mice treated with MDC-735 developed immunological resistance to tumor regrowth, indicating a role for adaptive immunity. In vitro co-culture experiments revealed that MDC-735-loaded macrophages induced T-cell activation and pro-inflammatory cytokine production. In vivo, MDC-735 enhanced tumor-infiltrating lymphocyte populations, reduced exhaustion marker expression, and decreased regulatory T-cell frequencies, further supporting its immune-modulating effects. Functional validation in immunodeficient models confirmed the critical involvement of lymphocytes in MDC-735's therapeutic efficacy. To explore clinical potential, we produced cryopreserved human MDC-735 using macrophages differentiated and loaded via automated platforms. MDC-735 administration in human glioblastoma-bearing mice was well-tolerated and led to tumor regression and survival benefits. Patient-derived glioblastoma samples co-cultured with MDC-735 exhibited preferential ferritin transfer to glioma cells and enhanced phagocytosis, underscoring its selective anti-tumor activity. These findings highlight MDC-735 as a promising immunotherapeutic strategy for GBM, capable of targeting drug-resistant cancer cells, modulating the tumor microenvironment, and inducing durable anti-tumor immunity. Importantly, MDC-735 is designed as an allogeneic, off-the-shelf cell-based therapy, enabling scalable and timely delivery for clinical applications, addressing a significant unmet medical need in glioblastoma treatment.

#3198 TK-6302, a supercharged PRAME TCR-T cell therapy containing a high affinity TCR, an activating CD8 coreceptor (costimCD8 CoR) and a Fas-based switch receptor, drives sustained anti-tumor responses.

Paul Najm, Kathrin Skibbe, Lia Walcher, Alvaro Haroun-Izquierdo, Laure Twyffels, Mikhail Steklov, Lorenz Knackstedt, Lucia Poncette, **Marleen M. van Loenen**, Elisa Kieback, Panagiota A. Sotiropoulou

T-knife Therapeutics Inc., San Francisco, CA

Background: T cell receptor (TCR) T cell therapy targeting PRAME mediates durable responses in melanoma and sarcoma but has shown limited efficacy in other solid tumors. Suboptimal T cell engraftment and fitness and immune suppression by the tumor microenvironment (TME) are main causes of the limited efficacy. We have developed TK-6302, a PRAME targeted TCR-T cell therapy with best-in-class potential, manufactured with a non-viral gene editing process, and incorporating a high-affinity TCR, a chimeric CD8 co-receptor that engages CD4 T cells and provides co-stimulation upon TCR engagement (costim CD8 CoR), and a Fas switch receptor (SwR) that boosts fitness in the periphery and prevents apoptosis in the tumor.

Methods: High-affinity PRAME TCRs were identified using T-knife's MyT^{TM} platform. Transcriptomic analysis of 4,622 stage III/IV tumors using Tempus^{TM} database identified consistent expression of FasL in cancer types with high PRAME prevalence. Supercharged PRAME TCR-T cells were generated using a non-viral gene editing process inserting all elements into the TRAC locus, and then compared to benchmark products based on dextramer binding, memory and activation/exhaustion phenotype by flow cytometry, cytokine secretion by LEGENDplex^{TM}, and cytotoxicity upon chronic or repeated antigen stimulation using Incucyte.

Results: Supercharged PRAME TCR-T cells incorporate three functional elements: (1) high-affinity TCR with EC50 $4.73x10^{-10}$ M, (2) costimCD8 CoR, a single-chain CD8 CoR with TRAF-binding costimulatory motifs, and (3) Fas-CD40/OX40 (Fas-TNFR) SwR selected based on inhibitory ligand screening of PRAME expressing indications and designed to provide higher resistance to FasL-induced apoptosis compared to the commonly used Fas-4-1BB SwR. Supercharged PRAME TCR-T demonstrated higher *in vitro* anti-tumor activity compared to known PRAME TCR-T approaches, including clinical candidates, with a minimum of two additional rounds of serial killing and higher levels of pro-inflammatory cytokines against cancer cells with low PRAME expression. Supercharged PRAME TCR-T maintained early memory phenotype upon serial killing compared to benchmark approaches. When PRAME TCR-T products were tested in a multi-cellular model with TME resembling that of PRAME-expressing indications, Supercharged PRAME TCR-T cells were protected from inhibitory signals, as shown by elevated cell numbers and higher cytotoxicity and cytokine production, while benchmark PRAME TCR-T cells failed to control long term growth of cancer cells.

Conclusions: Supercharged PRAME TCR-T therapy demonstrates best-in-class preclinical anti-tumor efficacy and T cell fitness compared to current clinical stage PRAME TCR-T approaches, providing the potential for deep and durable responses in hard-to-treat indications.

#3199 Radiomic features associated with anti-tumor activity in Non-Hodgkin lymphoma patients treated with CD19 directed allogenic CAR T therapy.

Andrew R. Dunn[1], Shashwat Deepali Nagar[1], Donald J. Kirsch[1], Leah M. Williams[1], Annie Y. Weaver[1], Philipp M. Altrock[2], William S. Denney[3], Chan Y. Cheah[4], P. Joy Ho[5], Joseph P. McGuirk[6], Paul Shaughnessy[7], Constantine S. Tam[8], Armin Ghobadi[9]

[1]CRISPR Therapeutics, South Boston, MA,[2]Modeling & Simulation, Altrock Scientific Consulting, Kronshagen, Germany,[3]Human Predictions, LLC, Boston, MA,[4]Sir Charles Gairdner Hospital, Perth, Australia,[5]Institute of Hematology, Royal Prince Alfred Hospital, New South Wales, Australia,[6]Division of Hematologic Malignancies & Cellular Therapeutics, University of Kansas Medical Center, Kansas City, KS,[7]Sarah Cannon Transplant and Cellular Therapy Program, Methodist Hospital, San Antonio, TX,[8]Alfred Hospital and Monash University, Melbourne, Australia,[9]Division of Oncology, Washington University School of Medicine, St. Louis, MO

Introduction: Radiomic features extracted from ^{18}F-fluorodeoxyglucose positron emission tomography/computed tomography ([^{18}F] FDG PET/CT) provide valuable insight into the anti-tumor activity of CD19-directed CAR T therapy in patients with non-Hodgkin lymphoma (NHL). This study examined an integrative approach combining radiomic features and patient-specific attributes to determine if these parameters are associated with anti-tumor response across two investigational allogeneic CD19-directed CAR T programs, CTX110 and CTX112. CTX112 contains two novel CRISPR-mediated gene edits to Regnase-1 and Transforming Growth Factor Beta Receptor 2 (TGFBR2), which are intended to increase CAR T cell expansion, functional persistence and potency.
Methods: Patients with R/R NHL of a variety of histologies were given LD chemo followed by either CTX110 or CTX112. Radiomic features were extracted from [^{18}F] FDG PET/CT scans at baseline (screening) and the first assessment at day 28. 48 patients treated with CTX110 and CTX112 at four dose levels ($3x10^7$ [DL1], $1x10^8$ [DL2], $3x10^8$ [DL3], and $6x10^8$ [DL4] CAR+ T cells) were analyzed. Potential features associated with anti-tumor activity were identified at three different levels: (1) subject-level, (2) total tumor burden-level, and (3) lesion-level. To understand the interplay between CAR T cells and tumor lesions, multiple feature selection techniques were employed to delineate different sets of features that correlate with anti-tumor activity.
Results:Median values for the total tumor burden (TB) as measured by the total metabolic tumor volume (MTV) for patients treated with CTX110 were less than CTX112 (CTX110 = 96 [38 to 291] mL and CTX112 = 146 [91 to 187], median [IQR]) indicating that the patients treated with CTX112 may have been more difficult to treat. CTX110 and CTX112 both showed dose-dependent activity, producing larger reductions in MTV with higher CAR T cell doses. However, CTX112 was observed to have similar % MTV reduction at $3x10^7$ cells (DL1) as CTX110 does at $3x10^8$ cells (DL3), suggesting CTX112 possess an estimated 10-fold higher anti-tumor activity than its predecessor. By estimating the effector to target (E:T) ratio in patients, whereby the CAR+ cells dose is normalized to the baseline MTV, patients with high E:T ratios were shown to have increased anti-tumor activity compared to low ratios for both CTX110 and CTX112.
Conclusions: Multivariate analysis of [^{18}F] FDG PET/CT scans shows that CTX110 and CTX112 exhibit consistent dose-dependent anti-tumor activity, as measured by decrease in MTV, across patients with diverse radiomic features. Across multiple methods estimating MTV-reduction efficacy, CTX112 is approximately 10-fold more efficacious than CTX110, despite the CTX112-treated cohort containing patients with baseline radiomic features associated with poor response.

CLINICAL RESEARCH: Immune Checkpoints
Poster Session

#3205 Artificial intelligence (AI) -powered H&E whole-slide image (WSI) analysis of tertiary lymphoid structure(TLS) to predict response to immunotherapy in non-small cell lung cancer (NSCLC).

Young Kwang Chae[1], Leeseul Kim[2], Sangwon Shin[3], Sooick Cho[3], Sanghoon Song[4], Borislav Alexiev[1], Behtash Nezami[1]

[1]Northwestern University Feinberg School of Medicine, Chicago, IL,[2]Department of Medicine, The University of Chicago, Chicago, IL,[3]Lunit Inc., Seoul, Korea, Republic of,[4]Lunit, Seoul, Korea, Republic of

Background: The efficacy of ICIs in treating NSCLC is limited to a subset of patients, necessitating reliable predictive biomarkers. TLSs within the tumor microenvironment have emerged as potential indicators. This study aims to investigate the association between an AI-powered TLS analysis and treatment response of NSCLC patients treated with ICIs.
Method: We collected H&E-stained WSI of primary and metastatic tumors and clinical data in a retrospective study of advanced-stage NSCLC patients treated with ICI (with or without chemotherapy) at at Northwestern University from May 2015 to November 2023. Following the assessment of the presence of TLS by a pathologist, the identical WSIs were evaluated by the AI-powered H&E WSI analyzer. We used Lunit SCOPE IO, an AI-powered H&E WSI analyzer developed using 21,096 H&E stained WSIs, which can segment various classes of tissue area including TLS within the TME. Survival analysis was performed using Kaplan-Meier curves, and differences in survival outcomes among TLS groups were evaluated using the log-rank.
Result: A total of 102 patients with advanced-stage NSCLC were included in the study. 30.3% (31/102) and 22.5% (23/102) of cases were found to contain TLS as determined by the AI analyzer and a pathologist respectively. The AI model achieved an accuracy of 88.2% (95% confidence interval [CI], 80.4%-93.8%) in identifying the presence of TLS compared to the pathologist's interpretation. The concordance between the pathologist's assessment and the AI model, as evaluated by Cohen's kappa, was 0.70. The median follow-up duration was 40.0 months. Based on TLS presence as assessed by a pathologist, the TLS (+) group demonstrated significantly improved PFS (HR: 0.29, 95% CI: 0.12-0.68, $p < 0.01$) and OS (HR: 0.43, 95% CI: 0.23-0.78, $p < 0.01$) compared to the TLS (-) group. When TLS presence was assessed by an AI analyzer, the TLS (+) group had a median PFS (mPFS) that was not reached (95% CI: 31 months-not reached), whereas the TLS (-) group had a mPFS of 11 months (95% CI: 6-28 months), with an HR of 0.39 (95% CI: 0.20-0.79, $p < 0.01$). The median OS (mOS) for the TLS (+) group was 26.2 months (95% CI: 17 months-not reached) compared to 13 months (95% CI: 9-21 months) in the TLS (-) group, with an HR of 0.55 (95% CI: 0.33-0.92, $p = 0.02$). There was no significant different in overall response rate between the two groups (17.7% in TLS (+) and 17.4% in TLS (-))
Conclusions: AI-powered TLS analysis can be potentially utilized as a predictive biomarker of survival outcomes of NSCLC patients treated with ICI.

#3206 Cadonilimabplus chemotherapy as first-line treatment in PD-L1 negative advanced non-small cell lung cancer (LungCadX): a phase II study.

Li Wang[1], Haoran Tang[2], Hang Dong[2], Chunxia Su[1]

[1]Department of Medical Oncology, Shanghai Pulmonary Hospital & Thoracic Cancer Institute, Tongji University School of Medicine, Shanghai, China,[2]Huidu (Shanghai) Medical Sciences, Ltd., Shanghai, China

Introduction: Immunotherapy against non-small-cell lung cancer (NSCLC) with PD-L1-negative remain an unmet need. Cadonilimab is a bispecific antibody that simultaneously targets programmed cell death receptor-1 and cytotoxic T lymphocyte-associated antigen-4. In this study, we aimed to assess the efficacy and safety of cadonilimab combined with chemotherapy for the first-line treatment of PD-L1-negative advanced NSCLC.

Methods: LungCadX (NCT06424821) is a multi-center, open-label, single-arm, phase II study. Patients received 4 cycles cadonilimab 10 mg/kg every three weeks plus chemotherapy, followed by cadonilimab maintenance therapy. The primary endpoint was the 12-month progression-free survival (PFS) rate by investigator assessment per RECIST 1.1. Secondary endpoints included overall survival (OS), PFS, objective response rate (ORR), duration of response (DOR), disease control rate (DCR) and the safety. Blood samples were collected at C1D1 and C3D1 for biomarker analysis. The study utilized PredicineALERT, a liquid biopsy methylation assay, to profile DNA methylation profiles in circulating tumor DNA (ctDNA) and monitor disease response.

Result: As of data cutoff on November 8, 2024, 56 patients were enrolled with a median age of 64 years old, and 47 (83.9%) of them had stage IV NSCLC. 46 patients had at least 1 post-baseline tumor assessment. At a median follow-up of 6.7 months (range, 3.3 -11.5 months), the investigator-assessed ORR was 60.9% (28/46), with a 80.9% ORR for squamous (17/21) and 40.9% for non-squamous (11/25), and disease control rate (DCR) was 100.0% (46/46). Of the 50 patients who received at least two cycles of treatment, treatment-related adverse events were reported in 45 (80.3%), with grade ≥3 TRAEs occurring in 27 (48.2%), serious TRAEs reported in 12 (21.4%). The most common adverse events included leukopenia, neutropenia, thrombocytopenia, and anemia. No treatment-related deaths were reported. We completed ctDNA methylation analysis on samples collected at C1D1 and C3D1 from 18 patients. Changes in methylation scores from baseline to C3D1 were correlated with the RECIST 1.1. Specifically, all nine patients with a partial response exhibited a decrease in the differentially methylated fragment (DMF) score. In contrast, two patients with stable disease showed a greater than 20% increase in the DMF score, indicative of methylation-based progression and suggesting potential treatment resistance.

Conclusions: Our preliminary result showed that cadonilimab plus chemotherapy showed promising anti-tumor activity and manageable safety as first-line treatment in patients with PD-L1 negative advanced NSCLC and may potentially be a promising treatment option. The ctDNA analysis underscores the potential of monitoring treatment efficacy by utilizing cfDNA methylation dynamic profiles.

#3207 TIM-3 expression in human cancer: A tissue microarray study on 17,172 patients.

Seyma Buyucek[1], Sam Etebar Farimani[1], Katharina Moller[1], Florian Viehweger[1], Ria Schlichter[1], Anne Menz[1], Andreas M Luebke[1], Ahmed Abdulwahab Bawahab[2], Viktor Reiswich[1], **Elena Bady**[1], Lisa Hornsteiner[1], Claudia Hube-Magg[1], Andrea Hinsch[1], Florian Lutz[1], Soren Weidemann[1], Frank Jacobsen[1], Maximilian Lennartz[1], David Dum[1], Christian Bernreuther[1], Patrick Lebok[1], Guido Sauter[1], Andreas H Marx[3], Ronald Simon[1], Christoph Fraune[1], Natalia Gorbokon[1], Eike Burandt[1], Sarah Minner[1], Stefan Steurer[1], Till S Clauditz[1], Till Krech[1]

[1]University Medical Center Hamburg-Eppendorf, Hamburg, Germany,[2]University of Jeddah, Jeddah, Saudi Arabia,[3]Academic Hospital Fuerth, Fuerth, Germany

TIM-3 (T-cell immunoglobulin and mucin-domain containing-3) is an inhibitory immune checkpoint molecule which mainly occurs in subsets of inflammatory cells. On the surface membrane of cancer cells TIM-3 may represent a druggable target. To assess the prevalence of TIM-3 expression in cancer, a tissue microarray containing 17,172 samples from 134 different tumor types and subtypes was analyzed by immunohistochemistry (IHC). TIM-3 expression of tumor cells and macrophages were semiquantitatively recorded. In cancer cells, a membranous TIM-3 positivity was predominantly seen in clear cell (61.9%) and papillary (62.5%) renal cell carcinomas (RCCs) but - less commonly - also in Hodgkin's (25.0%) and non-Hodgkin's lymphomas (up to 9.1%), epithelial thymomas (6.9%), ovarian carcinomas (0.7%-1.4%), seminomas (0.4%), and several mesenchymal neoplasms (up to 16.0%). High TIM-3 expression of tumor cells was linked to low grade (p=0.0079), low UICC stage (p=0.0085), low pT (p<0.0001), and pN0 (p=0.0067) in clear cell RCC (ccRCC), and to pM0 (p=0.0177) in papillary RCC (pRCC). TIM-3 expression of macrophages occurred in all tumor entities but its relationship with parameters of aggressive disease varied between entities. A high quantity of TIM-3 positive macrophages was linked to unfavorable tumor parameters such as high grade (p<0.0001), advanced pT stage (p=0.0126), and distant metastasis (p=0.0069) in ccRCC, as well as high grade (p<0.0001), HER2 positivity (p=0.0015), and absence of estrogen (p<0.0001) and progesterone receptor (p=0.0187) expression in invasive breast carcinomas of no special type. A high number of TIM-3 positive macrophages was linked to favorable tumor parameters such as L0 (p=0.0333) and V0 (p=0.0161) in mismatch repair protein proficient colorectal carcinoma, low pT (p=0.0128), L0 (p=0.0333), and V0 (p=0.0161), as well as a lack of rete testis (p=0.0053) and spermatic cord infiltration (p=0.0365) in testicular seminoma. It is concluded that tumor cell TIM-3 expression among epithelial or mesenchymal tumors is largely restricted to RCCs where high expression is associated with parameters of non-aggressive disease. TIM-3 expression in tumor associated macrophages is abundant and its clinical significance varies between tumor entities.

#3208 Immunomodulatory potential of mormodica balsamina crude extract as an immune checkpoint inhibitor on human cancer cells using chicken egg chorioallantoic membrane model.

Portia Pheladi Raphela-Choma, Mpho Suzan Choene, Lesetja Raymond Motadi

biochemistry, University of Johannesburg, Johannesburg, South Africa

The chorioallantoic membrane (CAM) is widely used as an *in vivo* model for the evaluation of tumorigenesis. Immune checkpoint molecules play a critical role in the immune system, respond to various infections, and protect against tissue damage. The purpose of this study was to investigate the immunomodulatory potential of *Mormodica balsamina (MMB)* crude extract in colorectal cancer cells using the CAM model. Human colon cancer cells were transplanted onto the CAM membrane of fertilized eggs, resulting in tumor development. The crude extract was injected intravenously into the chicken egg at different dosages. Comparative studies of the effect of MMB crude extract on colon cancer xenografts were conducted. The crude extract exhibited efficacy in inhibiting tumor progression and metastasis. The proteins (PDL1 and LAG3) were lowly expressed to inhibit cancer proliferation and promote apoptosis. In conclusion, the chicken egg tumor model has shown to be valuable in testing medicinal plants as therapies for human colon cancers. The crude extract may have the potential to be used as a drug target in future studies.

#3209 IND enabling study of NRT-YHD_001, a macrophage immune checkpoint inhibitor in liver cancer.

S. Nam[1], J. Ha[1], S. Kim[1], M. Na[1], S. Jeon[1], B. Yoo[2], I. Yoon[2], H. Lee[2], C. Park[2];
[1]Catholic University of Korea, College of Medicine, Seoul, Korea, Republic of, [2]NEORNAT Inc, Seoul, Korea, Republic of

NRT-YHD_001, a modified antisense miRNA targeting let-7i-5p for liver cancer therapy, acts as a key regulator of macrophage activity within the tumor microenvironment. Through *in vitro* pharmacology studies, we identified anticancer effects not only on cell growth, proliferation, viability, migration, and invasion but also through the enhancement of macrophage phagocytosis. To evaluate the *in vivo* efficacy of NRT-YHD_001, we used a *Ras*-transgenic mouse liver cancer model which develops spontaneous liver cancer mass after 15 ~ 20 weeks of birth. Based on dose-dependent and injection interval studies, the optimal regimen was determined to be 1 mg/kg administered weekly. We confirmed that weekly intravenous injections of 1mg/kg NRT-YHD_001 showed significantly greater therapeutic efficacy than the sorafenib-treated group. Additionally, xenograft assay using human liver cancer cells in athymic-nude mice showed that weekly injection of NRT-YHD_001 led to improved survival and tumor growth inhibition compared to the untreated group. We performed Absorption, Metabolism, Distribution, and Excretion studies for NRT-YHD_001, stability studies in serum and liver homogenate, and metabolite identification and profiling analysis were completed in mice and cynomolgus monkeys. In maximum tolerated dose (MTD) studies conducted in mice and cynomolgus monkeys, no toxicity of NRT-YHD_001 was observed at doses up to 500 mg/kg administered intravenously. Furthermore, comprehensive evaluations across 4-week repeated dose toxicity and toxicokinetic in mice and monkey, safety pharmacology, and genetic toxicity studies revealed no adverse findings with NRT-YHD_001. For NRT-YHD_001, Drug Substance (DS) and Drug Product (DP) were produced by a global CDMO with experience in U.S. FDA approval of oligonucleotide drugs, and the analysis method was established.These results enabled us to complete the IND-enabling study package for NRT-YHD_001, a liver cancer therapy candidate with FTO analysis completed and intellectual property (IP) fully secured. Regulatory approval submissions to the Korea MFDS and the U.S. FDA are planned for 2025.

#3210 Neoadjuvant-adjuvant pembrolizumab (PEMBRO) in advanced basal cell carcinoma (BCC) induces memory-like T cell expansion with therapeutic promise.

Yee Peng Phoon[1], Beatriz Coutinho de Oliveira[1], Grace Jones[1], James M. Isaacs[1], Jennifer Ko[1], Lucy B. Kennedy[1], Pauline Funchain[2], Thach-Giao Truong[1], Brian Gastman[1], Jan J. Melenhorst[1]

[1]Cleveland Clinic, Cleveland, OH,[2]Stanford Cancer Institute, Stanford, CA

Background: BCC is a prevalent form of skin cancer, and immunotherapy has been explored as a treatment option. Advancements in checkpoint inhibitors (CPI) and other systemic therapies have improved outcomes for unresectable BCC. However, alternatives for high-risk resectable disease remain scarce, with no approved neoadjuvant or adjuvant therapies. Our team conducted a phase IB trial evaluating PEMBRO in patients with resectable locally advanced BCC of the head and neck, with clinical outcomes previously reported. Here, we present our findings on immune cell function and the spatial tumor microenvironment dynamics in the enrolled patients.

Method: 13 patients were enrolled from July 2020 to May 2023, with analysis focusing on 11 who received surgery after at least one dose of PEMBRO. Immune modulation was assessed using 32-color flow cytometry on peripheral blood pre- and post-CPI, T cell analysis in FlowJo, and 33-plex spatial multiplexed immunofluorescence (mIF) analysis in QuPath for tumor biopsies. Cytokine profiling was conducted with IsoPlexis, and data were analyzed in GraphPad Prism.

Results: In this trial, 3 patients (27%) achieved a pathologic complete response at surgery and were classified as responders. With a median follow-up of 30 months, none of the responders experienced a relapse.

Flow cytometry analysis showed variation in CD4 levels across the groups. In some patients, CD4 levels increased by up to 2-fold post-CPI, accompanied by higher CD8 levels. Cluster analysis revealed an increase in CD4 central memory (T_{CM}) and CD8 effector memory (T_{EM}) T cells post-CPI, while naïve and exhausted T cells were more prominent pre-CPI. These clusters, particularly in responders, underscore the importance of a sustained anti-tumor immune response for better therapeutic outcomes.

Spatial mIF of tumor biopsies identified 204,601 cells across 45 sections, averaging 4,547 cells per section. Responders showed a significantly higher level of T cell infiltration than non-responders, with increased CD4 and CD8 T cell counts. Notably, responders had elevated CD45RO-expressing CD4 and CD8 T cell counts compared to non-responders. Patients showed a marked increase in CD8 T cell percentage post-CPI.

In responders, post-CPI plasma levels of IL-6, IL-17, and IFNγ were significantly elevated, indicating increased immune activation that likely enhanced treatment effectiveness.

Conclusion: Our study demonstrates that neoadjuvant-adjuvant PEMBRO stimulates T cell expansion and selectively enhances memory T cells in locally advanced BCC. The rise in memory T cells after CPI therapy indicates a more sustained immune response, which is associated with better recurrence-free survival in our trial cohort. These T cell modifications offer valuable insights into the potential effectiveness of CPI in other immune-sensitive tumor types.

#3211 A multiple blockade of PD-L1/TIGIT/TIM3 to enhance the therapeutic efficacy on B-cell lymphomas.

Jihyun Park[1], Seojeong Kim[1], Youngil Koh[1], Byung-Su Kim[2], Sung-Soo Yoon[1]

[1]Seoul National University Hospital, Seoul, Korea, Republic of,[2]Eunpyeong St. Mary Hospital, Seoul, Korea, Republic of

Hodgkin lymphoma exhibits high PD-L1 expression and responds well to PD-1 blocking antibodies. In contrast, most non-Hodgkin lymphomas express multiple checkpoints, reducing their sensitivity to PD-1/PD-L1 blockade. These findings highlight the complexity of immune evasion mechanisms and the potential of combinatorial therapeutic approaches in lymphoma. We established cell lines overexpressing murine CD155 and luciferase using lentivirus to measure tumor growth in mouse models of B cell lymphoma. All experimental procedures were approved by the Institutional Animal Care and Use Committee of Seoul National University Hospital (protocol 22-0333-S1A0). Female Balb/c mice (7-10 weeks old) were used, sourced from Koatech. For A20 tumor models, 5×106 cells were injected intraperitoneally. Mice received isotype control or specific blocking antibodies (anti-PD-L1, TIGIT, TIM3) three times per week. Tumor growth was monitored weekly via luminescence. After four weeks, spleen and lymph nodes were collected for lymphocyte analysis. Data acquisition was performed using a BD Symphony A3 flow cytometer, and analysis was conducted with FlowJo V10 software. We compared intraperitoneal versus intravenous injection of several different cell doses of hCD20-mCD155-A20 cells to optimize the lymphoma murine model. Intraperitoneal injection of $5x10^6$ cells was determined as the optimal dose, showing stable tumor growth for experimental analyses. Anti-PD-L1 and anti-TIGIT antibodies significantly inhibited tumor progression, whereas anti-TIM3 antibody promoted tumor growth. Mechanistic studies revealed that anti-PD-L1 antibody restored $CD4^+FoxP3^-$ and $CD8^+$ T cell populations and reduced Treg cells, modulating PD-1 expression differentially across immune subsets. Anti-TIGIT antibody increased the CD226/TIGIT ratio in splenic cells. Interestingly, treatment with anti-PD-L1 antibodies significantly increased the expression of both PD-1 and TIGIT on Tregs. Furthermore, the application of an anti-TIGIT blocking antibody decreased PD-1 expression on CD4+FoxP3- T cells, while concurrently enhancing PD-1 expression on CD8+ T cells. Immune checkpoint molecules on Tregs appear to be less affected compared to those on other immune cell populations. Conversely, anti-TIM3 antibody decreased effector T cells while increasing Tregs and PMN-MDSCs, fostering an immunosuppressive microenvironment. Our findings showed the distinct immunological effects of these checkpoint inhibitors, offering insights into their therapeutic potential and limitations in B cell lymphoma models. This research was a collaborative effort made possible through support from F. Hoffmann-La Roche for the imCORE Network.

#3212 IL2-mediated modulation of sEV secretion and PD-L1 expression: A novel perspective for neutralizing immune suppression within cancer cells.

Soojeong Noh[1], Suyeon Ryu[2], Dokyung Jung[2], Sanghee Shin[1], Inseong Jung[1], Sung-Min Kang[2], Christine Seulki Kim[1], Sung-Jin Choi[1], Hanchae Cho[2], Melanie Schwammle[3], Youngtae Jeong[1], Felicitas Bucher[4], Il-Kyu Choi[1], Shin Yup Lee[2], Sin-Hyeog Im[5], Kyungmoo Yea[1], Moon-Chang Baek[2]

[1]Daegu Gyeongbuk Institute of Science and Technology (DGIST), Daegu, Korea, Republic of,[2]Kyungpook National University, Daegu, Korea, Republic of,[3]University of Freiburg, freiburg, Germany,[4]University of Freiburg, Freiburg, Germany,[5]Pohang University of Science and Technology, Pohang, Korea, Republic of

IL2 is known to induce anticancer effects by activating immune cells expressing the IL2 receptor complex (IL2R). However, the potential impact of IL2 on cancer cells expressing IL2R, such as melanoma cells, has been understudied. Here, we demonstrate that IL2 significantly reduces the secretion of small extracellular vesicles (sEVs) and expression of programmed death ligand 1 (PD-L1) in melanoma cells, while increasing their sensitivity to $CD8^+$ T cell-mediated cytotoxicity. These effects are mediated through the activation of IL2R-MEK/ERK signaling in melanoma cells. To evaluate the direct effects of IL2 on melanoma cells *in vivo*, we developed a mouse model in which melanoma cells were engineered to express IL2 on their surface for self-stimulation. In this model, IL2 stimulation inhibited tumor growth and reduced PD-L1 expression in tumor tissues and plasma. Similar patterns were observed in lung cancer clinical samples. Our findings suggest that IL2 can directly elicit an anticancer immune response in IL2R-bearing cancers, highlighting its potential application in immunotherapy as an immune checkpoint modulator.

#3213 IA-05592: A breakthrough oral PD-L1 inhibitor with exceptional anti-tumor efficacy and immune activation potential.

Yeo Wool Kang[1], Ye Eun Kim[1], Garam Choi[1], Sol Lee[1], Deokmo Yang[1], Jongmin Sung[1], Kye Jung Shin[2], Tae-Hwe Heo[2], Taegwon Oh[1], Myung Jin Kim[1]

[1]ILAb Co.,Ltd., Bundang-gu, Seongnam-si, Gyeonggi-do, Korea, Republic of,[2]Integrated Research Institute of Pharmaceutical Sciences, College of Pharmacy, The Catholic University of Korea, Wonmi-gu, Bucheon, Gyeonggi-do, Korea, Republic of

Programmed death-ligand 1 (PD-L1) is a key immune checkpoint protein that interacts with PD-1 on T cells to suppress anti-tumor immunity. While PD-1/PD-L1 antibodies have become a cornerstone of cancer therapy, their limitations, including poor tumor penetration, immunogenicity, immune-related risks due to long half-life, and high production costs, have driven interest in small-molecule alternatives. IA-05592, a novel orally bioavailable small-molecule PD-L1 inhibitor, was developed using structure-based drug design to disrupt PD-1/PD-L1 interactions. This compound offers advantages such as oral bioavailability, reduced costs, and a novel mechanism of action involving PD-L1 internalization and degradation. Biochemical assays using fluorescence resonance energy transfer (FRET) demonstrated IA-05592's potency in disrupting PD-1/PD-L1 interactions, while cellular activity assays confirmed its ability to activate T cells, with an EC_{50} of 14 nM in NFAT reporter assays. IA-05592 reduced PD-L1 expression on tumor cells by inducing internalization and degradation, a mechanism confirmed in MC38 cells engineered to express human PD-L1 (MC38-hPD-L1). *In vivo*, daily oral administration of IA-05592 in a human PD-L1 knock-in MC38 syngeneic mouse model at doses of 10, 30, and 90 mg/kg resulted in dose-dependent tumor reduction. Combination studies with Fingolimod confirmed that IA-05592's anti-tumor effects are immune-mediated. Pharmacokinetic and ADME studies in rodents revealed high oral bioavailability and systemic exposure, further supporting its therapeutic potential. These findings position IA-05592 as a promising candidate for next-generation cancer immunotherapy, offering a unique mechanism of action and robust preclinical anti-tumor efficacy comparable to anti-PD-L1 antibodies. Ongoing studies aim to advance IA-05592 as a key component of all-oral cancer immunotherapy regimens.

#3214 The duration of immune checkpoint inhibitors (ICI) in oncology: Longer is not better.

Farah Mazahreh, Samuel L. Schach, Liyan Mazahreh, A. Mazin Safar

University of Arkansas for Medical Sciences, Little Rock, AR

ICI addition to the oncology armamentarium provided significant therapeutic benefits. Standard schedule of ICI calls for 2-year regimen without rational justification. Doses selected clearly do not adhere to classic maximal tolerated dose since ICIs were doubled at longer dose intervals. Theoretically however, multiple concerns can be proposed to question the 2-year duration. In human neoadjuvant melanoma studies examining ICI effect on effector T-cells comprehensively documented the expected clonal expansion in target cells but this was noted only for few weeks and did not continue upon repeated dosing, a major challenge to the current standard dosing schedule. Therapeutic T-cell transfers administer a single dose of 10^9 , a bulk that is expected to require 2-3 weeks of lymphocyte proliferation. Neutralizing antibodies have been reported in multiple studies, but notably without detriment to the therapeutic impact. Lastly, published and unpublished cases confirm lasting benefits (in years) after single ICI dosing. We hypothesized that benefits of ICI depend mostly, if not entirely, on the first, or few initial doses; that doses later in time can be delivered but add little if anything to the therapeutic impact.

Methods/Results: we reviewed published ICI monotherapy or chemo-ICI which provided individual swimmers' plot in stage 4 melanoma, renal cell and NSCLC. We extracted the median survival (MS) of those who received variable ICI durations excluding progression as the cause for halting therapy. Patients with progressive disease beyond 6 months, were included because they received considerable durations of ICI and might enjoy lasting benefits. We report the MS in the times depicted in the table. Our data reveal comparable results in all subgroups supporting our hypothesis.

Conclusions: Despite standard recommendations, there is considerable rationale in addition to our current data to challenge the common duration of ICI and substantiate a far more limited exposure to ICI.

Table

ICI Duration	Median Survival (Months)	Number of Cases
1-3 months	27	29
3-6 months	31.5	24
6-12 months	32	63
12-18 months	35	30
18-24 months	37	47
24+ months	48	32

#3215 Cystatin F changes in melanoma patients during therapy with immune checkpoint inhibitors.

Milica M. Perisic Nanut[1], Emanuela Senjor[1], Tanja Mesti[2], Simona Miceska[3], Janja Ocvirk[2], Janko Kos[4]

[1]Jozef Stefan Institute, Ljubljana, Slovenia,[2]Department of Medical Oncology, Institute of Oncology Ljubljana, Ljubljana, Slovenia,[3]Department of Medical Oncology, Institute of Oncology Ljubljana,Department of Medical Oncology, Institute of Oncology Ljubljana,, Ljubljana, Slovenia,[4]Department of Pharmaceutical Biology, Faculty of Pharmacy, University of Ljubljana, Ljubljana, Slovenia

Although immune checkpoint inhibitors (ICI) have achieved undeniable success in the treatment of metastatic melanoma, primary and secondary resistance to ICI therapy continues to pose a significant challenge for melanoma patients. Around 40-60% of patients respond to immunotherapy, achieving long-term benefits, but over two-thirds experience immune-related adverse events (irAEs) with ICIs. About 10% show pseudoprogression, marked by transient inflammation, while up to 30% experience hyperprogression with rapid cancer advancement. Despite irAEs, treatment interruption often leads to better outcomes and prolonged survival. The lack of clinically validated predictive biomarkers remains a major factor contributing to the unpredictable effects of immunotherapy. Implementing biological markers in clinical practice is essential to enhance personalized treatment and predict responses. We have identified a protease inhibitor cystatin F as a potent down regulator of cytotoxic efficacy of cytotoxic T lymphocytes (CTLs). Its expression was shown to be increased in hypo responsive and exhausted CTLs but also in the cancer tissue in several types of cancer. In order to elucidate its role in CTLs of patients with melanoma and correlation its expression with response to treatment we have examined cystatin F expression, along with the CTL PD-1 expression and IFNγ in peripheral blood CTLs form patients with advanced melanoma (TNM classification, stage IIID and IV) receiving first-line therapy with ICIs. Study-specific data were collected at three different time points: up to 4 weeks before the start of treatment, at the 12th (+/−2 weeks) and 28th week (+/−2 weeks) and the expression of markers on whole blood preparations or isolated CTLs was analysed using flow cytometry. We characterized the cellular sources of cystatin F in tumor tissue using multicolor immunofluorescence staining and confocal analysis on formalin-fixed melanoma tissue samples. Our findings reveal cystatin F expression in predominantly in non-lymphoid cells within the tumor microenvironment. Analysis of cystatin F in peripheral blood CTLs shows higher expression in non-responders and patients with irAEs, suggesting its potential as a marker for enhancing personalized treatment and predicting treatment responses.

EXPERIMENTAL AND MOLECULAR THERAPEUTICS: Identification of Molecular Targets 1

#3216 A dual-acting chimeric peptide inhibits tumor growth by inhibiting PD-L1 and inducing immunogenic cell death.
S.-Y. Park, S. Gurung, B. Lee;
Kyungpook National University, Jung-gu, Korea, Republic of

Blockade of the immune checkpoint proteins such as PD-L1 enables to overcome the resistance of cancer cells against the immune surveillance. Nevertheless, the blockade therapy itself lacks cytotoxic killing ability to cancer cells. In this study, we exploited PD-L1-targeted cytotoxic peptides that block PD-L1 on the surface of tumor cells and induce the tumor cell death as well. As targeting peptides, we used PD-L1Pep-1 and PD-L1Pep-2 that bind to and block PD-L1. As a cytotoxic peptide, the KLAKLAKKLAKLAK peptide (named K) was fused to the targeting peptide. PD-L1Pep-1-K and PD-L1Pep-2-K decreased cell survival in PD-L1-expressing tumor cells. Both peptides were internalized into tumor cells through the receptor-mediated endocytosis and localized at lysosomes and also at mitochondria. The peptide-induced cell death was accompanied by an increase in the exposure of CRT on the cell surface and extracellular release of ATP and HMGB1, which are markers of immunogenic cell death (ICD). PD-L1Pep-2-K rekindled the T-cell activity including proliferation and cytokine secretion when co-cultured with tumor cells. Systemic administration of PD-L1Pep-2-K inhibited tumor growth more efficiently than PD-L1Pep2 and anti-PD-L1 antibody. These results suggest that the PD-L1-targeted cytotoxic peptide is a novel dual-acting therapeutic agent capable of PD-L1 blocking and ICD induction for cancer immunotherapy.

#3218 The Secretome: a multigene biomarker for the prognosis and selection of solid tumor patients evaluated for treatment with immune checkpoint inhibitors..

Alessandro Porrello[1], Marjory Charlot[2], Michael M. Cunningham[3], Shruti Saxena-Beem[4], Leon G. Coleman[5], Rumey G. Ishizawar[6], Benjamin G. Vincent[7], Chad V. Pecot[1]

[1]Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC,[2]Department of Medicine, Division of Oncology, University of North Carolina at Chapel Hill, Chapel Hill, NC,[3]Department of Medicine, Division of Rheumatology, Allergy and Immunology, University of North Carolina at Chapel Hill, Chapel Hill, NC,[4]Thurston Arthritis Research Center, University of North Carolina at Chapel Hill, Chapel Hill, NC,[5]Bowles Center for Alcohol Studies, University of North Carolina at Chapel Hill, Chapel Hill, NC,[6]Department of Medicine, Division of Rheumatology, Allergy & Immunology, University of North Carolina at Chapel Hill, Chapel Hill, NC,[7]Department of Medicine, Division of Hematology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Introduction: The advent of immune checkpoint inhibitors (ICIs) has been revolutionary for cancer treatment. However, only a minority of solid tumor patients significantly benefit from them as a monotherapy. Approximately 3 out of 4 patients receiving ICIs experience a broad range of immune-related (ir) adverse events (AEs), including many AEs of grades 3 and 4 as well as fatalities (0.3 - 1.3%). Accurate criteria to select the best candidates, sparing other patients from unnecessary physical and financial burden, are urgently needed.
Methods: We developed a Secretome signature, based on 50 genes, utilizing The Cancer Genome Atlas (TCGA) lung squamous cancer (LUSC) RNA-Seq data, to identify patients whose tumor is characterized by abundant immune cell infiltration. This signature was generated through gene selection and generalized linear models. An algorithm was created to make this signature portable across multiple solid tumor types and sequencing platforms. We used this algorithm to assign a Secretory-like (SL) status to a cohort of 78 patients of the University of North Carolina (UNC) - Chapel Hill, mostly diagnosed with lung and head and neck cancer and having received ICIs. A retrospective chart review collected their socioeconomic and racial/ethnicity demographics, smoking and alcohol use, and characterized cancer outcome and irAEs. We used categorical data analysis to investigate salient features of the SL group. After dichotomizing patients according to their SL status, we performed Gene Set Enrichment Analysis (GSEA) of their RNA-Seq data. Using Kaplan-Meier Plotter - Immunotherapy, we assessed the role played by Secretome genes in overall survival (OS).
Results: GSEA shows that main features found in TCGA LUSC cohort (e.g. enrichment of the ‘Hallmark TNFA signaling via NFKB’ gene set) are also present in the UNC SL cohort. These results reveal that our model, which strongly constraints the number of genes, can still retrieve patients with key biological features displayed by the group of TCGA LUSC Secretory. SL lung cancers are more prevalent in Black and Hispanic/Latinx (BHL) than in White ($P = 0.02$), which generally points towards a worse prognosis for BHL patients. SL patients have > 3 times post-ICIs dermatologic AEs than non-SL ($P = 0.01$). Remarkably, the hazard ratios of high vs. low gene expression levels show that > 80% of testable Secretome genes are individually predictive of OS in patients receiving anti-PD1 ICIs, supporting the combined use of Secretome genes for optimal performance.
Conclusions: The Secretome can be used to identify patients, who are most likely to be associated with prolonged survival after ICI therapy. The Secretome can also characterize patients (i) expected to have a worse prognosis and (ii) who should be more closely monitored when using ICIs, since they have an increased risk of developing dermatologic AEs.

#3219 Assessing strategies to activate DNAM1 signaling and inhibit the TIGIT/PVRIG axis using mathematical modeling.

Oleg Demin Jr, Galina Kolesova, Dmitry Shchelokov

InSysBio CY, Paphos, Cyprus

PVR (CD155) and CD112 are ligands from the Nectin/Nectin-like family, frequently expressed on various tumor cells. PVR binds to the inhibitory receptors TIGIT and CD96, triggering a direct inhibitory signal in T and NK cells, and binds to the co-stimulatory receptor DNAM1 (CD226), leading to its downregulation. CD112 binds to the inhibitory receptor PVRIG and to DNAM1, stimulating T and NK cells. Late-stage clinical trials of anti-TIGIT monoclonal antibodies (mAbs) have shown mixed results regarding efficacy (Cho et al. ***Lancet Oncol***. 2022 Jun;23(6):781-792; Rudin et al. ***J Clin Oncol***. 2024 Jan 20;42(3):324-335). Numerous anti-PVR, anti-CD96, and anti-PVRIG mAbs, along with their combinations with anti-TIGIT mAbs and other therapies, are currently in early clinical development. This study aimed to compare how the complete inhibition of TIGIT, PVRIG, PVR, or their combinations affects the engagement of TIGIT, CD96, PVRIG, and DNAM1.

We developed a mechanistic model describing the surface expression of PVR and CD112 on cancer cells, and TIGIT, CD96, DNAM1, and PVRIG on CD8 T-cells. This model captures the interactions of these ligands and receptors within the immunological synapse (IS) between CD8 T-cells and cancer cells in the tumor. In vitro data and expression data of these ligands and receptors were used to identify parameters. The model was validated against data on the downmodulation of DNAM1 and TIGIT on CD8 T-cells in the tumor compared to the blood. We simulated total DNAM1 on the surface of CD8 T-cells in the tumor and the engagement of TIGIT, CD96, PVRIG, and DNAM1 in the IS (i.e., the number of PVR:TIGIT, PVR:CD96, CD112:PVRIG, PVR:DNAM1, and CD112:DNAM1 complexes) under 100% inhibition of TIGIT, PVR, PVRIG, TIGIT and PVRIG, or PVR and PVRIG.

TIGIT blockade did not increase DNAM1 engagement. Moreover, 100% inhibition of TIGIT led to the release of additional free PVR, resulting in the downmodulation of total DNAM1 and an increase in CD96 engagement. Inhibition of PVRIG resulted in an approximately 1.3-fold increase in bound DNAM1, but not in total DNAM1. The combination of TIGIT and PVRIG blockade did not increase engaged DNAM1 beyond the levels observed with anti-PVRIG monotherapy. Inhibition of PVR led to a significant increase in total DNAM1 and a moderate increase in bound DNAM1 (approximately 1.3-fold), along with the disruption of TIGIT and CD96 engagements. The combination of PVR and PVRIG blockade resulted in the strongest increase in engaged DNAM1 (approximately 2-fold), in addition to disrupting TIGIT, CD96, and PVRIG engagements.

The inability to increase DNAM1 engagement during TIGIT inhibition may be one of the reasons for the lack of efficacy observed in the phase 3 trial of tiragolumab (anti-TIGIT mAb) used in combination with atezolizumab. Targeting PVR alone or in combination with PVRIG appears to be a better strategy than targeting TIGIT or TIGIT in combination with PVRIG.

#3220 PD-1 antibody-bound progenitor-exhausted CD8$^+$T cells in lymph nodes enhance PD-1 blockade anti-tumor immunity in gastrointestinal cancer.

Takuro Saito[1], Yohei Nose[1], Yoshiaki Yasumizu[2], Naganari Ohkura[2], Hisashi Wada[3], Hidetoshi Eguchi[1], Yuichiro Doki[1]

[1]Department of Gastroenterological Surgery, Osaka University, Suita-shi, Osaka, Japan,[2]Experimental Immunology, WPI Immunology Frontier Research Center, Suita-shi, Osaka, Japan,[3]Department of Clinical Research in Tumor Immunology, Osaka University, Suita-shi, Osaka, Japan

Introduction: Progenitor-exhausted T (Tpex) cells, marked by TCF1 and PD-1 expression, are essential for the efficacy of immune checkpoint inhibitors (ICIs) like anti-PD-1 antibodies. These cells serve as precursors to intratumoral exhausted T (Tex) cells and may play a pivotal role in maintaining immune responses during cancer therapy. While Tpex cells are recognized for their importance, the detailed mechanisms by which ICIs influence their activation, proliferation, and migration remain unclear. Specifically, the dynamics of ICI-bound Tpex cells across lymph nodes (LNs) and tumors have not been fully characterized. To address this point, we investigated the spatial and functional behavior of Tpex cells in gastrointestinal cancer patients, focusing on how ICIs reprogram these cells to exert anti-tumor immunity.

Methods: We collected tumor, lymph node (LN), and blood samples from gastrointestinal cancer patients treated with or without anti-PD-1 antibodies. Purified lymphocytes were analyzed with flowcytometry and sequencing analysis. To identify ICI-binding T cells, we developed a method using IgG4 detection, which allowed us to detect cells directly bound by therapeutic anti-PD-1 antibodies. We further used combined sequencing technique including single-cell RNA sequencing, T cell receptor sequencing and CITE-sequencing for IgG4 detection (scRNA/TCR/CITE-seq) to profile 29,388 T cells across tissue compartments, including LNs, tumors, and blood.

Results: Our flowcytometry analysis revealed that CD8-Tpex cells were enriched in proximal LNs and exhibited significant proliferation following ICI treatment. Using IgG4 detection and sequencing, we confirmed that PD-1$^+$ Tpex cells in LNs directly bound therapeutic anti-PD-1 antibodies and underwent clonal expansion. Notably, these ICI-bound Tpex cells shared TCR clonotypes with intratumoral Tex cells, suggesting that Tpex cells migrate from LNs to tumors after treatment.

Conclusion: ICIs primarily target PD-1$^+$ Tpex cells in proximal LNs, driving their proliferation and migration to tumors, where they differentiate into Tex cells and contribute to sustained tumor destruction. These results not only deepen our understanding of the mechanisms underlying ICI therapy but also provide a robust methodological framework for tracking ICI-binding T cells across tissues.

#3221 Identification and characterization of FAK kinase as a novel regulator of PD-L1 stability and activity in cancer immune evasion.

A.-I. Boyd, P. Khanal, Y. Hao, X. Yang;
Queen's University, Kingston, ON, Canada

The PD-1/PD-L1 axis is an essential immune checkpoint that modulates T cell-mediated immune responses. Cancer cells exploit this checkpoint to inhibit anti-tumour immune activity, enabling immune evasion. Thus, blocking PD-1/PD-L1 using antibodies has become a cornerstone of cancer immunotherapies. However, despite promising results, these therapies show limited response rates in many cancer patients and often lead to adverse effects, impacting its overall efficacy. Therefore, understanding of the molecular mechanism underlying immunotherapy resistance is critical for successful cancer immunotherapy. Emerging research indicates that phosphorylation of PD-L1 by kinases significantly influence PD-L1 stability and functionality, thereby contributing to cancer cell immune evasion and influencing immunotherapy outcomes. However, although 560 kinases have been identified in the human kinome, there is no systematic screening of kinases regulating PD-L1 stability and its function in immune evasion. By using a PD-L1 NanoLuc luciferase biosensor, in this study, we performed a systematic kinome-wide screening and identified focal adhesion kinase (FAK) as a novel regulator of PD-L1 stability in cancer. Further investigation of FAK-mediated PD-L1 signalling and its role in immune evasion may provide a new therapeutic strategy for cancer treatment.

#3223 A highly selective and novel TCR-like antibody, IMB-202, targeting NK and T cell immune checkpoint for enhanced cancer immunotherapy.

Inyoung Lee, Hyeonju Kang, Chaerin Yoo, Hong Jai Lee, Sungmuk Kang, Sunghyun Byun, Yongjun Kang, Chungmin Lee, Gyongsik Ha

IMBiologics Corp., Suwon, Korea, Republic of

Human natural killer (NK) and T cells are essential cytotoxic effectors in tumor surveillance and elimination, with an increasingly important role in immune checkpoint inhibitor (ICI) therapies. While current ICIs have focused on inhibitory receptors on T cells, creating a paradigm shift in cancer treatment, challenges remain due to non-responders and treatment-associated adverse events. There is a growing need for alternatives that address these limitations and for strategies that enhance efficacy through combination with existing ICIs.

In this study, we developed IMB-202, a therapeutic anti-cancer antibody designed to target the ligands (TOI, Target of Interest), which are overexpressed on tumor cells, of an immune checkpoint receptor on NK and T cells. This TOI plays a crucial role in tumor escape mechanisms by transmitting inhibitory signals to NK and T cells. While this target holds significant promise for ICIs, its development as a therapeutic antibody has been particularly challenging due to the high sequence homology among related family proteins, which complicates achieving the specificity.

Through advanced phage display screening and affinity maturation, we successfully developed IMB-202 as a highly selective TCR-like antibody, capable of recognizing even a single amino acid difference in peptide sequences. IMB-202 binds with high affinity and specificity to TOI in various cancer cell lines and efficiently kills cancer cells by disrupting the immune evasion mechanisms, followed by activating NK and T cells, as well as through antibody-dependent cellular cytotoxicity (ADCC) *in vitro*. Additionally, IMB-202 demonstrated significant tumor growth inhibition in an *in vivo* xenograft mouse model. When applied to ePENDY technology, IMBiologics' proprietary multivalent antibody platform, IMB-202-ePENDY demonstrated enhanced avidity and increased NK and T cell cytotoxicity against cancer cells. Furthermore, its rapid internalization of IMB-202 supports its potential as an antibody-drug conjugate (ADC) candidate, with robust internalization also observed in the ePENDY platform format.

These findings highlight IMB-202 as a promising alternative to existing ICIs and as a first-in-class therapy, targeting a novel immune checkpoint ligand with exceptional selectivity. Additionally, IMB-202 demonstrates significant potential for superior anti-tumor efficacy, with the versatility to be applied across various therapeutic modalities.

#3224 An indirect Meta-analysis of efficacy and safety of PD-1 inhibitors versus PD-L1 inhibitors as preoperative therapy in patients with solid tumors.

Peng Wu, Chaoqi Zhang, Dongyu Li, Xuanyu Gu, Junhan Zhou, Chuqi Lin, Nan Sun, Jie He

Department of Thoracic Surgery, National Cancer Center/National Clinical Research Center for Cancer/Cancer Hospital, Chinese Academy of Medical Sciences, Peking Union Medical College, Beijing, China

Background: Programmed cell death 1 (PD-1) and ligand (PD-L1) immune checkpoint inhibitors (ICIs) in perioperative settings have improved clinical outcomes. However, it remains controversial which agent should be selected. We aim to compare the difference between anti-PD-1 and anti-PD-L1 efficacy and safety in neoadjuvant and/or adjuvant settings across randomized controlled trials.
Methods: We systematically searched PubMed, Embase, Cochrane CENTRAL, and major oncology conferences up to May 20th, 2024. Clinical trials comparing anti-PD1 or anti-PD-L1 with standard care in perioperative settings were collected. These studies were further paired based on comparable characteristics and integrated as mirror groups. The Preferred Reporting Items for Systematic Reviews and Meta-Analysis guideline was followed for data extraction. Specifically, trial names, author, publication year, study design, blinding status, phase, pathologic characteristics, number of patients, settings of treatment, drugs, biomarker status, incidence of adverse events (AEs), pathological complete response (pCR), and major pathological response (MPR), and hazard ratios (HRs) with 95% confidence interval (CI) for event-free survival (EFS), disease-free survival (DFS), and overall survival (OS) were extracted. A random or fixed model was used based on intertrial heterogeneity. Primary outcomes included pCR, MPR, EFS, DFS, OS, and AEs. Indirect comparisons between anti-PD-1 and anti-PD-L1 were conducted using Frequentist and Bayesian approaches.
Result: Totally, 31 studies involving 14974 patients were included. Overall, anti-PD-1 demonstrated superior pCR (risk ratio (RR): 1·65, 95% CI: 1·18-2·29, P = 0·003) and MPR (RR: 1·43; 95% CI: 1·04-1·96, P = 0·026) when compared with anti-PD-L1, and was associated with improved DFS (HR = 0·82, 95% CI: 0·71-0·96, P = 0·0106). For PD-L1 expression, no differential benefits were observed between anti-PD-1 and anti-PD-L1. No significant discrepancies in overall safety profiles were noted, however, anti-PD-1 was linked to a higher incidence of 3-5 grade immune-related adverse event (irAE). Frequentist and Bayesian data were largely consistent.
Conclusions: Anti-PD-1 therapy showed better clinical outcomes and higher incidence of serious irAEs to anti-PD-L1 in perioperative settings. These results may guide clinical decisions and trial designs, and further tumor-specific evaluations and mature trial data are needed.

#3225 A meta-analysis of single agent versus combination immune checkpoint inhibitors in metastatic triple negative breast cancer.

Phaedon D. Zavras[1], Hugo R. Lara-Martinez[2], Qi Nie[3], Julius Y. Kattoula[3], Nicole Strossman[3], Zehui He[3], Ming Li[3], Romualdo Barroso-Sousa[4], Isaac Chan[5], Sara M. Tolaney[6], Vered Stearns[7], Cesar A. Santa-Maria[1], Evanthia T. Roussos Torres[3]

[1]Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins, Baltimore, MD,[2]University of Texas, MD Anderson Cancer Center, Houston, TX,[3]University of Southern California, Keck School of Medicine, Norris Comprehensive Cancer Center, Los Angeles, CA,[4]Dasa Institute for Education and Research (IEPD), Brazilia, Brazil,[5]Department of Internal Medicine, Division of Hematology and Oncology, University of Texas Southwestern Medical Center, Dallas, TX,[6]Dana Farber Cancer Institute, Boston, MA,[7]Weill Cornell Medicine, Meyer Cancer Center, New York, NY

Background: Immune checkpoint inhibitors (ICIs) are active against triple-negative breast cancer (TNBC), and approved in combination with chemotherapy, or as a single agent in patients with high tumor mutational burden and/or microsatellite instability/mismatch repair deficiency. A number of studies have been conducted with single-agent inhibitors of programmed cell death 1 or its ligand (PD1/PD-L1i), however, responses are typically low, especially in the later line setting. Few studies have evaluated the efficacy of PD1/PD-L1i combined with inhibitors of cytotoxic T-lymphocyte associated protein 4 (CTLA-4i) in metastatic TNBC, and none compared single agent vs combination ICI approaches. The purpose of this meta-analysis is to evaluate the efficacy of PD1/PD-L1i with or without CTLA-4i in TNBC.

Methods: A comprehensive literature search across PubMed, Embase, and Cochrane Library identified 870 unique clinical trials from 2010 - 2024. Studies eligible for inclusion were those of patients with: (1) metastatic TNBC, (2) >1 line of prior therapy, (3) received PD1/PD-L1i with or without CTLA-4i. Studies of combination of ICI with chemotherapy or targeted treatments were excluded with the exception of histone-deacetylase inhibitor (HDACi) combinations. Data were selected and extracted by two reviewers based on the PRISMA-A guidelines. The primary objective of the meta-analysis was objective response rate (ORR). Progression-free (PFS) and overall survival (OS) were also determined when available.

Results: A total of 10 clinical trials were eligible and included in the meta-analysis, six for single ICI and four for combination ICI. The heterogeneity test indicated no significant heterogeneity (I^2) in either of the groups, thus, a fixed-effect model was used. A total of 611 patients with metastatic TNBC (>1L) treated with single ICI showed a pooled ORR of 8.3% (95% CI, 6.1-10.7%), median PFS of 1.7 months (95% CI 1.40-2.06) and OS of 9.13 months (95% CI, 8.09-10.17). Among 42 patients treated with combination ICI, a pooled ORR was 27.7% (95% CI, 14.1%-43.3%). A sensitivity analysis excluding patients that received an HDACi showed an ORR of 7.2% (95% CI, 4.4%-10.6%) vs. 24% (95% CI, 9.5%-41.6%) for the single and combination ICI groups, respectively.

Conclusion: The use of combination ICI therapy led to an overall response rate of 27% compared to 8% in the single ICI studies. Our results provide rationale for further studies evaluating combination ICI approaches in patients with metastatic TNBC.

#3226 Intratumoral manipulation of melanoma using novel hyperthermic treatment to enhance anti-PD-L1 therapy.

Nicole DeSouza[1], Danielle Quaranto[1], Kaci Kopec[1], Jan Geliebter[1], Raj K. Tiwari[1], Mark D. Hurwitz[2]

[1]New York Medical College, Valhalla, NY,[2]Westchester Medical Center, Valhalla, NY

Despite tremendous advancement in the understanding and manipulation of immune checkpoint molecules in immunotherapeutic design, there are still vast limitations in treatment efficacy. Immunotherapy manipulates the immune checkpoint blockade (ICB), blocking negative regulators of the immune system-preventing tumor immune evasion. Combination therapy enhances the mechanistic actions of each individual component, enhancing tumoricidal behavior. Thermal ablation to induce cancer cell death as a therapeutic adjuvant is an understudied area.

B16-F10 melanoma cells were grown at 37°C or 41°C. B16-F10 cells grown at 41°C decreased cell migration by 70% in 24 hours. B16-F10 cell proliferation was decreased at 41°C by 62% at 48 hours and 94% at 72 hours.

Protein expression profiles were evaluated under hyperthermic conditions in vitro. Expression of pERK and ERK decreased by 86% and 50% and Caspase-3 increased by 31% at 41°C. Cell stress can induce death pathways and the heat shock protein response simultaneously, therefore we investigated inducible Hsp70 expression. Hsp70 expression was undetectable at 37°C and 188% at 41°C. Cytokine analysis of conditioned media showed that at 41°C, TNF-α expression was increased and IL-4 expression was decreased, suggesting a proinflammatory shift in cytokine profiles at higher temperatures. In support of our data, hyperthermia-induced TNF-α apoptotic responses have been reported.

Programmed cell death ligand (PD-L1) is expressed by tumors to suppress immune cells and induce tolerogenic phenotypes within the tumor microenvironment. We observed that hyperthermic potentiation decreased the expression of this checkpoint molecule in B16-F10 by 35%. Therefore, we hypothesize that hyperthermia modulates the tumor microenvironment to enhance their responsiveness to checkpoint immunotherapies. Based on these promising in vitro results, we plan to further explore the clinical aspect of our findings through a translation in vivo. B16-F10 cells will be implanted onto C57BL/6 mice and treated with infrared radiation in combination with either anti-PD-L1, anti-PD-1, or IL-15.

#3227 Components of interleukin-4 signaling are enriched in melanoma patients who respond to anti-PD-1 or anti-CTLA-4 therapy.

Szonja Anna Kovacs, Janos Tibor Fekete, **Balazs Gyorffy**

Semmelweis University, Budapest, Hungary

Background: Immune checkpoint inhibitors represent an advanced class of immunotherapy drugs used to treat various cancers, including melanoma, particularly in advanced stages. These therapies work by targeting immune checkpoints — proteins such as PD-1, PD-L1, and CTLA-4 — that act as brakes on the immune system. Prognostic biomarkers are essential for predicting disease outcomes, thereby enabling improved patient management.
Methods: We obtained transcriptomic and clinical data from melanoma patients treated with immune checkpoint inhibitors through the NCBI Gene Expression Omnibus and CRI iAtlas. After reviewing 246 datasets, we excluded those involving cell lines, unrelated diseases, or treatments. The expression data were quantile-normalized, and statistical analyses were conducted using the R environment. Survival data were excluded for patients without an event if follow-up ended before 12 months. Cox regression was applied to overall survival (OS) data.
Results: Altogether, 423 melanoma samples had sufficient data for survival analysis. Elevated expression of IL4R (interleukin-4 receptor, HR=0.33, FDR=2%, log-rank P=5.7E-04), JAK1 (Janus kinase 1, HR=0.3, FDR=1%, log-rank P=2.8E-04), GFI1 (growth factor independence 1, HR=0.35, FDR=5%, log-rank P=2.2E-03), and PTPN6 (protein tyrosine phosphatase non-receptor type 6, also known as SHP-1, HR=0.31, FDR=5%, log-rank P=1.9E-03) correlated with improved OS after anti-PD-1 therapy. Similar findings were observed after anti-CTLA-4 therapy for IL4R (HR=0.13, FDR=1%, log-rank P=3.2E-04), JAK1 (HR=0.14, FDR=1%, log-rank P=9.3E-04), and PTPN6 (HR=0.09, FDR=1%, log-rank P=2E-04). Signals mediated by interleukin-4 and interleukin-13 through these genes promote improved immune responses, cell survival, and differentiation. Finally, the Kaplan-Meier Plotter (www.kmplot.com) web platform was updated with our newly compiled immunotherapy cohort.
Conclusions: In melanoma patients, elevated expression of IL4R, JAK1, GFI1, and PTPN6 following anti-PD-1 and anti-CTLA-4 immunotherapies may enhance immune cell recognition, increase treatment efficacy, and extend survival. Our analytical platform supports a deeper understanding of patient responses and facilitates biomarker validation in a large cohort of melanoma patients.

#3228 Characterization of multi-organ system involvement of immune-related adverse events after anti-PD-(L)1 monotherapies: A pooled analysis of clinical trial data submitted to FDA.

Abhilasha Nair[1], **Matthew J. Hadfield**[2], Yue Huang[3], Flora Mulkey[4], Ilynn Bulatao[3], Marc R. Theoret[3], Kerry L. Reynolds[5]

[1]Office of Oncologic Diseases, Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD,[2]Division of Hematology/Oncology, Dept of Medicine, Warren Alpert Medical School, Brown University, Legorreta Cancer Center, Providence, RI,[3]Oncology Center of Excellence, US Food and Drug Administration, Silver Spring, MD,[4]Office of Biostatistics, Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD,[5]Department of Medicine, Division of Hematology-Oncology, Massachusetts General Hospital, Harvard Medical School, Boston, MA

Background: Treatment with PD-(L)1 blocking antibodies has dramatically improved outcomes across multiple cancer types. Such benefits must be carefully weighed against the risks of serious immune-related adverse events (irAEs) involving various organs, the occurrence patterns of which have not yet been well characterized. This large novel analysis of pooled clinical trial data submitted to FDA aims at uncovering and gaining deeper insights into the multiorgan patterns of irAEs associated with these agents.
Methods: This retrospective pooled analysis is based on patient-level, monotherapy, PD-(L)1 blocking antibody data from 18 clinical trials completed between 2019 and 2023, supporting FDA approvals across 7 cancer types. Only FDA authors had access to and analyzed patient level data. Patients with irAEs were identified using each PD-(L)1 development program's pre-defined definitions based on MedDRA preferred terms. Preferred terms were grouped into 30 irAEs based on the involved organs. IrAEs starting before or within 7 days of the end date of the preceding irAE, were considered co-occurring.
Results: Among the 5863 patients, 64% (n=3771) had at least one irAE; the most common irAEs (>10%) were skin reaction (53.5%), colitis/diarrhea (33.2%), hepatitis (23%), hypothyroidism (19.3%), and nephritis/renal dysfunction (11.7%). 50% (n= 1890) had more than one irAE type, with 59.7% experiencing 2, 24.8% experiencing 3, 9.7% experiencing 4, and 5.8% experiencing 5 to a maximum of 8 distinct irAE types, regardless of timing during their treatment course. Median time-to-onset of irAE in patients with a single type of irAE was 45 days while median time-to-onset of first irAE in subjects with more than one type of irAE was 30.5 days. Among the 1743 patients evaluable for co-occurrence analysis, 1285 (73.7%) experienced co-occurring irAEs. The 5 most frequently co-occurring irAEs were: skin reaction and colitis/diarrhea (15.8%); skin reaction and hepatitis (8.2%); skin reaction and hypothyroidism (7.5%); skin reaction and nephritis/renal dysfunction (4.8%); and colitis/diarrhea and hepatitis (4.2%).
Conclusions: This is the largest study of patient level clinical trial data evaluating the incidence and occurrence patterns of multi-system irAEs. The study demonstrated that the median time-to-onset of the first irAE was shorter for patients who experienced multi-organ irAEs than in those with single organ irAEs. Notably, half of the patients with an irAE experienced more than one distinct irAE during treatment, the majority of whom demonstrated co-occurrence of irAEs. These findings underscore the importance of vigilant monitoring and comprehensive management strategies to address the interconnected nature of irAEs, aiding providers in understanding, predicting, and managing patients experiencing irAEs.

#3229 Investigating the transcriptomic signature of HHLA2-mediated suppression of NK cell activity.

Nahuel Perrot[1], Nikolaos Kalavros[1], Deepthi Chowbene[1], Shoushuo Wang[1], Yered Pita-Juarez[1], Antonella Arruda de amaral[1], David McDermott[1], Gordon Freeman[2], Ioannis Vlachos[1], **Kathleen Mahoney**[1]

[1]Harvard Medical School/Beth Israel Deaconess Medical Center, Boston, MA,[2]Harvard Medical School/Dana-Farber Cancer Institue, Boston, MA

Determining how immune checkpoint inhibitors (ICI) alter functional characteristics of lymphocytes can improve our understanding of ICI. HERV-H LTR-associating 2 (HHLA2, B7-H7) is an immune checkpoint expressed by many tumors. Multiple HHLA2:KIR3DL3 blocking antibodies are currently in Phase I clinical trials and enrolling cancer patients (NCT05958199, NCT06240728), but little is known about how different subsets of NK cells are affected by HHLA2 expression. Our group previously found that in addition to an activating receptor, TMIGD2, HHLA2 has an inhibitory receptor, KIR3DL3. The KIR family of receptors is expressed in NK cells as well as T cells. Through co-culture experiments of CD56+ NK cells in the presence of K562 cells, we sought to investigate the mechanisms of NK cell engagement. Additionally, we generated transgenic K562 cell lines, over-expressing HHLA2, validated through flow cytometry, to maximize our ability to glean insight into HHLA2-KIR3DL3 mediated activation of NK cells. To this end, we generated a high quality scRNA-seq dataset of more than 100,000 cells, comprising of more than 90,000 NK cells, with approximately 30,000 cells either cultured alone, co-cultured with K562 or K562 over-expressing HHLA2 tumor cells, allowing unprecedented granularity. In conjunction with published NK cell states and newly identified ones through this study, we recapitulate important known cytokines, growth factors and other regulators underlying NK cell maturation and substates that are differentially affected by treatment, in abundance, expression, and regulation. Furthermore, we shed some light on the complex interplay of positive and negative regulators, including CD48 - 2B4 and CD56 related interactions in CCL4 and XCL2 high NK cells, as well as TGFb related pathways. Uncovering NK cell activity modulators, such as amphiregulin, NKG7, FAM49B, and TXNIP, we then focused on NK cells in the context of KIR3DL or TMIGD2 expression. We add to previous efforts to understand immune checkpoint inhibition by the HHLA2-KIR3DL3 axis and in a concerted effort with blocking antibodies, provide evidence of enhanced NK cell efficacy. Better understanding of how HHLA2 pathway affects the function of different subsets of lymphocytes could determine which patients may best benefit from targeting this pathway.

#3230 Preclinical double humanized CD47/SIRPA mouse model and MC38 cell line expressing human CD47 for efficacy and safety assessment of anti-CD47/SIRPA-targeting therapies.

Philippe De La Rochere, Angela Pappalardo, Gaelle Martin, Yacine Cherifi, Patricia Isnard-Petit, **Fabiane Sonego**, Kader Thiam

genOway, Lyon, France

CD47 is overexpressed on many human tumor cells and interacts with its ligand, the signal-regulating protein alpha (SIRPα), a protein expressed on macrophages and dendritic cells, to induce a “don’t eat me” signal. CD47 and its interaction with phagocytes is therefore a promising therapeutic target to treat cancer (S.B. Willingham *et al.*, Proc Natl Acad Sci U S A. 2012). Herein, we describe a double humanized CD47/SIRPα model for efficacy and safety assessment of human CD47/SIRPα-targeting therapies in immunocompetent mice. The double humanized CD47 and SIRPα mouse model (hCD47/hSIRPα) was generated by intercrossing hCD47 and hSIRPα mice. Both hCD47 and hSIRPα are humanized and their model design enables expression of all human isoforms. hCD47 and hSIRPα are expressed at physiological levels, which enabled the biodistribution assessment of anti-SIRPα nanobodies, used as tracers in non-invasive in vivo imaging of tumors (T.R. Wagner et al., Front.Immunol. 2023). Activity of anti-CD47-targeting compounds were investigated in the model and a MC38 tumor cell line expressing hCD47 was developed to reproduce as much as possible the interactions between hCD47 and hSIRPα upon tumor engraftment in the mouse model. Tumor growth inhibition studies in the hCD47/hSIRPα model with the corresponding cell line have shown significant reduction of tumor growth in mice treated with Magrolimab (Hu5F9-G4). Furthermore, safety assessment of Magrolimab in MC38-hCD47-bearing hCD47/hSIRPα mice in tumor context recapitulates the clinical findings (C.K. Brierley *et al.*, Transfusion. 2019), with a decline in hemoglobin and red blood cells post treatment. Altogether, these data suggest that the hCD47/hSIRPα model enables assessment of efficacy and safety of CD47 and/or SIRPα-targeting agents. The model is currently being upgraded to express humanized FcγR to enable assessment of Fc-mediated function of human antibodies targeting human CD47 and/or SIRPα.

#3231 Inhibition of focal adhesion kinase enhances antitumor response of immune checkpoint inhibitor therapy in laryngeal cancer.

Atish Ranjan Mohanty[1], Dana Do[1], Sharad Singhal[1], Haiqing Li[1], Sravani Ramisetty[1], Raju Pillai[1], Sultatna Shoukath[2], Prakash Kulkarni[1], Michelle Afkhami[1], Sue Chang[1], Ellie Maghami[1], Ravi Salgia[1], Erminia Massarelli[1]

[1]City of Hope National Medical Center, Monrovia, CA,[2]University of Texas at Tyler School of Medicine, Tyler, TX

Introduction: Laryngeal squamous cell carcinoma (LSCC), a subtype of head and neck squamous cell carcinoma (HNSCC), is projected to account for 12,650 new cases and 3,880 deaths in the United States in 2024. Key risk factors include smoking, alcohol abuse, and exposure to carcinogens like agent orange and asbestos. Active-duty service members and veterans face a heightened risk of developing LSCC. Curative standard treatment involves surgery, radiation, and platinum-based chemoradiation for laryngeal preservation. However, 25-50% of patients develop recurrence, often requiring salvage laryngectomy, which severely impacts their quality of life. We investigated the efficacy of Focal adhesion kinase inhibitors (FAKi), alone and in combination with immune checkpoint inhibitors (ICI), as potential therapeutic options for platinum-resistant LSCC.

Methods: We conducted an IRB-approved retrospective pilot study of 12 formalin-fixed paraffin-embedded (FFPE) LSCC tumor samples from smokers treated at the City of Hope. RNA was extracted from tumors and normal tissues and analyzed by NanoString Cancer and Immune Profiling Panels. FAKi screening was conducted using the CCK-8 cell viability assay. RNA-seq was performed to assess global changes in gene expression profiles. Syngeneic mouse models using MOC2 cell lines were utilized to evaluate the therapeutic efficacy of the FAKi in combination with ICI.

Results: Comparative analysis between normal and tumor tissues of 12 FFPE LSCC revealed upregulation of genes associated with cell-to-cell and cell-to-matrix adhesion, contributing to PI3K/AKT signaling. Tumor tissues also showed increased expression of genes involved in cell cycle regulation and DNA repair. Immune profiling of the same LSCC samples revealed CD4+ regulatory cells as the primary tumor infiltrating lymphocytes, underscoring the predominant immunosuppressive environment of LSCC. To investigate the significance of adhesion-dependent signaling, we used two human laryngeal cancer cell lines resistant to cisplatin: SCC17a and SQ20B. Among ten FAKi, TAE226 showed the most powerful inhibitory effect on cell growth in both cell lines. RNA-seq analysis revealed that TAE226 inhibits FAK phosphorylation, leading to the inhibition of genes that contribute to PI3K signaling. Additionally, it suppresses the expression of genes involved in the cell cycle and DNA repair. In the syngeneic mouse model, TAE226 showed a powerful synergistic effect with the ICI on the suppression of tumor growth, significantly prolonging the survival of the mice compared to ICI or the FAKi monotherapy groups.

Conclusion: Our study is the first to show synergism of FAKi and ICI in platinum-resistant LSCC in vitro and in a syngeneic HPV-negative HNSCC mouse model *in vivo*. This represents an important rationale for the translation of this therapeutic combination in platinum-resistant LSCC.

#3232 Developing PRMT5 inhibition-based Immuno-oncology combination therapies in MTAP-loss tumors.

Si Chen

Biology and Biochemistry, University of Houston, Houston, TX

Hyperactivated protein arginine methyltransferases (PRMTs) are implicated in human cancers. Inhibiting tumor-intrinsic PRMT5 has been shown to enhance antitumor immune responses, suggesting the potential of combining PRMT5 inhibitors (PRMT5i) with immunotherapy. However, global PRMT5 inhibition can impair immune cells functions. This study aims to identify strategies for tumor-specific PRMT5 inhibition and PRMT5i-based immuno-oncology (IO) combinations, especially for methylthioadenosine phosphorylase (MTAP)-loss cancers. Isogeneic tumor lines with and without MTAP loss were generated using CRISPR/Cas9 knockout. MTAP inactivation was confirmed by methylthioadenosine (MTA) accumulation and reduced symmetric dimethylarginine levels in MTAP-KO cell lines. Two PRMT5 inhibitors, GSK3326595 (substrate-competitive) and MRTX1719 (MTA-cooperative), were evaluated on tumor and immune cells. As shown in the Table 1, GSK3326595 suppressed PRMT5 activity and cell proliferation in both tumors and immune cells, regardless of MTAP status. Conversely, MRTX1719 selectively inhibited PRMT5 in MTAP-loss tumors, while treated T cells retained cytokine production and cytotoxicity. Transcriptomic and proteomic analyses revealed that MRTX1719 reduced PI3K pathway activation, a well-characterized immune resistant mechanism. In MTAP-loss syngeneic murine models, MRTX1719 combined with anti-PD-1 slowed tumor growth and extended survival (e.g., MC38/gp100 MTAP-KO tumor day 21: Ctrl 95.82±8.87 mm^2, PRMT5i 99.99±6.34 mm^2, anti-PD-1 94.47±6.76 mm^2, combination 72.81±4.14 mm^2; B16 MTAP-KO tumor day 18: Ctrl 108.24±9.13 mm^2, PRMT5i 106.45±22.54 mm^2, anti-PD-1 92.72±28.07 mm^2, combination 47.97±22.23 mm^2). The combination also increased $CD8^+$ T cell proliferation in MTAP-KO tumor tissues. Collectively, our results provide a strong rationale for the clinical development of MRTX1719-based IO combinations in MTAP-loss tumors.

Characterization of tumors and T cells in response to PRMT5i treatment

Cell line	MTA level (ng/ml) Mean±SEM	IC50 of GSK3326595 (uM)	IC50 of MRTX1719 (uM)
MC38 WT	2.93±0.96	3.118	2.747
MC38 MTAP-KO	362.50±0.71	3.315	0.356
B16 WT	1.89±0.08	0.834	3.853
B16 MTAP-KO	117.50±4.95	0.346	0.068
D4M WT	1.70±0.04	6.848	7.756

#3236 Analytical validation of a tumor-agnostic DNA methylation-based assay for minimal residual disease detection in lung cancer.

Bo Yang[1], Yuan Sun[1], Lei Wang[1], Peiru Liu[1], Simei Qiu[1], Lei Chen[1], Fujun Qiu[1], Yalan Jin[1], Shuailai Wu[1], Yu Xu[1], Lei Zhang[1], Zhihong Zhang[1], Kezhong Chen[2]

[1]Burning Rock Dx, Guangzhou, China,[2]Department of Thoracic Surgery, Peking University People's Hospital, Beijing, China

Background: Minimal residual disease (MRD) detection methods are pivotal for non-invasive tumor fraction assessment in lung cancer, enabling disease monitoring and prognosis. Mutation-based assays, such as Signatera and PROPHET [1], have shown favorable performance in detecting MRD. Since DNA methylation can also reflect cancer features, we hereby developed the STELLA, a tumor-agnostic assay leveraging targeted DNA methylation sequencing of cell-free DNA (cfDNA) from blood, to explore the efficacy of DNA methylation in tracking MRD in lung cancer.
Methods: To demonstrate proof-of-concept, we designed and validated a STELLA pilot panel, which includes 341 lung-cancer-specific hypermethylated regions with low background noise level (≤1e-5) derived from 2,485 healthy samples. The ctDNA fraction in plasma samples was quantified using a maximum likelihood method based on the cumulative probability p-values across the selected regions.
Results: Analytical validation revealed that our assay can detect tumor fractions as low as 0.02% with a DNA input of 30 ng. In a cohort of 126 PROPHET-positive and 436 PROPHET-negative lung cancer samples, STELLA achieved a PPA of 73.8% and NPA of 97.9% using PROPHET as an orthogonal reference, with tumor fraction measurements strongly correlating with PROPHET ($R = 0.73$, $P < 0.001$). Probit regression analysis established a limit of detection (LOD) of 0.019%. In an independent cohort of 87 PROPHET-positive and 338 PROPHET-negative samples from 148 surgically treated lung cancer patients in the MEDAL cohort [1], STELLA demonstrated a PPA of 41.4% and NPA of 98%, using PROPHET as an orthogonal reference relative to PROPHET. In preoperative plasma samples, STELLA detected circulating tumor DNA (ctDNA) with a sensitivity of 32.6%, outperforming a mutation-based tumor-naïve assay (21.7%) but underperforming PROPHET (58.7%). Critically, postoperative STELLA-positive results correlated with significantly shorter disease-free survival (hazard ratio [HR]: 3.98; 95% CI: 1.74-9.13; $P < 0.001$).
Conclusion: These findings underscore the potential of DNA methylation-based, tumor-agnostic cfDNA methods like STELLA to detect MRD in lung cancer with a tumor fraction as low as 0.02% and an NPA of 98%. STELLA offers a promising approach for tumor burden assessment, providing timely insights for treatment decisions and enhancing patient care.

#3237 Advancing non-invasive multiomics for early breast cancer detection: Transitioning from cfMeDIP-seq to single-molecule sequencing of cell-free DNA in the RENOVATE study.

Martina Dameri[1], Francesco Ravera[2], Pamela Becherini[2], Mario Stabile[2], Alberto Tagliafico[3], Marilena Iorio[4], Gianmaria Frige[5], Luca Mazzarella[5], Giovanni Scala[6], Michele Ceccarelli[7], Massimo Calabrese[8], Michele Piana[9], Alberto Ballestrero[2], Lorenzo Ferrando[1], Gabriele Zoppoli[2]

[1]IRCCS Ospedale Policlinico San Martino, Genoa, Italy,[2]Department of Internal Medicine and Medical Specialties, University of Genoa, Genoa, Italy,[3]Department of Health Sciences (DISSAL), University of Genoa, Genova, Italy,[4]Department of Experimental Oncology, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan, Italy,[5]Department of Experimental Oncology, IEO European Institute of Oncology IRCCS, Milan, Italy,[6]Department of Biology, University of Naples Federico II, Naples, Italy,[7]Sylvester Comprehensive Cancer Center, University of Miami, Miami, FL,[8]Department of Radiology, IRCCS Ospedale Policlinico San Martino, Genoa, Italy,[9]Department of Mathematics, University of Genoa, Genoa, Italy

Introduction: Tissue biopsy for suspicious breast lesions (BI-RADS 3-5) is invasive, costly, anxiety-inducing, and often yields false positives, with benign lesions (BLs) like fibroadenomas identified in approximately one-third of cases. Liquid biopsy, which analyzes the genomic and epigenomic features of cell-free DNA (cfDNA), offers a promising alternative. Techniques such as cell-free methylated DNA immunoprecipitation and high-throughput sequencing (cfMeDIP-seq) and cfDNA profiling using single-molecule Nanopore sequencing (NP-seq) could leverage the potential of cfDNA multiomics in early cancer detection.
Methods: In the RENOVATE trial (NCT04781062) conducted at IRCCS Ospedale Policlinico San Martino (Genoa, IT), we collected PAXgene plasma samples from 366 women. Over a recruitment period of 18 months, we included in the final analysis, per protocol criteria, 64 patients with pT1N1/pT2N0 breast cancer (BC) and 115 women with BLs. After extracting cfDNA from these samples, we prepared cfMeDIP-seq and low-pass whole genome sequencing (WGS) libraries following the protocol described by Shen et al. (Nat Prot, 2019) with minor modifications. Libraries were sequenced on a NovaSeq6000 (Illumina). Differentially methylated regions were analyzed using the MEDIPS package. Additionally, a subset of RENOVATE cfDNA samples was used to implement NP-seq. Libraries were prepared according to Ligation Sequencing V14 Human cfDNA multiplex protocol and sequenced on the Oxford Nanopore Technologies P2 Solo device.
Results: CfMeDIP-seq libraries achieved an average of 45 MegaReads per sample (3-5x coverage), while low-pass WGS libraries were sequenced to obtain 1-2x coverage. CfMeDIP-seq analysis identified 2,133 hypomethylated regions and 1,299 hypermethylated regions, allowing us to determine methylomic variables that distinguish BC from BLs. For representative RENOVATE samples, we obtained NP-seq data showing that an average of 30 million basecalled reads and 11 GB of output data can be achieved for each sample. Preliminary data indicate that NP-seq can replicate genomic and epigenomic features while also enabling complex analyses due to the richness of information generated.
Conclusions: The assessment of cfDNA multiomics to differentiate BLs from BC holds great potential in early BC management. Advanced sequencing technologies like cfMeDIP-seq and NP-seq extract key cfDNA features, including copy number variations (CNVs), fragment length, and 5mC for both methods, but unprecedented capability to simultaneously capture native fragment features, as well as previously poorly characterized epigenetic modifications for NP-seq, such as 5hmC and 8-oxodG. This approach could have clinically relevant implications, reducing unnecessary biopsies and benefiting both patients and healthcare systems globally.

#3238 Prognostic significance of ctDNA tumor fraction quantification in advanced HR-positive breast cancer.

Hao Liao[1], Jianxin Zhong[1], Xiaoran Liu[1], Bin Shao[1], **Haoran Tang**[2], Cancan Jia[2], Feng Xie[2], Yue Zhang[2], Huiping Li[1]

[1]Peking University Cancer Hospital, Haidian District, Beijing, China,[2]Huidu Shanghai Medical Sciences, Ltd., Fengxian District, Shanghai, China

Introduction: Hormone receptor (HR)-positive breast cancer is the most common breast cancer subtype worldwide. While treatments with CDK4/6 inhibitors and endocrine therapies like aromatase inhibitors (AIs) have improved patient outcomes, the risk of disease progression persists. This study employs circulating tumor DNA (ctDNA) Next-Generation Sequencing (NGS) assays to profile gene variations and quantify tumor fraction in patients with advanced HR-positive breast cancer, aiming to identify relevant gene biomarkers and enhance patient management.

Methods: In this retrospective study, plasma samples were collected from 136 patients with advanced HR-positive breast cancer before initiating first-line treatments, including CDK4/6 inhibitors, endocrine monotherapies, and chemotherapies. The study employed PredicineCARE™, a targeted NGS liquid biopsy assay with 20,000X coverage, to detect somatic alterations and calculate tumor fractions in ctDNA. Additionally, plasma samples were collected from 58 patients after first-line AI therapy and before initiating second-line treatment with fulvestrant. To detect potential residual or progressive disease in these patients, the study utilized PredicineCARE™ Ultra, an ultra-sensitive NGS liquid biopsy assay with coverage exceeding 100,000X.

Results: In baseline samples collected before first-line treatments from 136 patients, the ctDNA assay identified positive tumor fractions in 92 patients, detecting a total of 247 somatic mutations and 311 gene copy number variations. Patients with positive tumor fractions had significantly poorer progression-free survival (PFS) (median PFS: 9.4 months vs. 15.7 months; p=0.006) and overall survival (OS) (median OS: 82 months vs. 108 months; p=0.030). Among patients with positive tumor fractions, the median tumor fraction was 9.4%, ranging from 0.5% to 88.2%. When applying a cutoff value of 1%, patients with higher tumor fractions experienced significantly poorer PFS compared to those with lower tumor fractions (median PFS: 9.4 months vs. 15.7 months; p=0.006). In the post-AI-treatment samples from 58 patients, the ultra-sensitive ctDNA assay identified positive tumor fractions in 43 patients, detecting 93 somatic mutations. When applying the same tumor fraction cutoff of 1%, patients with high tumor fractions exhibited significantly poorer OS compared to those with low tumor fractions (median OS: 19 months vs. 46 months; p=0.015).

Conclusion: Quantification of tumor fractions using ctDNA NGS assays demonstrated significant prognostic value in advanced HR-positive breast cancer, not only at baseline but also in patients undergoing treatment with potential residual or progressive disease. These findings emphasize the critical role of tumor fraction as a prognostic indicator and underscore the potential of integrating ctDNA tumor fraction assessment into clinical practice.

#3239 Advancing cancer genomics with Agilent Avida DNA onco panels: a breakthrough in targeted sequencing.

Akanksha Khare, Nishita M. Balaguruvappa, Katherine Wilkins, Bonita Lam, Semen Leyn, Carole Durand, Alessandro Agostino, Kyeong S. Jeong, Michael Ruvolo

Agilent Technologies, Inc., Santa Clara, CA

Introduction: The Agilent Avida DNA Onco panels, developed to address the requirements of the European OncNGS Consortium, represent a significant leap forward in next-generation sequencing (NGS) solutions for cancer research. Optimized for low-input circulating cell-free DNA (cfDNA) from liquid biopsies & compatible with fragmented genomic DNA (gDNA) from diverse sample types, including FFPE & fresh/frozen tissues, the Avida technology delivers ultra-sensitive & rapid analysis of cancer-related genomic alterations. Designed for modularity & cost-effectiveness, these panels enable genomic profiling across solid tumor cancers & lymphoma samples. Its innovative synergistic-probe system hybridization chemistry ensures unparalleled recovery & efficiency, achieving deep DNA analysis within hours. With a streamlined workflow & ready to use design, these panels set a new standard for high-performance, reliable genomic insights in both liquid biopsy research applications & translational cancer research.
Methods: The Avida DNA Onco LB Panels focus on Tier 1 & 2 targets in ESCAT & OncoKB Levels 1 & 2, ensuring relevance for standard research applications. For broader research applications, the Avida DNA Onco LB Plus Panel combines Onco LB panel with additional content, spanning 1.75Mb with 437 genes, enabling expanded capabilities. The Avida DNA Lymphoma Panel encompasses 85 genes across 378kb to include key markers relevant to hematologic malignancies for research applications. The performance of these panels was evaluated using a comprehensive set of reference materials, including Seraseq ctDNA Mutation Mix v4, Seraseq® ctDNA Lymphoma Mix (Lymphoma Panel) reference samples with known biomarkers, human cfDNA control (Biochain Z2121001), & Coriell male HapMap gDNA (NA24385). Libraries were prepared using the Avida targeted sequencing workflow & sequenced to assess capture specificity & target region coverage.
Results: Using a set of well-characterized reference standards, the Avida DNA Onco LB Panels & Avida DNA Lymphoma Panels both demonstrated robust performance, achieving >90% sensitivity for SNPs, indels, & translocations at a limit of detection (LOD) of 0.5% allele frequency (AF) across all input amounts. For copy number variant (CNV) detection, the LOD was determined to be 1.3-fold amplification, demonstrating high accuracy. The panel achieved >90% sensitivity & >97% specificity for most samples with variants at or above the LOD, irrespective of input amount, confirming its reliability & consistency in detecting genomic alterations. Translocation detection sensitivity was >90% for AF ≥0.5% & DNA input ≥25ng.
Conclusions: The newly developed Agilent Avida DNA Onco panels offer a modular approach designed to address diverse genomic profiling needs across cancer research & applications. PR7001-3583For Research Use Only. Not for use in diagnostic procedures.

#3240 Analytical validation of CancerDetect™ RUO assay: a minimal residual disease detection test that integrates tumor-informed and tumor-agnostic approaches with large-scale mutation monitoring.

Sunghoon Heo[1], Seon-Kyu Ham[1], Hayoon Lee[1], Hwang-Phill Kim[1], Duhee Bang[2], Sang-Hyun Song[1], Tae-You Kim[1]

[1]IMBdx, Inc, Seoul, Korea, Republic of,[2]Department of Chemistry, Yonsei University, Seoul, Korea, Republic of

Background: Detection of circulating tumor DNA (ctDNA) has demonstrated clinical utility as a prognostic marker for recurrence by indicating minimal residual disease (MRD). Because the abundance of ctDNA is below the detection limit (LoD) of current tumor genotyping methods (<0.1%), novel technology is required. Currently developed methods adopted personalized tumor genotype informed (tumor-informed) strategy with suboptimal LoD (~0.01%). Increasing MRD positivity by lowering LoD is required to screen high-risk recurrence patients. Additionally, most of the currently developed MRD test lack clinically actionable information.

Methods: A clinically validated personalized large-scale mutation profiling strategy MRD platform, CancerDetect™, was improved by adding actionable mutation targets across 15 genes recurrently mutated in solid cancers. For analytical validation of personalized mutation regions, well-characterized mixtures of two germline gDNA (NA12891, NA12892) mixture were used, varying mixing ration from 0%, 0.0001%, 0.001%, 0.005%, 0.01%, 0.05% and 0.1%. For analytical validation of the clinically actionable regions, commercially available reference standard (Seraseq® ctDNA MRD Panel Mix) was used with dilution ranged from 0.01% to 0.5%. The panel was designed to target more than 100 different genotype loci (Twist Biosciences).

Results: The new iteration of CancerDetect™ integrates personalized tumor-informed large-scale mutation profiling strategy and drug target mutations (tumor-agnostic region) targeting strategy. Results showed that the limit of detection (LoD_{95}) was reached down to 0.001% for tumor-informed region with 99.9% specificity and 0.1% for drug target mutations with 95% specificity. The precision analysis showed 100% and interference test showed that the test performance was not affected by interfering materials (Bilirubin. Wash Buffer) near LoD fraction. Increased sensitivity achieved MRD positivity if 27.2% in a prospective cohort of 551 patients with stage II/III CRC after one month of curative surgery and 45.2% in stage II/III gastric cancer after 3-10 weeks of surgery.

Conclusion: The new iteration of CancerDetect™ showed the limit of detection of 0.001% with 99.9% specificity for tumor-informed region and 0.1% with 95% specificity for the tumor-agnostic region. The test result was not affected by the interfering materials and precision analysis showed 100% result. This indicates the new iteration of CancerDetect™ is a robust, sensitive MRD test.

#3241 Cell-free DNA fragmentomes for treatment response monitoring in patients with metastatic colorectal cancer: the DOLPHIN study.

Denise E. van Steijn[1], Jamie Medina[2], Lorenzo Rinaldi[2], Adria Closa[1], Lana Meiqari[1], Erica Peters[2], Alissa Konicki[2], Frederieke H. van der Baan[3], Mariska Bierkens[1], Haoyue Wang[4], Marjolein J. E. Greuter[4], Birgit I. Lissenberg-Witte[4], Veerle M. H. Coupe[4], Marie V. Coignet[2], Victor E. Velculescu[2], Daan van den Broek[1], Gerrit A. Meijer[1], Max J. Lahaye[1], Manon N.G. J.A Braat[3], Jeanine M. L. Roodhart[3], Nicholas C. Dracopoli[2], Geraldine R. Vink[3], Niels F. M. Kok[1], Remond J. A. Fijneman[1]

[1]Netherlands Cancer Institute, Amsterdam, Netherlands,[2]Delfi Diagnostics, Baltimore, MD,[3]University Medical Center Utrecht, Utrecht, Netherlands,[4]Amsterdam University Medical Centers, Amsterdam, Netherlands

Accurate monitoring of treatment response in patients with metastatic colorectal cancer (mCRC) is essential for optimizing therapeutic strategies. Current response evaluation relies on imaging-based assessment of tumor size changes. However, this approach is limited by suboptimal sensitivity for detecting lymph node and peritoneal metastases, as well as inter-reader variability. Circulating tumor DNA (ctDNA) is indicative of the number of neoplastic cells and could have clinical value to CT imaging for assessment of treatment response. A mutation- and tumor-independent ctDNA assay was recently developed, demonstrating its potential for longitudinal assessment of treatment response: the DELFI-tumor fraction (DELFI-TF) score. The DOLPHIN study aims to investigate the added clinical value of the DELFI-TF score compared to CT imaging for treatment response monitoring in patients with mCRC. DOLPHIN is a prospective, observational, multi-center substudy of the Prospective Dutch ColoRectal Cancer cohort (PLCRC). Clinical data, images, and blood samples from 400 patients receiving systemic therapy in 11 hospitals in the Netherlands are being collected. Blood samples are drawn longitudinally in conjunction with routine CT imaging. The plasma cfDNA fragmentomes will be assessed using the DELFI-TF. DELFI-TF is a locked and validated machine learning model that quantifies tumor burden uses using cell-free DNA (cfDNA) fragmentomes data derived from low-coverage whole genome sequencing. Droplet digital PCR (ddPCR) ctDNA testing will be used as a reference for patients with confirmed RAS/BRAF mutations. The primary objective is to evaluate the association between ctDNA changes and clinical response. Secondary objectives include analyzing the association between ctDNA changes and RECIST criteria (I), correlation with serum carcinoembryonic antigen (CEA) levels at specified points during systemic therapy (II), lead time of ctDNA-testing versus CT imaging for detecting disease progression (III), the prognostic value of longitudinal ctDNA-testing (IV). Until November 2024, 385 patients have been enrolled, with the anticipated inclusion target of 400 patients expected to be reached by December 2024. A comprehensive overview of the DOLPHIN study population will be presented at the conference. Application of DELFI-TF and ddPCR ctDNA testing on the initial cohort of collected samples is scheduled to commence in early 2025. The DOLPHIN study will assess the clinical validity of the DELFI-TF in monitoring treatment response and investigate whether longitudinal ctDNA-testing can complement or partially replace imaging-based treatment response monitoring. These findings could pave the way for ctDNA-guided decision-making, supporting and enhancing accurate assessment of therapeutic effectiveness and therapeutic decision-making for patients with mCRC.

#3242 DNA methylation profiling of Epstein-Barr virus (EBV) in lymphoproliferative disease reveals diagnostic and therapeutic applications.

Christoph Weigel[1], Haley L. Klimaszewski[2], Cara Noel[2], Ada C. Sher[1], Kurtis M. Host[1], Yue-Zhong Wu[1], Sarah Y. Schlotter[1], Eric Brooks[1], Charles T. Gregory[1], Esko Kautto[1], Elshafa H. Ahmed[1], Rosemary Rochford[3], James S. Blachly[1], Mark Lustberg[4], Timothy Voorhees[1], Christopher C. Oakes[1], Robert A. Baiocchi[1]

[1]Division of Hematology, Department of Internal Medicine, The Ohio State University, Columbus, OH,[2]College of Medicine, The Ohio State University, Columbus, OH,[3]Department of Immunology and Microbiology, School of Medicine, University of Colorado, Aurora, CO,[4]Division of Infectious Diseases, Yale School of Medicine, New Haven, CT

Introduction: Epstein-Barr Virus (EBV) is an oncogenic herpesvirus linked to hematologic malignancies. EBV enters latency within host cells and can undergo lytic activation, resulting in release of infectious virions. Latent EBV mediates malignant transformation, while lytic EBV is a frequent complication in immune suppression settings like post-transplant lymphoproliferative disease (PTLD). Current clinical assays detect only the presence of EBV via qPCR, limiting their diagnostic use. DNA methylation on EBV genomes is essential for interconversion of lytic/latent states, making it a promising virology biomarker.
Methods: We have developed a high-throughput multiplex PCR profiling assay (iPLEX) to assess quantitative EBV DNA methylation at n=35 CpG dinucleotide sites in liquid biopsies (plasma/serum). We applied this assay to a cohort of n=246 plasma samples collected at the OSU Wexner Medical Center via the Leukemia Tissue Bank Shared Resource. Our cohort consisted of viremic patients with EBV-associated lymphoma or non-malignant EBV activation, including n=118 organ transplant recipients. We complemented our analysis with single molecule readout of EBV plasma methylomes (n=27) using Nanopore sequencing of native DNA methylation.
Results: Low EBV methylation distinguished lytic from latent EBV (sensitivity: 93.3%, specificity: 97.2%), outperforming clinical EBV qPCR. We revealed distinct EBV methylation in lymphoma subtypes, ranging from intermediate (Hodgkin lymphoma, polymorphic PTLD) to high (Burkitt-, NK/T-cell lymphoma, monomorphic PTLD). Assessment of EBV methylation in treatment follow-up (n=55) highlighted malleable EBV methylation was associated with improved survival under treatment (p=0.0005). We further identified unique EBV methylation dynamics under epigenetic therapies, including DNA methyltransferase (DNMT) inhibitor decitabine. DNA methylation in the EBV protein kinase gene *BGLF4* was further associated with response to antiviral ganciclovir (GCV) use. Lastly, assessment of overall methylation patterns revealed four EBV methylation groups. Single molecule methylome analysis via Nanopore sequencing validated our data and identified distinct states of molecular epigenetic heterogeneity in EBV lymphoma and PTLDs. Methylation groups showed highly significant association with overall survival in multiple disease entities, including Hodgkin- and diffuse large B-cell lymphoma (DLBCL).
Conclusion: Our data reveal the epigenetic EBV landscape in lymphoma and non-malignant viremic conditions. EBV methylation can identify lymphoma through a minimally invasive plasma test for earlier and more reliable diagnosis of EBV-driven malignancy. EBV methylation could guide informed treatment decisions, especially with regard to epigenetic- and antiviral drug use, and aid in personalized care in the future.

#3243 Fragmentomic features of plasma cell-free DNA in patients with osteosarcoma.

Anastasia E. Mackeracher[1], Joanna Przybyl[2]

[1]Cancer Sciences, McGill University, Montreal, QC, Canada,[2]McGill University, Montreal, QC, Canada

The rapid advancement of liquid biopsy technologies represents a major breakthrough in cancer management, allowing for sensitive detection of tumor-derived molecules and providing real-time insights into disease progression. Osteosarcoma (OS), the most common primary bone malignancy, currently lacks robust biomarkers for therapy response. We hypothesize that a multi-omic and multi-modal approach to identifying OS-specific markers in circulating tumor DNA (ctDNA) will facilitate precise patient stratification and improve treatment outcomes. It has been demonstrated by others that plasma ctDNA in OS patients carry specific genomic markers, such as point mutations and copy number alterations. However, the fragmentomic features of cell-free DNA (e.g., fragment length and nucleotide composition) remain poorly characterized in OS patients.

To provide the rationale for studying fragmentomic features of plasma DNA in OS, we sought to demonstrate the feasibility of detecting distinct fragmentomic patterns in the publicly available whole genome sequencing data from cfDNA of 3 OS patients (NCBI SRA accession number PRJNA917431) together with our previously published shallow whole genome sequencing data from cell-free DNA of 7 patients with leiomyosarcoma, 12 patients with leiomyoma, 3 patients with dedifferentiated liposarcoma and 3 patients with well-differentiated liposarcoma (PMIDs: 29463554, 32232185, 34986184). We determined the first 4 nucleotide sequence (i.e., a 4-mer motif) on each 5′ fragment end of plasma DNA molecules. We calculated the frequency of each of the 256 possible motifs and normalized it to the total number of reads in each specimen. We applied multiclass differential analysis of the frequency of these motifs in 5 different types of tumors, and identified 64 motifs significantly enriched in OS (mean frequency difference between groups > 2.5-fold, false discovery rate < 0.05). In OS cell-free DNA, we observed decrease of motifs associated with DNASE1L3 nuclease (e.g., CCCA, CCAG, CCTG) and increase of motifs such as TAAA, AAAA, and TTTT. In the next steps, we will examine the expression of different DNA nucleases in patient tissue specimens by immunohistochemistry and will analyze plasma DNA from a new cohort of 50 OS patients to validate our preliminary findings. We will investigate whether these fragmentomic patterns of cell-free DNA have the predictive and prognostic value in OS patients. Our preliminary results warrant further studies of the frequency and diversity of the 4-mer motifs and expression of different DNA nucleases in OS.

#3244 *cfTrack-methyl*: A personalized approach using cfDNA methylomes for ultra-sensitive MRD detection.

Li Shuo[1], Weihua Zeng[1], Xiaohui Ni[2], Chun-Chi Liu[2], Yonggang Zhou[1], Mary L. Stackpole[2], Wenyuan Li[1], Arjan Gower[3], Kostyantyn Krysan[3], Andrew Melehy[4], Angela H. Yeh[1], Megumi Yokomizo[5], Preeti Ahuja[5], Lopa Mishra[6], Kirti Shetty[7], Yazhen Zhu[1], Hsian-Rong Tseng[8], Clara Lajonchere[9], Daniel H. Geschwind[9], David S. Lu[5], Steven S. Raman[5], William Hsu[5], Clara E. Magyar[1], Samuel W. French[1], Denise R. Aberle[5], Steven-Huy B. Han[3], Edward B. Garon[3], Vatche G. Agopian[4], Wing H. Wong[10], Steven M. Dubinett[3], Xianghong Jasmine Zhou[1]

[1]Pathology and Laboratory Medicine, UCLA - University of California Los Angeles, Los Angeles, CA,[2]EarlyDiagnostics Inc, Los Angeles, CA,[3]Medicine, UCLA - University of California Los Angeles, Los Angeles, CA,[4]Surgery, UCLA - University of California Los Angeles, Los Angeles, CA,[5]Radiological Sciences, UCLA - University of California Los Angeles, Los Angeles, CA,[6]Surgery, George Washington University, Washington, DC,[7]Medicine, University of Maryland, Baltimore, MD,[8]Molecular and Medical Pharmacology, UCLA - University of California Los Angeles, Los Angeles, CA,[9]Institute for Precision Health, UCLA - University of California Los Angeles, Los Angeles, CA,[10]Statistics, Stanford University, Stanford, CA

Methylation alterations are pervasive in cancer, making cfDNA methylomes a promising tool for cancer detection and minimal residual disease (MRD) monitoring. However, cfDNA methylation-based MRD detection faces unique challenges. Unlike genomic mutations, methylation signals are prone to noise from non-tumor-related factors, such as heterogeneous cell types and environmental influences. This noise introduces confounding signals and dilutes tumor-specific methylation markers. While patient-specific tumor methylation profiles offer personalized insights, they often contain inherent noise that compromises their performance. Existing approaches failed to address this challenge, as they either (1) disregard personal tumor methylation profiles, yielding suboptimal performance, or (2) fail to account for noise, treating all personal markers as equally informative. These limitations underscore a crucial need for a novel method that integrates personal markers while mitigating noise.

To address this challenge, we developed *cfTrack-methyl*, a personalized approach that integrates personal and population cancer methylome data (i.e., data from other patients). This method identifies methylome-wide personal tumor markers from the patient's tumor tissue or pre-treatment plasma and evaluates their prevalence across population cancer methylome data. Population prevalence quantifies the cancer relevance of noisy personal markers, filtering out non-tumor-related signals and prioritizing true tumor markers. With these purified personal markers, *cfTrack-methyl* achieves sensitive and specific MRD detection, even at ultra-low tumor fractions. In the titration series between fragmented liver tumor and WBC gDNA, the detection limit of *cfTrack-methyl* was calculated as < 0.01% with 100% sensitivity and 100% specificity. In simulated data with plasma spike-ins from various cancer types, *cfTrack-methyl* achieved a median AUC of 99.6% at a tumor fraction of 0.01% when tumor tissue was informed and maintained robust performance with a median AUC = 100.0% at a tumor fraction of 0.01% when tumor tissue was unavailable and pre-treatment plasma was used. Further, in liver cancer patients with complex comorbidities (cirrhosis or HBV), *cfTrack-methyl* achieved comparable detection limits, with a median AUC = 99.9% at a tumor fraction of 0.01%. In all scenarios, *cfTrack-methyl* outperformed the MRD detection using general cancer markers.

In conclusion, *cfTrack-methyl* delivers unprecedented sensitivity for MRD detection in cfDNA at low tumor fractions across diverse clinical scenarios. By integrating personal and population data, this approach maximizes the potential of cfDNA methylomes for ultra-sensitive MRD detection. Ongoing studies using serial samples from patients with surgically resected tumors aim to further validate this personalized strategy.

#3245 Analytical validation of a sensitive, tissue-free blood test for tumor burden monitoring.

Qiancheng You, Jing Su, Jiayue Xu, Xingyu Yang, Sa Zhang, Zeliang Deng, Guangyou Li, Xinyue Kang, Xiaoling Li, Si Zhang, Meifang Wu, **Bingsi Li**

Innovation Center, Burning Rock Biotech, Shanghai, China

Background: Liquid biopsy stands as a valuable tool in the field of precision medicine, with its utility extending across cancer detection, recurrence monitoring, and treatment selection. However, achieving the desired level of sensitivity often requires access to tumor tissue, which can be a limiting factor. Recent studies have shown that analyzing methylation patterns in circulating tumor DNA (ctDNA) enables a sensitive and accurate measurement of tumor burden in a tissue-independent manner, thus opening up new applications in relapse monitoring and therapy response assessment. Here, we report the initial validation of OverC Monitor™, a multi-cancer blood test that interrogates methylation information from over 2,000 genes at single-base resolution across various solid tumors.

Methods: Analytical performance of OverC Monitor™ was assessed using 672 contrived cell line samples and cell-free DNA (cfDNA) samples with 10-30ng input amounts. Analytical sensitivity was evaluated using a dilution series of cell line and cfDNA samples across different tumor allele fraction (TAF) levels, ranging from 0.001% to 0.5%. The limit of detection (LoD_{95}) was determined as the lowest tumor methylated fraction (TMeF) that achieved ≥95% detection probability through Probit regression for each cancer type. In addition, both ultra-deep sequencing (HS-UMI) and droplet digital PCR (ddPCR) were employed to verify the accuracy of TMeF in these dilution mixtures. The limit of blank (LoB) was evaluated by per-sample positive rate in 72 age-matched cancer-free donors. The combined precision and accuracy study was carried out by testing clinical samples from patients with lung cancer (LC), colorectal cancer (CRC), liver cancer (HCC) and non-cancer donors for a total of 216 replicates across different conditions.

Results: For sample-level methylation, the limits of detection (LoDs) were reached as low as 0.004% for cell line dilutions, and 0.02% for circulating-free DNA (cfDNA) titrations. The per-sample false positive rate was 0% (95%CI, 0-5.0%) among age-matched cancer-free donors. The positive predictive agreement (PPA) and negative predictive agreement (NPA) across different instruments, operators, and reagent lots were 100% (95%CI, 97.1-99.8%) and 100% (95%CI, 91.7-100%), respectively. Additional validation is ongoing, and data will be presented as it becomes available.

Conclusions: OverC Monitor™ is a patient-care-ready liquid biopsy capable of detecting common solid tumors even at ultra-low tumor burden. It requires no prior knowledge for downstream analysis, offering a new opportunity to improved sensitivity in a cost-effective manner. In addition, it is designed to be compatible with conventional tumor genotyping methods, adding a new dimension in the continuum of cancer management.

#3247 Liquid based methylation profiling for quantification of breast cancer subtypes.

Caroline Weipert, Denis Tolkunov, Sara Wienke, Derek Dustin, Michael Weindel, Catalin Barbacioru, Justin Odegaard, Darya Chudova

Guardant Health, Palo Alto, CA

Background: Hormone receptor (HR) status, typically determined through immunohistochemistry (IHC), and human epidermal growth factor receptor 2 (HER2) status, assessed by IHC and FISH, are critical factors in guiding breast cancer treatment. However, in metastatic breast cancer, resistance to endocrine or anti-HER2 therapies often develops, and receptor status may change over time due to tumor evolution under selective treatment pressures. Both IHC and FISH require tissue biopsies, which can become increasingly difficult to obtain in later treatment stages. Moreover, HR and HER2 status may evolve as the tumor adapts to therapy, highlighting the need for ongoing monitoring. A non-invasive, blood-based method could provide a practical alternative, enabling real-time assessment of receptor status. DNA methylation offers a potential avenue for identifying subtype changes in breast cancer. This could serve as an early indicator of resistance to treatment. In this study, we investigated whether methylation-based signatures in cell-free DNA (cfDNA) could act as a surrogate to predict breast cancer subtypes.

Methods: A novel cfDNA methylation-based deconvolution model was developed to quantify the proportional contributions of each breast cancer subtype in patient blood samples. The model leverages methylation signals across 4,500 cancer-associated genomic regions to estimate the contribution of each subtype while simultaneously predicting patient-specific subtype methylation signatures. A novel probabilistic model was developed to calculate the posterior probability of methylation for each region, based on hypermethylated molecule counts. To improve reliability, regions with high noise were filtered out, and penalized logistic regression models were created for each subtype using these posterior probabilities. Using a training set of 1,078 patients with breast cancer subtype derived from real-world data (HER2+ N=114, HR+ N=277, and TNBC N=71, with tumor fraction > 0.5%), logistic regression models were trained and optimized to predict HR, TNBC, and HER2 statuses.

Results: Model performance was evaluated by comparing the predicted histological subtypes to the known histological subtype annotations of 366 breast cancer samples. The overall accuracy on the test set was 80.1%, with the highest accuracy for TNBC (90.5%), followed by HR+/HER2+ (88%), HR+/HER2- (80%) and HR-/HER2+ (80%). Importantly, the model demonstrated the ability to detect sub-type in samples with tumor fraction as low as 0.5%.

Conclusions: Our methylation-based subtype deconvolution model provides a highly accurate method for predicting breast cancer subtypes from patient blood samples. This approach may enable the early non-invasive detection of growing treatment-resistance amongst breast cancer subtypes, with the potential to allow for more informed clinical decision-making and personalized treatment selection.

#3248 Circulating tumor DNA analysis of patients with BRAF-mutated advanced unresectable solid tumors treated with plixorafenib (FORE8394/PLX8394) in phase 1/2a study.

Rona Yaeger[1], Eric J. Sherman[1], Macarena de la Fuente[2], Frank Q. Tsai[3], Nicholas Butowski[4], Carl E. Allen[5], Natraj R. Ammakkanavar[6], Philip Lammers[7], **Jessica C. Jang**[8], Michael Paz[8], Sam Wang[8], Stacie Peacock Shepherd[8], Ping Jiang[8], Jordi Rodon[9]

[1]Memorial Sloan Kettering Cancer Center, New York, NY,[2]University of Miami, Miami, FL,[3]HonorHealth Cancer Care, Scottsdale, AZ,[4]University of California, San Francisco, San Francisco, CA,[5]Texas Children's Hospital, Houston, TX,[6]Community Health Network, Anderson, IN,[7]Baptist Cancer Center, Bartlett, TN,[8]Fore Biotherapeutics Inc., Philadelphia, PA,[9]The University of Texas MD Anderson Cancer Center, Houston, TX

Plixorafenib is a selective, potent BRAFi that inhibits class 1, 2, and fusion BRAF mutations. Plixorafenib evades paradoxical MAPK activation by disrupting BRAF dimerization and reduces toxicities and resistance that were observed in early generation BRAFi. Circulating tumor DNA (ctDNA) has proven its predictive or prognostic value for patients (pts) on treatment. We present here the analysis of longitudinal ctDNA from plixorafenib-treated pts, an exploratory endpoint from this Phase 1/2a study (NCT02428712).

A total of 211 plasma samples from 71 pts, 65 with BRAF alterations ($BRAF^{mut}$ not required in dose escalation study) were tested using PredicineCARE, which detects SNVs, INDELs, CNVs and fusions in ctDNA down to 0.05% allele frequency. Samples were obtained prior to treatment, at subsequent cycles, and at disease progression.

The ctDNA concordance with tissue-based NGS data at baseline (BL) was 83.3% for V600E, 72.7% for class 2 SNVs, and 33.3% for BRAF fusions. Most discordance in V600E was found in papillary thyroid carcinoma pts. V600E variant allele frequency (VAF) decreased from C1D1 to C2D1 in 17/20 pts. Decreases were greater in responders. BL V600E VAF was higher in non-responders. In 6 pts with available paired tumor biopsies, decreases in pERK validated ctDNA results after treatment. Class 2 and fusion VAFs also declined after treatment, supporting differentiated activity from early generation BRAFi. In longitudinal samples, changes in ctDNA correspond to tumor size across tumor types, suggesting that ctDNA may be a surrogate marker for monitoring disease. Genomic profiles at disease progression were compared to BL to assess new mutations and pathways between subjects in response group (CR+PR+SD) and non-response (PD) group (non-CRC due to intrinsic resistance). No new mutations in MAPK pathway genes were observed, supporting the dimer breaker property of plixorafenib. In ovarian cancer pts, BRAF VAF dominated over other mutations and matched tumor volume, suggesting that BRAF VAFs drove disease outcome. In non-responders, heterogeneity of genomic profile, co-occurrent RAS, MAPK-associated or NF1 mutations were seen, including melanoma pts who all received prior MAPKi therapies. In CRC, multiple driver mutations were found at BL associated with receptor tyrosine kinase activation, confirming resistance pathways and supporting clinical utility of combination. Despite genomic heterogeneity in V600+ melanoma and CRC, early decreases in BRAF VAF were observed.

ctDNA accurately detects BRAF mutations identified in tumor biopsy and longitudinal ctDNA levels is a potential surrogate marker for monitoring disease. Response to plixorafenib was observed through declines in ctDNA BRAF VAF and pERK. Furthermore, the “paradox breaking” property of plixorafenib was confirmed, as no new MAPK mutations emerged after treatment.

#3249 The development of a tissue-agnostic genome-wide methylome enrichment assay for lung cancer.

H. I. Pass[1], C. A. Melton[2], S. Shen[2], B. Brown[2], J. M. Burgener[2], J. Zhang[2], Y. Wang[2], J. Min[2], O. Hall[2], K. Budhraja[2], A. Licon[2], A. Williams[2], S. V. Bratman[3], B. A. Allen[2], J. Zhang[2], D. D. De Carvalho[3], A.-R. Hartman[2];

[1]New York University, New York, NY, [2]Adela, Inc., Foster City, CA, [3]Princess Margaret Cancer Centre, University Health Network, University of Toronto, Toronto, ON, Canada

Background: Lung cancer remains the leading cause of cancer-related death in the United States. Precision oncology is revolutionizing early-stage non-small cell lung cancer (NSCLC) treatment, showing promising results in improving outcomes. Utilization of molecular residual disease (MRD) testing has the potential to improve outcomes by detecting relapse ahead of clinical presentation. Currently, up to 38% of patients are ineligible for tumor-informed MRD tests due to insufficient tissue, often resulting from risks associated with invasive procedures, small biopsy sizes (e.g., FNAs), low tumor purity, competing demands for tissue (e.g., PD-L1 staining), or complete response to neoadjuvant treatment.[1,2] Herein, we demonstrate the feasibility of a tissue-agnostic genome-wide methylome enrichment platform utilizing cell-free methylated DNA immunoprecipitation followed by high-throughput sequencing (cfMeDIP-seq) for cancer detection, cancer signal quantification, and prognostication in lung cancer. [3,4]

Methods: In this feasibility study, a total of 24 patients (136 samples) with early-stage lung cancers (87.5% Stage I [IA (50%), IB (37.5%), IIA (4.2%) and IIB (8.3%)]); 19 were analyzed based on inclusion/exclusion criteria and assessed for their correlation with recurrence-free survival (RFS). Blood collections for each patient occurred prior to surgery, after surgery and at irregular intervals before recurrence or last clinical follow-up. 5-10 ng of cfDNA isolated from each plasma sample was used for cfMeDIP-seq. The analysis considers multiple MRD tests over a surveillance period following surgery. RFS is compared between groups using a log-rank test. The Hazard Ratio (HR) is estimated using Cox proportional hazards model.

Results: With a median follow up duration of 85.6 months, 10 patients experienced recurrence, and 9 patients remained recurrence-free. Patients with a positive MRD test showed significantly worse RFS than those who tested negative (HR 3.58; 95% CI, 1.00,12.89). The lead time between MRD positivity and clinical recurrence was up to 35.91 months, with a median of 13.08 months.

Conclusions:The analysis demonstrates that MRD detection with a tissue-agnostic, genome-wide methylome enrichment platform in patients with lung cancer after curative intent treatment correlates strongly with RFS. Introduction: Monitoring minimal residual disease (MRD) is critical in multiple myeloma (MM) to predict outcomes and guide therapy. Traditional bone marrow (BM) aspirates for MRD detection are invasive and limited by sample quality. We therefore explored cell-free DNA (cfDNA) fragmentation as a less invasive alternative for MRD detection.

Methods: We performed 30-40X whole-genome sequencing (WGS) on peripheral blood cfDNA from 45 MM patients, collecting baseline (n = 45) and follow-up samples (n = 98) from eight Canadian sites (M4 and IMMAGINE studies) and one U.S. site (SPORE study), plus 25 healthy controls. Samples were collected post-induction therapy (n = 13), 100 days post-autologous stem cell transplantation (ACST, n = 36), and during maintenance therapy (n = 49). Multiparameter flow cytometry (MFC) MRD testing was conducted on 77 samples. We evaluated insert size metrics and MM-specific chromatin accessibility (from Ordoñez et al., 2020) using Griffin (described in Doebley et al., 2022).

Results: Baseline samples had a higher proportion of short fragments (20-150 bp) than follow-up samples ($p = 0.0037$) and healthy controls ($p = 0.019$). A fragment score (FS) based on weighted fragment distribution (per Vessies et al., 2022) was highest at baseline (mean = -0.384), followed by MRD-positive (mean = -0.495) and MRD-negative (mean = -0.550) samples. MRD-negative FS was lower than baseline samples ($p < 0.001$) but higher than healthy controls (mean = -0.639; $p = 0.016$).

Baseline samples had lower coverage at MM-specific chromatin regions than MRD timepoints ($p < 0.05$; baseline mean = 0.982; MRD-positive = 0.989; MRD-negative = 0.994; healthy = 0.993), suggesting higher transcriptional activity pre-treatment. MRD-negative samples had higher coverage than MRD-positive cases ($p < 0.01$).

Using logistic regression, we assessed the predictive performance of FS and coverage at MM-specific sites. FS alone achieved an AUC of 0.632 (sensitivity [SN] 39.4%, specificity [SP] 92.1%, accuracy [AC] 67.6%). Coverage yielded an AUC of 0.681 (SN 75.8%, SP 60.5%, AC 67.6%). Combining FS and coverage at MM sites improved performance (AUC = 0.734; SN 48.5%, SP 92.1%, AC 71.8%). We next evaluated whether adjusting the BM tumor cell percentage cutoff by MFC could improve performance. At 0.017% (1 in 5,789 cells) for MRD positivity, the combined model's accuracy reached 83% with an AUC of 0.757 (SN 17%, SP 97%).

Conclusions: cfDNA fragmentomic analysis achieved high specificity (92-97%) in detecting MRD, providing a less invasive alternative to facilitate serial monitoring. While sensitivity remains an area for improvement, the high specificity of cfDNA makes it valuable for confirming MRD negativity and reducing invasive procedures. Future efforts aim to enhance sensitivity by integrating additional fragmentomic features.

#3251 Immediate postoperative minimal residual disease detection with MAESTRO predicts recurrence and survival in head and neck cancer patients.

Edward S. Sim[1], Justin Rhoades[2], Kan Xiong[2], Laurel Walsh[2], Andjela Crnjac[2], Timothy Blewett[2], Yana Al-Inaya[1], Julia Mendel[1], Daniel Ruiz[1], Vasileios Efthymiou[1], Gjystina Lumaj[1], William J. Benjamin[1], G. Mike Makrigiorgos[3], Shervin Tabrizi[2], Viktor A. Adalsteinsson[2], Daniel L. Faden[1]

[1]Department of Otolaryngology-Head and Neck Surgery, Massachusetts Eye and Ear, Boston, MA,[2]Gerstner Center for Cancer Diagnostics, Broad Institute of MIT and Harvard, Cambridge, MA,[3]Department of Radiation Oncology, Dana-Farber Cancer Institute, Boston, MA

Introduction: Most head and neck squamous cell carcinoma (HNSCC) patients are diagnosed with locoregionally advanced disease and face high recurrence rates despite standard-of-care treatments. Using circulating tumor DNA (ctDNA) to detect minimal residual disease (MRD) has emerged as a promising biomarker for assessing recurrence risk and treatment efficacy across various cancers. However, the sensitivity of commercially available assays for detecting MRD remains limited, often failing to capture subtle dynamic changes. As a result, the dynamics of ctDNA immediately following treatment and its potential as a reliable biomarker for guiding early post-operative adjuvant treatment decision making remain poorly understood.

Methods: Our group has developed MAESTRO (minor-allele-enriched sequencing through recognition oligonucleotides) that uses patient-specific probes to selectively enrich ctDNA carrying thousands of genome-wide tumor mutations, enabling highly sensitive MRD detection with minimal sequencing. We utilized MAESTRO to prospectively monitor MRD in HNSCC patients after surgery during the immediate post-operative window—serial blood samples taken while patients were in the hospital recovering from surgery—and the surveillance period, aiming to evaluate its potential to predict disease progression. Kaplan Meier survival analysis and Cox proportional hazards regression were applied to assess the association of MRD detection during the immediate post-operative window with event-free survival (EFS).

Results: 24 HNSCC patients were enrolled. Patients were pre-dominantly HPV-negative [23/24 (95.8%)] and had advanced stage III/IV disease [22/24 (91.7%)]. Serial sampling in the days following surgery revealed rapid ctDNA clearance on the first post-operative blood draw (1-3 days postop) of patients without MRD. MAESTRO detected ctDNA in 13 of the 15 (86.7%) patients who experienced an event (recurrence or death). In 8 of the 13 (61.5%) patients with an event and detectable MRD, tumor fractions were below the limit of detection of leading commercial assays. MRD detection was associated with worse EFS (HR = 27.4; 95% CI 3.5-214.5; $P < 0.0001$) and remained an independent predictor of EFS when controlling for high-risk pathologic features (23.8; 3.0-192.1; $P = 0.003$).

Conclusions: Tumor fractions of HNSCC patients treated effectively with surgery were undetectable as early as the first postoperative day. Most tumor fraction levels detected by MAESTRO were outside the sensitivity range of leading commercially available assays. MRD detection of patients in the immediate post-operative period was predictive of recurrence and worse survival. MAESTRO-based MRD detection may enable highly-sensitive identification of high-risk HNSCC patients and guide therapy including whether treatment escalation may be necessary.

#3252 Circulating tumor DNA (ctDNA) enables enhanced measurable residual disease (MRD) detection and non-invasive clonal profiling in acute myeloid leukemia (AML).

Ruwan Gunaratne[1], Crystal Zhou[1], Sanjeeth Rajaram[1], Jesse W. Tai[1], Sky Kim[1], Kailee Tanaka[1], Charu Tiwari[1], Grace Gao[1], Mia Carleton[2], Brian J. Sworder[3], Gabriel N. Mannis[1], Michael S. Khodadoust[2], Ravindra Majeti[1], David Kurtz[2], Tian Yi Zhang[1]

[1]Division of Hematology, Stanford University School of Medicine, Stanford, CA,[2]Division of Oncology, Stanford University School of Medicine, Stanford, CA,[3]Division of Hematology and Oncology, University of California Irvine, Irvine, CA

Introduction: Current MRD detection methods for AML (multiparameter flow cytometry and single-gene assays) are limited by suboptimal sensitivity, narrow coverage for molecular monitoring and clonal resolution, and/or reliance on invasive bone marrow biopsies. To address these issues, we developed AML-CAPP-Seq, a ctDNA-based assay leveraging a customized Cancer Personalized Profiling by Deep Sequencing (CAPP-Seq) approach to detect MRD and track clonal evolution.
Methods: AML-CAPP-Seq integrates patient-specific hybrid capture panels (based on whole exome sequencing, WES) with a shared panel of 58 recurrently mutated 'canonical' AML genes to generate personalized MRD assays. We analyzed > 1000 biological samples from 56 AML patients (median follow-up: 19.5 months) and 21 healthy controls, comparing MRD detection in bone marrow mononuclear cells (BMMCs), peripheral blood mononuclear cells (PBMCs), and cell-free DNA from plasma (PB-ctDNA) and bone marrow (BM-ctDNA) against standard-of-care (SOC) MRD assays.
Results: WES identified a median of 32.5 tumor single nucleotide variants (SNVs) per patient, allowing MRD detection in 100% of patients with a detection limit of <0.01% tumor fraction. Use of only canonical AML genes reduced coverage to 84%, while SOC single gene molecular MRD methods were applicable to just 32% of patients. Tumor burden in PB-ctDNA was highly correlated ($r > 0.9$) with other compartments and showed significantly higher tumor DNA levels at low disease burden states (median 3.8- and 2.9-fold enrichment compared to PBMCs and BMMCs respectively, $p < 0.02$), particularly in cases of extramedullary involvement. PB-ctDNA detected residual disease in 98.5% of samples with +MRD by SOC marrow-based methods and identified MRD in 47.4% of SOC-negative samples. Of these, 46.8% were from patients who later relapsed, while 50% ultimately reached MRD-negative status after further therapy. In CR1 patients (n = 48), PB-ctDNA identified MRD in 89.3% of those who relapsed, compared to 46.4% by SOC MRD and 35.7% by flow alone. PB-ctDNA MRD robustly predicted relapse-free survival (RFS, HR = 11.9, p = 7e-8) and overall survival (HR = 19.7, p = 5e-9), outperforming SOC methods (HR = 3.4, p = 5e-4 and HR = 5.2, p = 4e-6 respectively). For patients undergoing allogeneic SCT (n = 27), PB-ctDNA MRD clearance before and after SCT predicted RFS (p = 4e-4). Additionally, by monitoring dozens of tumor variants including indels and copy number alternations in a time-resolved fashion, AML-CAPP-Seq allowed detailed tracking of clonal dynamics over time.
Conclusions: AML-CAPP-Seq offers ultrasensitive, noninvasive MRD detection in ctDNA superior to SOC methods without need for invasive BM evaluation. Personalized variant tracking ensures universal applicability across AML patients, enabling both MRD monitoring and clonal evolution profiling.

#3254 Cell-free DNA molecular response predicts clinical efficacy in HGSOC patients treated with azenosertib.

Jinkil Jeong[1], Jianhui Ma[1], Mona Abed[1], Heekyung Chung[1], Doris Kim[1], Nandini Molden[1], Divya Rajendran[1], Chang Shim[1], Danielle D. Jandial[1], Mark R. Lackner[1], Fiona Simpkins[2], Funda Meric-Bernstam[3], Leslie M. Randall[4], Olivier Harismendy[1]

[1]Zentalis Pharmaceuticals, San Diego, CA,[2]University of Pennsylvania, Philadelphia, PA,[3]University of Texas MD Anderson Cancer Center, Houston, TX,[4]Inova Health, Fairfax, VA

Background: Azenosertib is a novel selective WEE1 inhibitor showing promising activity in the treatment of gynecologic tumors, including high-grade serous ovarian cancer (HGSOC). The clinical development of azenosertib in HGSOC is conducted via several efficacy studies using Objective Response Rate (ORR) and progression free survival (PFS) as primary and secondary endpoints. Molecular response (MR), as measured by longitudinal changes of tumor DNA fraction in cell free DNA (cfDNA), can represent a cost-effective, and early efficacy endpoint, which needs further evaluation in HGSOC clinical studies.
Method: Patients (N=139) enrolled in single-agent azenosertib studies (NCT04158336, NCT05128825, NCT05198804) were included in the analysis when 1) assigned to receive at least 300mg QD of azenosertib and 2) plasma cfDNA successfully profiled (Tempus xF+ Liquid Biopsy Assay) at baseline (C1D1) and at least one on-treatment timepoint (C2D1 or C3D1). Efficacy was extracted from an unlocked clinical database. MR positivity was defined as a decrease of TP53 variant allelic fraction greater than 50% between baseline and the earliest evaluable sample.
Results: Most patients (123/139 88.5%) had detectable baseline TP53 mutations and were evaluable for MR of which 70/123 (57%) were MR+ including 28 with complete MR (mCR: 100% decrease). MR+ patients had a higher ORR (20/70 29% vs 4/53 8%, p=5.1e-3, Odds ratio=0.20). Stages of molecular response correlated with best tumor size change (Kruskal-Wallis p<2e-4) including 31% median tumor shrinkage in mCR patients. Consistently, MR predicted time to progression (TTP median 5.12 mo vs 2.69 mo, p=2.8e-4, HR=0.46) and a longer TTP was observed in mCR patients (median 5.68 mo). Remarkably, MR helped further stratify patients with stable disease at first assessment (SD1A patients), with MR+ patients showing a longer TTP (6.08 mo vs 3.42 mo, p=0.012, HR=0.45). In particular, 5/6 SD1A patients who eventually responded had positive MR identified at least 12 weeks (median 14w) prior to confirmation, while 24/39 SD1A patients who progressed had negative MR identified at least 2 weeks (median 7w) prior to progression. Of the 65 patients profiled at both C2D1 and C3D1, 38/65 (58%) had confirmed MR at C3D1. These confirmed MR were more likely to respond to the therapy (16/38 42% vs 4/27 15%, Odds ratio=0.24) and had a longer TTP (5.58 mo vs 3.25 mo, p=0.044, HR=0.52). Interestingly, confirmed MR patients were not more likely to have mCR at C2D1 (16/38 in confirmed vs 3/7 in unconfirmed MR) suggesting that the depth and duration of MR provide independent prognostic values.
Conclusion: Molecular response by cfDNA is an early and reliable surrogate endpoint to measure clinical efficacy in HGSOC studies. Molecular response, duration, and depth were predictive of response or stable disease from azenosertib treatment, supporting its further clinical development.

#3255 Analytical validation of cancer gene promoter methylation detection in cfDNA liquid biopsy assay.

Janice A. Patterson, Martina Lefterova, Brooke Overstreet, Colby Jenkins, Katie Quinn, Darya Chudova

Guardant Health, Palo Alto, CA

Introduction: Promoter methylation (PM) is a critical epigenetic mechanism that is involved in gene silencing and is associated with key pathways in cancer progression. Traditionally, PM detection has relied on single-gene testing of tissue biopsies, which are invasive, less clinically accessible, and impractical for tracking tumor evolution. Here, we evaluate PM within clinical multi-modal assessments using Guardant Infinity smart liquid biopsy platform, providing an innovative approach for monitoring epigenetic alterations.
Methods: Data across >17k samples, including >5k cancer-free samples, and cancer-positive samples from >100 cancer types were used to define promoter regions associated with hypermethylation in cancer-related genes. PM regions were refined to ensure (a) the methylation signal is present exclusively in cancer and low in cancer-free samples, and (b) a negative correlation between gene expression and methylation in The Cancer Genome Atlas Program (TCGA) cancer samples. PM regions are quantified relative to constitutively hypermethylated control regions, measuring gene PM relative to total cfDNA. Analytical accuracy was demonstrated using an orthogonal Enzymatic Methyl Sequencing (EM-seq) assay on a cohort of clinical cfDNA and contrived samples. Limit of detection, precision, and limit of blank were established based on cancer cfDNA samples, cell line dilutions, and healthy donor samples. Gene PM prevalence was assessed in a test cohort of >7k samples across multiple cancer types to compare the relative prevalence to published tissue data sets.
Results: Guardant Infinity PM limit of detection (>95% variant level) was established at PM mutant allele frequency (MAF) 1.6% across a panel of promoter genes. PM above the limit of detection is highly concordant with orthogonal EM-Seq, with 98.2% positive and 98% negative concordance. MLH1 PM was identified in 54% of patients with colorectal cancer (CRC) and 100% of patients with endometrial cancer (EC) who also had MSI-H detected. MLH1 PM in our cohort of CRC showed significant enrichment for BRAF V600E (36%, $p<0.001$). High prevalence of BRCA1 PM was observed in breast (BC) and ovarian cancer (OC), consistent with what is observed in literature. Enrichment of BRCA1 PM in BC was observed with loss of heterozygosity (LOH) (6%, $p=0.02$). The relative PM prevalence for individual genes across tumor types is largely consistent with what has been reported in tissue datasets.
Conclusion: PM in liquid biopsy is consistent with tissue-based findings and correlates with underlying tumor characteristics, such as MSI-H and LOH events, thus demonstrating Guardant Infinity's ability to identify potentially actionable PM patterns in a non-invasive manner. This analysis represents a fraction of the PM landscape observed, highlighting the broader potential of methylation as a novel biomarker for cancer detection and characterization.

#3256 Circulating tumor DNA as a prognostic biomarker in locally advanced esophageal cancer.

Marisa Sewell[1], Matthew Bott[1], Katherine Gray[1], Steve Maron[2], Yelena Janjigian[2], Hans Gerdes[3], Pari Shah[3], Abraham Wu[4], Bernard J. Park[1], David R. Jones[1], Daniela Molena[1]

[1]Thoracic Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York CIty, NY,[2]Gastrointestinal Oncology Service, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York CIty, NY,[3]Gastroenterology, Hepatology, and Nutrition Service, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York CIty, NY,[4]Radiology, Memorial Sloan Kettering Cancer Center, New York CIty, NY

Introduction: The role of plasma circulating tumor DNA (ctDNA) as a prognostic biomarker in locally advanced esophageal cancer has not been well defined. We aim to evaluate the prognostic value of pre- and on-treatment ctDNA detection.
Methods: In this retrospective single institution study, patients with esophageal cancer undergoing definitive local therapy via endoscopic resection (ER), esophagectomy, or definitive chemoradiation (CRT) underwent baseline and post-treatment ctDNA analysis utilizing a plasma-based tumor informed assay. ctDNA detection and quantification was annotated to clinicopathologic characteristics.
Results: Between 2022 and 2024, 37 treatment-naïve esophageal cancer patients with stage I-IVA disease were analyzed. Overall, 28 underwent esophagectomy, 7 underwent definitive CRT, and 2 underwent ER. At baseline, ctDNA was detectable in 62% (23/37), with a mean 2.74 mean tumor molecules per milliliter of plasma (MTM/ml) (SD 6.37). Among those with detectable baseline ctDNA, 87% (13/15) achieved ctDNA clearance within a median of 45 days postoperatively. The rate of achievement of ctDNA clearance did not differ between the surgical or CRT groups (92% v. 83%, p>0.99).
Of those patients who underwent surgery, 79% (22/28) had neoadjuvant therapy. Baseline ctDNA was detectable in 73% (16/22) of those patients, with a mean ctDNA level of 2.34 MTM/ml (SD 6.10). ctDNA remained detectable in 18% (3/17) after neoadjuvant therapy. Following surgery, 93% (14/15) achieved ctDNA clearance. When examining pathologic response among patients that had neoadjuvant therapy, 27% (6/22) had no residual disease at the time of resection. Patients with no residual disease had significantly lower ctDNA at baseline than those who did have residual disease (0.37 MTM/ml v 1.51 MTM/ml, p=0.005). Of the 14 patients that were detectable at baseline who achieved ctDNA clearance preoperatively, only 3 of those had no residual disease. Among the 28 esophagectomy patients, 11 had nodal metastases. While ctDNA detection rates at baseline were similar between pN0 and pN+ patients (58% v. 64%, p=0.70), patients with nodal metastases had significantly higher pre-treatment ctDNA levels (3.0 MTM/ml vs. 1.2 MTM/ml, p<0.001).
Conclusion: Local therapy for esophageal cancer effectively clears ctDNA. Additionally, quantitative analysis of baseline ctDNA may be a useful prognostic indicator for patients likely to have nodal metastases and poor treatment response at the time of surgery.

#3258 Predicting genitourinary cancer tissue-of-origin using urine cell-free DNA fragmentomics and cell-free RNA.

Pradeep Singh Chauhan[1], Irfan Alahi[1], Jessica Linford[1], Arpit Panda[2], Nathan Colon[3], Ryan Mueller[3], Faridi Qaium[1], Peter K. Harris[3], John Sheng[3], Eric H. Kim[3], Melissa A. Reimers[3], Zachary L. Smith[4], Woodson W. Smelser[3], Aadel A. Chaudhuri[1]

[1]Mayo Clinic, Rochester, MN,[2]University of Chicago, Chicago, IL,[3]Washington University School of Medicine in St. Louis, St. Louis, MO,[4]Advent Health, Orlando, FL

Introduction: We previously developed a urine liquid biopsy assay to measure urine tumor DNA (utDNA) levels in bladder cancer (BC) patients. Here, we extended this approach significantly by layering in cell-free DNA fragmentomic and cell-free RNA analysis, and extending the method to the full spectrum of genitourinary (GU) cancers, to enable both GU cancer detection and tumor tissue of origin prediction.
Methods: A total of 155 GU cancer patients and 34 healthy adults were enrolled in this prospective study. Preoperative urine was collected from 94 bladder cancer (BC) patients, including 65 with muscle-invasive disease, all undergoing cystectomy. Additionally, urine samples were collected from 18 renal cell carcinoma (RCC) patients undergoing nephrectomy and 42 metastatic prostate cancer (mPC) patients. Urine cfDNA and cfRNA were isolated and sequenced, with cfRNA sequenced to 100 million reads per sample on an Illumina NovaSeq X and cfDNA sequenced at 5x genome-wide coverage on a Novoseq S4 flow cell. To identify malignant tissue of origin, we analyzed somatic copy number alterations (CNAs), genome-wide fragment length ratios, and 4-mer end motifs. Tumor fraction (TFx) was estimated using ichorCNA, while DELFI was employed for fragment length ratios in 5 megabase bins across the genome and chromosome arm-level z-scores. Individual logistic regression models were developed based on each fragmentomic feature, and validated using a training and held-out testing approach. Outputs from these models were combined into a single comprehensive model, also trained and held-out tested using the same approach. Urine cfRNA transcript isoform abundance was quantified using Salmon and normalized to Transcripts Per Million (TPM) to account for sequencing depth variations.
Results: Bladder cancer (BC) showed the highest mean tumor fraction (TFx, 10.5%), followed by RCC (3.8%) and mPC (3.4%). Among 94 BC patients, 42% achieved a pCR, while 58% had residual disease and did not. Patients without pCR had significantly higher urine TFx compared to those with pCR (14.7% vs. 4.7%, p=0.0008). A machine learning model based on genome-wide fragment length ratios achieved an ROC AUC of 0.74, while models using genome-wide CNAs and end motifs achieved AUCs of 0.81 and 0.88, respectively. Combining all features into a single model yielded an AUC of 0.92, with classification accuracies of 89% for bladder cancer, 80% for RCC, and 60% for prostate cancer. Additionally, urine cfRNA analysis using the top 1,000 coding transcripts achieved an AUC of 0.95, with classification accuracies of 100% for mPC, 87% for BC, and 78% for RCC.
Conclusion: Fragmentomic features from urine cfDNA and transcriptomic features from urine cfRNA demonstrate strong potential for predicting tumor tissue-of-origin in GU cancers, underscoring the promise of non-invasive diagnosis across the spectrum of GU malignancies through urine liquid biopsy.

#3259 Beyond tumor size: Biological and clinical predictors of ctDNA shedding in colon cancer.

Nerma Crnovsanin*[1], **Carmen Rubio Alarcon***[2], Vincent Pappalardo[2], Ingrid Franken[3], Steven L. C. Ketelaars[2], Renske de Wit[4], Soufyan Lakbir[4], Marcos da Silva[2], Geraldine R. Vink[5], Gerrit A. Meijer[2], Mark Sausen[6], Renee Menezes[2], Jeanine M. L. Roodhart[2], Sanne Abeln[7], Remond J. A. Fijneman[2]

[1]Netherlands Cancer Institute / University Hospital Heidelberg, Amsterdam / Heidelberg, Netherlands,[2]Netherlands Cancer Institute, Amsterdam, Netherlands,[3]University Medical Center Utrecht / Utrecht University, Utrecht, Netherlands,[4]Netherlands Cancer Institute / Vrije Universiteit Amsterdam, Amsterdam, Netherlands,[5]University Medical Center Utrecht / Utrecht University / Netherlands Comprehensive Cancer Organisation, Utrecht, Netherlands,[6]Labcorp, Baltimore, MD,[7]Vrije Universiteit Amsterdam / Utrecht University, Amsterdam / Utrecht, Netherlands

Introduction: Circulating tumor DNA (ctDNA) detection in liquid biopsies has multiple applications in oncology and is becoming part of routine diagnostics. However, the inter-patient variability regarding ctDNA presence and levels in blood hampers the interpretation of ctDNA testing results. A better understanding of the underlying biology of ctDNA shedding could facilitate ctDNA testing implementation, by identifying the patients for whom the test might be informative to guide clinical decisions. This study aims to explore the clinicopathological and molecular characteristics influencing ctDNA shedding in patients with colon cancer.
Methods: Pre-surgery ctDNA levels were measured in 150 stage III colon cancer patients (PLCRC-PROVENC3 cohort) using Labcorp Plasma Detect, a highly sensitive tumor-informed, whole genome sequencing (WGS)-based ctDNA test. Chromosomal instability was assessed via WGS and SNVs using a 505-gene panel (PGDx elio tissue complete). RNA exome sequencing evaluated gene expression and immune cell composition. Features were analyzed independently and integrated using Lasso regression.
Results: High ctDNA levels were associated with large tumor diameter (FDR<0.001), necrosis (FDR = 0.003), angioinvasion (FDR = 0.008), MSI status (FDR = 0.032) and more advanced substages (FDR = 0.004). In the MSS subgroup, genomic analyses showed correlation with more indels (FDR=0.001) and loss of chr10p/chr10q (FDR = 0.018). Transcriptomic analyses revealed association with epithelial-mesenchymal-transition (FDR < 0.001), TNF-alpha signaling (FDR < 0.001), angiogenesis (FDR < 0.001) and higher fraction of cancer-associated fibroblasts (FDR = 0.008) in high shedders, while low shedders showed enrichment in oxidative phosphorylation (FDR < 0.001). Importantly, factors influencing ctDNA shedding independent of tumor diameter included advanced lymph node involvement (FDR = 0.049), necrosis (FDR = 0.066), enrichment in the E2F-Targets (FDR = 0.006), G2M-checkpoint (FDR = 0.005), and Wnt-β- catenin (FDR = 0.022) pathways. Low ctDNA levels were associated with upregulation of KRAS signaling (FDR=0.049) and high expression of CPS1 (FDR < 0.001) and MUC4 (FDR=0.015). Lasso regression identified large tumor diameter and necrosis as the strongest overall predictors of ctDNA levels.
Conclusion: Tumor diameter is the most important feature determining ctDNA levels in blood. High-shedding tumors are larger, show advanced lymph node involvement, necrosis, and activation of proliferation and invasion pathways driving ctDNA release. In contrast, low-shedding tumors are smaller, less aggressive, and metabolically distinct, relying on mitochondrial processes like oxidative phosphorylation. Our findings improve the understanding of the biology behind ctDNA shedding in non-metastatic colon cancer and have the potential to improve patient selection for ctDNA-based clinical decisions.

#3260 Perioperative tumor-informed ctDNA monitoring for minimal residual disease in triple-negative and HER2-positive breast cancer patients.

Yongjun Cha[1], Junghoon Shin[2], Jongseong Ahn[1], Sunghoon Heo[1], Hwang-Phill Kim[1], Duhee Bang[3], Sang-Hyun Song[1], Young-Hyuck Im[2], Ji-Yeon Kim[2], Tae-You Kim[1]

[1]IMBdx, Inc, Seoul, Korea, Republic of,[2]Division of Hematology-Oncology, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea, Republic of,[3]Department of Chemistry, Yonsei University, Seoul, Korea, Republic of

Introduction: Circulating tumor DNA (ctDNA) enables non-invasive monitoring in solid tumors. This study evaluates the prognostic and predictive value of minimal residual disease (MRD) detection using a personalized ctDNA assay during neoadjuvant chemotherapy (NAC) and post-surgical follow-up in triple-negative breast cancer (TNBC) or HER2-positive breast cancer (BC) patients.
Methods: Patients with stage IA-IIIC TNBC or HER2-positive BC scheduled for NAC followed by curative surgery were prospectively enrolled. Peripheral blood samples (20 mL) were collected at three time points: before NAC (P0), perioperatively (pre- or one month post-operatively, P1), and one year post-operatively (P2). The CancerDetect™ assay (IMBdx, Inc.), a tumor-informed MRD test, identified patient-specific mutations (up to 100) through whole exome sequencing (WES) of tumor tissue and peripheral blood mononuclear cells. CtDNA positivity was defined as the presence of more than two tumor-derived mutations in plasma.
Results: Of 145 patients analyzed (68 TNBC, 77 HER2-positive, median age 49 years), stages included stage I (2.1%), stage II (64.1%), and stage III (33.8%). The median number of mutations identified through WES was 59 (range 9-234), higher in TNBC (71 vs. 50, P = 0.002) but not by stage (P = 0.668). Baseline ctDNA positivity (P0) was 86.9% (median 20 mutations; range 0-97), significantly higher in TNBC (100% vs. 75.3%, P < 0.001) and stage III (95.9% vs. 82.3%, P = 0.021).After NAC, ctDNA clearance occurred in 86.5% of P1-positive patients, with overall ctDNA positivity at P1 dropping to 11.7%, slightly higher in TNBC (14.7% vs. 9.1%, P = 0.314). Pathologic complete response (pCR) rates post-NAC were 55.6%, similar across subtypes and stages. P1 positivity tended to be higher in non-pCR patients (15.6% vs. 7.5%, P = 0.202). CtDNA clearance was associated with higher pCR (60.6%) compared to persistent positive (37.5%, P = 0.106) or persistent negative (42.1%, P = 0.207). For TNBC, P1 positivity was associated with non-pCR (22.6% vs. 5.6%, P = 0.070), unlike HER2-positive BC (9.1% for both).At P2, 90.4% were ctDNA-negative, with positivity in 8.2% (6/73; 4 persistent positives, 2 conversions). At 23 months' median follow-up, 5 patients developed distant metastases. Persistent positivity at P0-P1 (23.5% vs. 0.8%, P < 0.001) or P1-P2 (75.0% vs. 0%, P < 0.001) was linked to higher recurrence rates.
Conclusion: The personalized ctDNA assay detected BC effectively and correlated with subtypes and stages. Post-NAC ctDNA monitoring predicted treatment response and recurrence risk. We are planning longer-term follow-up in the enrolled cohort to better validate its power in recurrence prediction.

#3261 Plasma whole-genome sequencing to monitor pancreatic cancer.

Yuanchang Fang[1], Michelle Chan-Seng-Yue[2], Karen Ng[3], Amy Zhang[2], Nguyen Hoang[3], Gun Ho Jang[2], Sabiq Chaudhary[2], Eugenia Flores-Figueroa[3], Daniela Bevacqua[3], Stephanie Ramotar[3], Ayelet Borgida[3], Shawn Hutchinson[3], Anna Dodd[3], Julie Wilson[2], Barbara Grunwald[4], Robert Grant[3], Erica Tsang[3], George Zogopoulos[5], Jennifer Knox[3], Masoom Haider[1], Steven Gallinger[3], Faiyaz Notta[1]

[1]University of Toronto, Toronto, ON, Canada,[2]Ontario Institute for Cancer Research, Toronto, ON, Canada,[3]University Health Network, Toronto, ON, Canada,[4]University Hospital Essen, Essen, Germany,[5]McGill University, Montreal, QC, Canada

Pancreatic ductal adenocarcinoma (PDA) is a highly aggressive disease with a 5-year survival rate of 12%. Patients are typically diagnosed at the metastatic stage due to lack of symptoms and current treatment options do not effectively control the disease. There is an urgent need to develop sensitive strategies to detect PDA at an early stage before it spreads. Characterizing circulating tumor DNA (ctDNA) in plasma is an effective approach to detect and monitor cancer. Typically, cancer genomes contain thousands of mutations, but targeted sequencing approaches only focus on pre-determined diver genes, which largely limits its performance in detecting ctDNA. Whole-genome sequencing (WGS) however, tracks all the tumor mutations simultaneously, and has a higher sensitivity than targeted approaches, especially in low tumor burden samples. In this study, we aim to use plasma WGS to build a liquid biopsy platform for PDA detection and characterization. To date, we have established the largest plasma WGS (20-60x) cohort for PDA which consists of over 200 baseline and longitudinal plasma samples from patients, with additional 45 plasma samples from age-matched healthy individuals. Paired tumor tissue WGS and RNAseq are also available. We have developed and validated a bioinformatics tool to detect cancer mutations in plasma and estimate plasma tumor fraction (TFx) for tumor burden. In the PDA cohort, the median of plasma TFx was 1% with a wide range between statistically undetectable and 70%. Plasma TFx increased with clinical stages, from a median of 0.5% in resectable PDA to 5% in metastatic cases. Plasma TFx was positively correlated with liver metastasis size, but not with the primary pancreatic tumor size. These results suggest that in PDA, metastases are the major site to shed ctDNA, but not the primary tumors. A positive correlation between serum CA19-9 and plasma TFx was found in metastatic but not in resectable PDA. Higher baseline plasma TFx was associated with worse prognosis, which was more evident in the metastatic PDA. Using the paired tumor WGS and RNAseq, we found that higher ctDNA shedding was associated with higher cell cycle, lower immunity and polyploid genomes in the tumors. No difference was found in plasma TFx between Basal-like and Classical PDA subtypes. In summary, the current study provides insights of the interplay between ctDNA dynamics and clinical features in PDA. We aspire to deliver a freely accessible computational platform for cfDNA genomic profiling, PDA early detection and progression monitoring using plasma.

#3262 Whole genome sequencing of ctDNA enables disease monitoring and residual disease detection in head and neck cancer patients.

Shetal A. Patel[1], Melanie Lou[2], Eddie Ho[2], Michelle Harwood[2], Seng Saelee[2], Dinesh Kumar[2], Steven Johnson[1], Siddarth Sheth[1], Jeffrey Blumberg[1], Catherine Lumley[1], Wendell Yarbrough[1], Michael K. Gibson[3], Jessica Bauman[4], Trevor Hackman[1], Jared Weiss[1], Sowmi Utiramerur[2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC,[2]Roche Diagnostics Solutions, Pleasanton, CA,[3]Vanderbilt-Ingram Cancer Center, Nashville, TN,[4]Fox Chase Cancer Center, Philadelphia, PA

Detection of circulating tumor DNA (ctDNA) has clinical value as a non-invasive method for therapeutic response monitoring and detection of minimal residual disease (MRD). In this study, we employed a tumor-informed approach for detecting ctDNA from plasma in a cohort of head and neck cancer (HNSCC) patients with matched sets of FFPE tissue (FFPET), peripheral blood, and plasma samples. Patients with locally advanced HNSCC were treated with induction chemoimmunotherapy, followed by surgical resection, and risk-adapted adjuvant therapy. Plasma was collected pre-treatment, post-induction (on-treatment), and after completion of all treatment (post-treatment). By leveraging whole genome sequencing (WGS), we can overcome the sparsity of ctDNA fragments in low tumor fraction (TF) settings *via* tracking of hundreds to thousands of single nucleotide variants (SNVs). Our approach identifies a patient's unique compendium of tumor-related SNVs from their FFPET sample (after germline subtraction) and tracks this compendium of variants in their plasma samples to detect the presence of ctDNA. Three patients failed quality control criteria and were excluded from further analysis due to the presence of high proportions of C>T:G>A and C>A:G>T variants, known to be FFPE-related and oxidative damage-related artifacts, respectively. Three plasma samples from the post-induction timepoint were also excluded due to insufficient material for sequencing. Post-induction ctDNA was detected in 13 of 22 evaluable samples. Among the ctDNA positive (ctDNA+) post-induction patients, all of them (13/13) had measurable residual tumors on pathologic review, while (2/9) in the ctDNA negative (ctDNA-) group had measurable tumors. For patients with measurable tumors, mean tumor size in the ctDNA+ group (n=13) was 4 cm, while the mean in the ctDNA- group (n=2) was 2.6 cm. Post-treatment ctDNA was detected in 2 of 18 evaluable samples. Among the ctDNA+ post-treatment patients, 100% (2/2) had disease recurrence within 6 months, while disease recurrence was observed in 12.5% (2/16) of the ctDNA- group (occurring 7- and 32-months post-treatment completion). Lastly, we estimated plasma tumor fraction (TF) following Zivran et al (2020). ctDNA+ post-induction samples had a mean TF of 2.4×10^{-4} (n=13; ranging from 2.3×10^{-5} to 1.1×10^{-3}) and ctDNA+ post-treatment samples had an order of magnitude lower mean TF of 5.8×10^{-5} (n=2; ranging from 5.7×10^{-5} to 5.8×10^{-5}) indicating partial molecular response to treatment even in the presence of detectable residual ctDNA. In this albeit small clinical study, our tumor-informed ctDNA assay achieved clinical sensitivity of 87% and 50% at post-induction and post-treatment, respectively, and clinical specificity of 100% at both time points. Our findings underscore the utility of ctDNA as a promising biomarker for disease monitoring in head and neck cancer patients.

#3263 Assessing molecular residual disease via early postoperative plasma circulating tumor DNA for recurrence risk evaluation in non-small cell lung cancer following radical resection.

J. Tang[1], Y. Tian[1], S. Wang[2], Y. Liu[2], M. Chen[1], X. Yang[1], X. Tong[1], M. Wang[1], Y. Zhao[1], J. Pang[2], Q. Ou[2], **H. Tang**[2], X. Chen[1]; [1]The First Affiliated Hospital of Kunming Medical University, Kunming, China, [2]Nanjing Geneseeq Technology Inc., Nanjing, China

Background: The significant risk of tumor relapse in resectable non-small cell lung cancer (NSCLC) highlights the need for biomarkers to identify patients at increased risk of recurrence and inform personalized treatment. Investigating the potential of plasma-derived circulating tumor DNA (ctDNA) for molecular residual disease (MRD) detection and prognosis is essential, particularly in the context of lung cancer risk variations. Xuanwei, a city in Yunnan province, China, provides a valuable model for exploring molecular features related to lung cancer susceptibility.

Methods: This study included 226 stage I-III NSCLC patients who received radical tumor resection. Paired surgical tumor and postoperative plasma samples within 3-7 days (median: 4.5 days, interquartile range: 4.0-6.0 days) were analyzed to evaluate post-surgical ctDNA detection and its association with disease-free survival (DFS) and overall survival (OS) using a tumor-informed method.

Results: Among the 226 patients with surgically resectable NSCLC, 31 were from the Xuanwei region, exhibiting a higher incidence of multifocal lesions (P<0.01) and elevated tumor mutation burden (P<0.001). Subgroup analysis revealed that Xuanwei patients had a higher prevalence of uncommon *EGFR* mutations (P<0.001 and P<0.01 for p.G719X and p.S768I, respectively), as well as mutations in oncogenes and tumor suppressor genes, including *KRAS* (P<0.001), *LRP1B* (P<0.01), *MED12* (P<0.01), and *PIK3CA* (P=0.03). Detectable ctDNA demonstrated high specificity for predicting tumor relapse (0.96; 95% confidence interval [CI]: 0.92-0.98), with specificity increased to 0.97 (95% CI: 0.94-0.99) in stage I patients and 0.73 (95% CI: 0.39-0.94) in stage II-III patients. While sensitivity was relatively lower, it still reached 0.67 (95% CI: 0.49-0.81) in the overall population, with 0.38 (95% CI: 0.14-0.68) for stage I and 0.83 (95% CI: 0.61-0.95) for stage II-III patients. Multivariate Cox regression analysis, incorporating clinical and mutational features with a mutation frequency of ≥ 5%, revealed that post-surgical MRD status was significantly associated with DFS independent of clinical stage and *RB1* variants, and served as the most significant predictor among all these clinicopathological risk factors (hazard ratio [HR]: 9.25; 95% CI: 3.57-24.00; P<0.001). Detectable ctDNA also effectively stratified OS in subgroups, including patients above 60 years of age and those with stage II-III disease.

Conclusions: Our findings reinforce the clinical significance of evaluating ctDNA status within one-week post-surgery for detecting MRD, thereby informing precise individualized treatment and surveillance strategies for NSCLC patients.

#3264 Digital profiling of tumor-derived extracellular vesicle RNA: a novel approach for early diagnosis and monitoring of pancreatic cancer patients.

Taewon Son[1], Hyojin Um[2], Yeochan Kim[2], Elizabeth Maria Clarissa[1], Hanna Kim[3], Jihye Ahn[2], Juhee Park[1], Beomhee Ahn Ahn[2], Kyusang Lee[3], Song Cheol Kim[4], **Beomseok Lee**[3], Yoon-Kyoung Cho[1]

[1]Biomedical Engineering, UNIST, Ulsan, Korea, Republic of,[2]LS Research Institue, LabSpinner, Inc, Ulsan, Korea, Republic of,[3]ExoDiscovery Research Institue, ExoDiscovery LLC, Cedar Park, TX,[4]Department of Hepatobiliary and Pancreatic Surgery, Asan Medical Center, Seoul, Korea, Republic of

Introduction: Pancreatic cancer remains a leading cause of cancer-related deaths due to challenges in early diagnosis and the lack of effective biomarkers. Current diagnostic methods are insufficient, necessitating novel approaches. This study explores the use of extracellular vesicle RNA (EV-RNA) from plasma as a diagnostic tool, leveraging a new assay that facilitates membrane fusion between EVs and liposomes.
Methods: The study introduces a digital EV-RNA profiling assay (LiquiDyne) that uses charge-mediated fusion between extracellular vesicles and charged liposomes (CLIPs) carrying molecular beacons. This process occurs on a droplet microfluidic chip, where the surface charge of CLIPs is adjusted to optimize fusion efficiency. The assay was validated analytically using EVs from pancreatic cancer cell lines (MIA-PaCa-2, PANC-1, PSN-1, Capan-2) with known KRAS mutations (G12C, G12D, G12R, G12V). Clinical validation involved testing retrospective patient samples across all stages of pancreatic cancer.
Results: The assay requires only 20 µL of plasma, removing the need for prior EV isolation or RNA preparation and thus minimizing sample loss. It successfully detected KRAS mutations in both cell lines and patient samples with high accuracy, demonstrating its potential as a reliable diagnostic tool.
Conclusions: This innovative assay offers a promising method for early pancreatic cancer diagnosis by enabling precise quantification of rare EV subpopulations. It holds potential not only for diagnosis but also for monitoring minimal residual disease, thus addressing critical gaps in current pancreatic cancer diagnostics.

#3265 5-methylcytosine and 5-hydroxymethylcytosine are synergistic biomarkers for early detection of colorectal cancer.

Fabio Puddu[1], Annelie Johansson[1], Aurelie Modat[1], Jamie Scotcher[1], Riccha Sethi[1], Nicholas J. Harding[1], Mark S. Hill[1], Ermira Lleshi[1], Casper K. Lumby[1], Jean Teyssandier[1], Michael J. Wilson[2], Robert Crawford[1], Tom Charlesworth[1], Robert J. Osborne[1], Shankar Balasubramanian[3], **Paidi Creed**[1]

[1]biomodal, Cambridge, United Kingdom,[2]Princeton University, Princeton, NJ,[3]Yusuf Hamied Department of Chemistry, University of Cambridge, Cambridge, United Kingdom

Early cancer detection has the potential to significantly improve treatment outcomes and survival rates. Epigenetic biomarkers in cell-free DNA, including DNA methylation, have been shown to differentiate between cancer and non-cancer and are already being integrated into liquid biopsy development programs. Traditional DNA methylation sequencing provides a conflated modified Cytosine (modC) readout, measuring CpGs that are 5-methylcytosine (5mC) or 5-hydroxymethylcytosine (5hmC) but not discriminating between the two states. Dynamic DNA demethylation occurs through TET enzyme activity, with conversion of 5mC to 5hmC preceding eventual loss of methylation. Hence, we hypothesized that obtaining separate measurements of 5mC and 5hmC would improve the ability to detect the development of colorectal cancer at the earliest stage.

We have therefore applied a technology which provides the 6-base genome (the complete genetic sequence whilst simultaneously distinguishing 5mC and 5hmC) from low nanogram input quantities of cfDNA. We generated whole genome 6-base data from cfDNA extracted from plasma of 32 healthy volunteers and 37 patients with colorectal cancer (CRC) at stages I and IV. We used machine learning approaches to build classifiers with features based on modC, 5mC alone, 5hmC alone, and both 5mC and 5hmC, to differentiate between cfDNA from patients with cancer and individuals without cancer, as well as between stage I CRC and Stage IV CRC.

Our findings indicate that using features based separate measurements of 5mC and 5hmC significantly enhances diagnostic accuracy for the detection of stage I CRC (AUC = 0.95) compared to traditional approaches that conflate these markers (modified C, AUC = 0.66). Notably, most regions with an increase in 5hmC in stage I CRC cfDNA also decreased in 5mC in stage IV CRC, suggesting that 5hmC can effectively track regions undergoing demethylation during tumor development. These results support the hypothesis that distinguishing between 5mC and 5hmC can improve the sensitivity of liquid biopsy tests for early cancer detection.

We feel there is merit in applying 6-base sequencing to larger clinical cohorts, across different indications, to more broadly evaluate the potential of 6-base data to improve the earlier detection, diagnosis, and treatment of disease.

CLINICAL RESEARCH: Modifiers of the Tumor Microenvironment
Poster Session

#3269 LRRC15/COL11A1$^+$cancer-associated fibroblasts drive immunosuppression and chemotherapy resistance in pancreatic ductal adenocarcinoma.

Juanfei Peng[1], Kristina Althoff[1], Sven-Thorsten Liffers[1], Luay Farah[1], Marija Trajkovic-Arsic[1], Rui Fang[1], Savvatakis Konstantinos[1], Jan Mengeler[1], Stefan Selbert[2], Doron Shmerling[2], Phyllis Fung-Yi Cheung[1], Jens T. Siveke[1]

[1]Bridge Institute of Experimental Tumor Therapy, West German Cancer Center, Essen University Hospital, Essen, Germany,[2]PolyGene AG, Rumlang, Switzerland

Background and Objectives: Pancreatic ductal adenocarcinoma (PDAC) is characterized by a highly immunosuppressive tumor microenvironment (TME), which contributes to immune evasion, chemotherapy resistance, and poor prognosis. Cancer-associated fibroblasts (CAFs) are key components of the TME and are closely associated with tumor progression. This study investigated the role of LRRC15/COL11A1$^+$ CAFs in shaping the TME, mediating immunosuppression, and driving chemotherapy resistance in PDAC.
Methods and Results: Using single-cell transcriptomic analysis, we identified a CAF subset with co-expression of LRRC15 and COL11A1, which was significantly associated with reduced CD8$^+$ T cell infiltration and increased infiltration of MARCO$^+$ macrophages. These LRRC15/COL11A1$^+$ CAFs were enriched in chemotherapy non-responsive groups and exhibited higher activity in modulating the immune microenvironment by secreting soluble factors such as TGF-β, GAS6, GRN, EGF, VEGF, and CXCL12, which interact with myeloid cells and T cells. To study the temporal dynamics of LRRC15/COL11A1$^+$ CAFs during chemotherapy, we established ultrasound-guided orthotopic PDAC models in mice and administered FIRINOX-based chemotherapy. Serial tumor biopsies were collected from the same tumor before treatment and one and two weeks post-treatment, and at treatment endpoint. Transcriptomic analysis of sequential biopsy samples using ClusterGVis revealed downregulation of various immune response-related pathways (e.g., T-cell receptor signaling, natural killer cell-mediated cytotoxicity, and allograft rejection) after chemotherapy. In contrast, immunosuppressive cytokines including CCL12, CCL2, CCL9, CXCL12, CXCR1, CXCR4, CCR2, CCR5, and IL10, were all significantly upregulated. Additionally, marker genes of LRRC15/COL11A1$^+$ CAFs were also upregulated, recapitulating findings in chemotherapy-treated PDAC patients. We found high correlation of COL11A1 with LRRC15. Multiplex immunofluorescence of the biopsy tissues showed an increase in COL11A1$^+$ CAFs after chemotherapy, which was accompanied by reductions in CD8$^+$ and CD4$^+$ T cell infiltration, and increase in MARCO$^+$ macrophage infiltration. Using a new genetic mouse model we observed an increase in CD8$^+$ T cell infiltration upon diphteria toxin-mediated targeted genetic ablation of COL11A1$^+$ CAFs.
Conclusions: LRRC15/COL11A1$^+$ CAFs reshape the TME by immunosuppression and contribute to chemotherapy resistance in PDAC. Targeting LRRC15/COL11A1$^+$ CAFs may represent a potential strategy to enhance immune responses and improve the efficacy of chemotherapy of PDAC.

#3270 Modulating the tumor microenvironment and boosting T cell immunity with smart enzyme-loaded virus-like particles.
Orikeda Trashi, Jeremiah Gassensmith

UT Dallas, Richardson, TX

Virus-like particles (VLPs) are biomaterials engineered to structurally and functionally mimic viruses without carrying viral genetic material, making them non-infectious. These icosahedral structures, composed of coat proteins, offer a versatile platform for chemical and genetic modifications. In this project, we modify VLPs with receptors targeting the overexpressed Platelet-Derived Growth Factor Receptor Beta (PDGFRβ) in cancers such as lung, liver, and colorectal cancers, enabling precise tumor targeting. Additionally, we address the metabolic challenges posed by the Warburg effect, which leads to lactate accumulation, acidifying the tumor microenvironment and impairing T cell function. To counteract this, we encapsulate lactate oxidase (LOX) and catalase (CAT) within VLPs. LOX reduces lactate levels by converting it to pyruvate and hydrogen peroxide (H_2O_2), while CAT mitigates excess H_2O_2, alleviating oxidative stress and hypoxia. Together, these enzymes reprogram the tumor microenvironment, enhance anti-tumor immunity, and suppress tumor progression. This innovative strategy combines targeted tumor delivery and immune activation, positioning enzyme-loaded VLPs as a promising platform for next-generation cancer therapies.

#3271 Targeted cancer therapy using a novel recombinant il-24s/il-15 chimeric fusion cytokine.

Amit Kumar, Padmanabhan Mannangatti, Swadesh K. Das, Paul B. Fisher

Virginia Commonwealth University, Richmond, VA

Melanoma Differentiation Associated Gene-7/Interleukin-24 (IL-24) and IL-15 provide therapeutic benefit in treating specific cancers. IL-24 displays cancer-specific apoptosis/toxic autophagy-inducing properties in a broad spectrum of human tumors without harming normal cells. IL-15 induces both differentiation and proliferation of T lymphocyte (T) and natural killer (NK) cells, enhances the cytolytic activity of CD8+ T cells, and induces the maturation of dendritic cells (DCs). *In vivo* administration of IL-15 has antitumor effects in several mouse tumor models; however, administration of IL-15 alone is not optimal. Various combination strategies have been explored to increase the efficacy of IL-15 immunotherapy, including coadministration of other cytokines or inhibitory antibodies against immune-suppression molecules. These approaches enhance antitumor responses as compared with IL-15 alone. Using an engineered form of IL-24 (IL-24S; a Superkine) that is secreted more robustly and is more stable, we created a recombinant IL-24S/IL-15 fusion construct in which IL-24S and IL-15 are linked by a flexible linker. This fusion construct was introduced into an adenovirus type 5 for effective delivery and expression. In the present study, we used focused ultrasound (FUS) paired with microbubbles (MB) to deliver the adenoviruses equipped with the IL-24S/IL-15 fusion construct into the mouse brain containing glioblastoma (GBM) and compared the antitumor effect of IL-24S/IL-15 with the individual factors IL-24S and/or IL-15. IL-24S/IL-15 displayed higher antitumor activity and survival benefits than the combination of the individual cytokines in GBM cancer models. There was a significant induction of apoptosis of cancer cells as well as an increase in tumor infiltration of T cells, DCs, Macrophages and NK cells. Antibody neutralization indicates that a primary immune mediator of anticancer activity of FSK is through recruitment and activation of NK cells. However, unlike immunocompetent mice, there was no increase in the survival rate by IL-24S/IL-15 when compared to the IL-24S or IL-15 treated group in SCID mice. Therefore, the increase in the survival rate by IL-24S/IL-15 in immunocompetent mice was achieved through the regulation of the anti-tumor immune response. Global cytokine analyses indicated no changes in inflammatory cytokines during therapy, suggesting that this strategy will be safe. In addition, IL-24S/IL-15 treatment resulted in enhanced GBM cell death vs. the individual cytokines. The antitumor inducing activity of IL-24S/IL-5 is likely due to induction of cancer-specific apoptosis (a function of IL-24S) as well as diverse effects on immune cells (both IL-15 and IL-24S). In summary, IL-24S/IL-15 may provide a new therapeutic reagent to enhance antitumor immunity and treat cancer.

#3273 BTK inhibitors reshape tumor transcriptome and lymph node microenvironment in CLL.

V. M. Rogness, R. Herur, B. Dileep Kumar, C. Gruessner, C. Sun, C. Underbayev, A. Wiestner;
National Institutes of Health, Bethesda, MD

Bruton tyrosine kinase inhibitors (BTKis) have transformed the treatment landscape for patients with chronic lymphocytic leukemia (CLL). BTKis target pathways critical for CLL cell survival and proliferation. We evaluated the effects of BTKis on CLL cell transcriptome and the composition of the tumor microenvironment (TME) in CLL.

Lymph node (LN) biopsies from 65 patients treated with ibrutinib (n=35) collected pre-treatment and at 24 and 72 hours from first dose or acalabrutinib (n=30) collected pre-treatment and after 3 days of treatment at 4, 12, 24, and 36 hours from the last dose of drug were submitted for RNA sequencing. We used gene set enrichment analysis (GSEA) to interrogate activation of signaling pathways and cellular response and quantified the degree of CLL activation using a previously published gene signature derived from single-cell RNA sequencing. Immune cell composition was assessed with CIBERSORT. GSEA highlighted significant downregulation of key CLL-related pathways by BTKis, including MYC, KRAS, HIF-1, NOTCH, NF-κB, and BCR, all with adjusted $p = 0.007$. Consistently, the CLL activation gene signature showed a significant decrease on BTKis ($p = 0.015$). To better understand the timing of decreased activation, we analyzed ibrutinib timepoints separately. Activation score decreased by 23% after 24 hours ($p = 0.24$) and by 87% after 72 hours of ibrutinib ($p = 0.014$). We then investigated the acalabrutinib timepoints: the activation score decreased by 73.7% at 4 hours ($p = 0.013$), 61.7% at 12 hours ($p = 0.016$), 101.6% at 24 hours ($p = 0.056$).

How BTKis affect the LN TME is not well known. The LN TME in CLL differs from normal LNs in several respects, including increased presence of T follicular helper (Tfh) cells, and decreased presence of CD4+ naïve T cells and M0 macrophages. In ibrutinib treated LN biopsies, CIBERSORT identified a significant decrease of Tfh after 72 hours ($p=0.001$) but not after 24 hours, while the proportion of resting CD4 memory T cells increased ($p = 0.003$). LN biopsies taken >72 hours after the start of acalabrutinib revealed significant decreases in Tfh cells ($p = 0.00003$), CD4 memory activated T cells ($p = 0.03$), M0 macrophages ($p = 0.028$), and increases in CD4 naïve T cells ($p = 0.018$), CD4 memory resting T cells ($p = 0.012$), M2 macrophages ($p = 0.03$), and resting mast cells ($p = 0.0097$).

In conclusion, BTKis not only rapidly reduced activating signaling in CLL cells but also significantly altered the composition of the LN TME. The virtually immediate impact on tumor transcriptomes was paralleled by equally rapid if slightly delayed reorganization of the TME. These data suggest that the effects of BTKis spread beyond the immediate drug target and disrupt the tumor-supportive TME.

#3274 Stage-specific deregulation of the Wnt signaling pathway in colorectal cancer among Puerto Rican Hispanics.

Elba V. Caraballo, **Camille Zenon-Melendez**, Josue Perez-Santiago, Sheila Lopez-Acevedo, Marcia R. Cruz-Correa

University of Puerto Rico Comprehensive Cancer Center, San Juan, Puerto Rico

Background: Colorectal cancer (CRC) is a significant global public health concern. It remains one of the leading causes of cancer-related deaths among Puerto Rican Hispanics (PRH), with 60-70% of cases diagnosed at advanced stages (III/IV). This highlights the urgent need for novel diagnostic biomarkers for early-stage CRC detection while monitoring those in advanced stages, which is crucial for understanding progression and guiding therapy. The *Wnt* signaling pathway plays a vital role in cell proliferation, differentiation, apoptosis, and cancer progression. This study aims to identify stage-specific biomarkers linked to the *Wnt* signaling pathway and the molecular mechanisms associated with CRC disease progression.

Methods: A retrospective case-case study was conducted on 30 tissue samples from PRH recruited through the Puerto Rico Familial Colorectal Cancer Registry (PURIFICAR). Transcriptomic analysis was performed in tissue samples from early (n=7) and advanced CRC stages (n=8) compared to their respective adjacent mucosal tissue as controls (adjusted p-value < 0.05). We used R statistical software (package DESeq2) for gene expression analysis between groups stratified by CRC tumor stage. Protein-protein interaction networks were generated using the STRING database to explore functional associations. Specific *Wnt* signaling markers, target genes, and molecular processes associated with each CRC stage will be validated using Quantinova PCR.

Results: Functional interaction networks analysis (≥ 5 genes) revealed 10 *Wnt* signaling-associated genes uniquely deregulated in early-stage CRC and 10 in advanced-stage CRC. Differentially expressed genes in early stages included WNT1, DKK1, and DKK2, while WNT3 was exclusive to advanced stages. Additional *Wnt*-related genes, such as WNT2, WNT7B, and WNT5, were differentially expressed in both early and advanced stages. These findings highlight distinct patterns of *Wnt* signaling pathway involvement across CRC stages.

Conclusion: Differential gene expression analysis of early and advanced CRC stages revealed significant deregulation of *Wnt* signaling pathway genes, emphasizing their potential as stage-specific diagnostic biomarkers and therapeutic targets. Future studies will focus on the modulation of these genes to study the expression and molecular mechanisms that can contribute to CRC disease progression. Understanding these molecular mechanisms is of utmost importance, as it will facilitate the development of more effective, targeted strategies for CRC diagnosis and treatment, improving outcomes for at-risk populations particularly PRH.

#3275 Reprogramming of MDSCs by ST316, a clinical peptide antagonist of b-Catenin/BCL9, enhances anti-tumor immuno- and chemotherapy.

Claudio Scuoppo, Julia Diehl, Ricardo Ramirez, Barry J. Kappel, Abi Vainstein-Haras, Jim A. Rotolo

Sapience Therapeutics, Inc., Tarrytown, NY

Myeloid-derived suppressor cells (MDSCs) are a diverse group of immune cells that play critical roles in mediating immune-suppression. They are often associated with poor responses in various cancer types and represent an attractive target for immunotherapy. Challenges in defining the genetic dependencies of MDSCs have hindered the development of effective therapeutic strategies aimed at targeting them. The Wnt/β-catenin signaling pathway is a key oncogenic driver that has been implicated in immune-exclusion, although additional roles in immune-suppression remain unclear. ST316 is a clinical-stage peptide antagonist of the interaction between β-catenin and its co-activators, BCL9 and BCL9L. Currently, ST316 is being evaluated in a Phase 2 study (NCT05848739) in patients with advanced colorectal cancer (CRC) in combination with standard-of-care agents. We demonstrated in a Phase 1 dose escalation study that ST316 suppresses MDSC expansion in the peripheral blood of treated patients and corroborated these findings in non-clinical CRC murine models. Here, we characterize the role of the Wnt/β-catenin/BCL9 pathway in MDSC programming and investigate the mechanism by which ST316 reduces MDSC expression and immuno-suppressive activity. Transcriptional profiling of MDSCs from tumor-bearing mice indicates that β-catenin and other Wnt pathway components are highly expressed in these cells. Our findings indicate that exposure to ST316 reduces the expression of receptor systems linked to MDSC-mediated T-cell suppression, thereby activating T-cell responses in vivo. In combination studies, ST316 significantly enhances the anti-tumor efficacy of anti-PD-1 immunotherapy and standard-of-care chemotherapies for advanced CRC such as FOLFIRI. Moreover, while anti-PD-1 and FOLFIRI alone each resulted in expansion of immunosuppressive MDSCs, combination with ST316 prevented this expansion. Our results reveal a novel role for Wnt/β-catenin signaling in MDSC biology and demonstrate that ST316 can suppress the increase of therapy-driven MDSCs in vivo. These data suggest that therapeutically targeting the BCL9/β-catenin interaction may be an effective strategy to enhance both chemotherapy and immunotherapy in Wnt-driven tumors that respond poorly to monotherapy.

#3276 Clinical PK, PD and safety analysis of a phase I clinical trial of DT-9081, an EP4R-antagonist, for RP2D determination in patients with advanced solid tumours.

Christophe Le Tourneau[1], Zahra Castel-Ajgal[1], Jean-Pascal Machiels[2], Rachel Galot[2], Nuria Kotecki[3], Christiane Jungels[3], Jean-Pierre Delord[4], Iphigenie Korakis[4], Anne-Laure Blayo[5], Lola Lecru[5], Thibaut Brugat[5], **Stephan Schann**[5], Nathalie Lenne[5], Samira El-Farouk[5], Claire Jouffroy-Zeller[5], Anne Quesnel[5], Carolina Duarte[5], Karim Taamma[5]

[1]Institut Curie, Paris, France,[2]UC Louvain, Woluwe-Saint-Lambert, Belgium,[3]Institut Jules Bordet, Bruxelles, Belgium,[4]IUCT Oncopole, Toulouse, France,[5]Domain Therapeutics, Illkirch, France

Prostaglandin E2 (PGE2) is a lipid known to promote tumor growth and immune evasion through the EP4 receptor (EP4R). DT-9081, a novel EP4R antagonist, is under investigation for its potential to inhibit tumor growth and enhance immune response. Here are presented the preliminary pharmacokinetic (PK), pharmacodynamic (PD) and safety assessments from the dose escalation phase 1 clinical trial (NCT05582850) allowing the determination of the recommended phase 2 dose (RP2D).

This dose-escalation study employed a modified 3+3 design. DT-9081 was administered orally once daily in doses ranging from 25 to 600 mg. Plasma concentrations of DT-9081 were quantified using LC-MS/MS for PK analysis. PD endpoints included changes in immune activation markers as well as blocking of EP4R agonist (TCS2510)-induced cytokine modulation in blood. Safety assessments were based on NCI-CTCAE v5.0 criteria, with adverse events (AEs) recorded by occurrence and severity.Currently, a total of 29 patients treated with DT-9081 over 6 dose levels (25 mg to 600 mg) are available for analysis. Primary cancer sites included head and neck, ovary, kidney, oesophagus, cervix, gall bladder, lung, pancreas, stomach, prostate, thyroid and rectum carcinoma. Overall, DT-9081 was well tolerated at all tested dose levels. MTD was not reached. Treatment-related AEs (TRAEs) were mostly grade 1 or 2. The most frequent TRAEs (n≥5) were diarrhoea, decreased appetite, nausea and abdominal pain across all cohorts. Grade ≥3 TEAEs included diarrhoea and abdominal pain in one participant from the 50 mg cohort. One dose-limiting toxicity (hepatic enzyme increased grade 3) was observed for another participant at the 50 mg cohort.PK data showed linear increases of C_{max} and AUC in a dose-dependent fashion, with suitable exposure to cover the target IC_{50} for 24h with once-daily dosing. Blood PD data demonstrated that DT-9081 was able to prevent the immunosuppressive activity of TCS2510 by restoring IFN-γ and TNF-α secretion at all dose levels, with a maximum reversion observed around 2h post dosing, in line with PK profile (T_{max}). A long-lasting effect until 10h post-dosing was also observed after 15 days of treatment. Analysis of paired biopsies and PBMCs is ongoing to evaluate the impact of DT-9081 on intra-tumoral and peripheral immune response.

DT-9081 was well tolerated and exhibited a linear PK profile and an exposure supportive of once-daily dosing scheme. PD findings demonstrated the EP4R engagement and inhibition induced by DT-9081 across all dose levels tested and were consistent with the PK data. The collective evaluation of the available PK, PD, safety and tolerability data appoints the 600 mg dose as the potential RP2D, upon finalization of the last ongoing cohort at this dose. Additional PD assessments in peripheral blood and paired tumor biopsies will be available in the poster presentation.

#3277 Investigating the link between metabolic reprogramming and immune modulation in tumors: exploring the therapeutic potential of BPM31510.

Maria-D. Nastke[1], Sylwia Stopka[1], Abbas Khojestah[2], Juan J. Aristizabal-Henao[1], Archna Ravi[1], Kaila M. Bennett[1], Niven R. Narain[1], Lawrence Recht[2], Michael A. Kiebish[1], Stephane Gesta[1]

[1]BPGbio Inc., Framingham, MA,[2]Stanford University, Palo Alto, CA

BPM31510, a CoQ10-lipid nanoparticle, has been shown in previous studies to deliver supraphysiological levels of oxidized CoQ10 to tumors, leading to the induction of mitochondrial Reactive Oxygen Species (ROS) and subsequent apoptotic cell death. Since mitochondrial metabolism is crucial for immune cell function, we investigated whether BPM31510 could influence the tumor microenvironment (TME) to influence immune-mediated tumor elimination. In tumor models such as MC38 and PAN02, we have demonstrated that BPM31510 induces cytotoxic T cell infiltration while concurrently reducing tumor-associated macrophages (TAMs). Additionally, in a rat glioblastoma (GBM) model, BPM31510 was found to metabolically reprogram tumors, further suggesting a potential link between immune modulation and metabolic changes within the TME. These findings support the hypothesis that BPM31510's ability to reprogram tumor metabolism and induce T cell infiltration may be interconnected. This dual mechanism positions BPM31510 as a promising therapeutic for enhancing immune responses in 'immunologically cold' tumors, such as GBM and pancreatic cancer. To explore this connection further, we propose focused studies in syngeneic murine models to examine how BPM31510's immune-modulatory and metabolic effects interact within the TME. These studies will involve detailed analysis of both tumor and lymphoid tissues using advanced flow cytometry and TIMSTOF FLEX spatial omics technology. The goal is to investigate how different dosing and scheduling regimens of BPM31510 impact the relationship between tumor metabolism, immune cell phenotype, and immune activity. Ultimately, this study aims to provide new insights into optimizing BPM31510 treatment strategies, potentially enhancing the effectiveness of immune-based therapies for these difficult-to-treat cancers. By understanding how BPM31510 influences both the immune landscape and metabolic reprogramming of tumors, we hope to develop more effective therapeutic approaches for 'cold' tumors like GBM and pancreatic cancer.

#3278 Neoadjuvant EGFR-TKI therapy reshapes tumor immune microenvironment in resectable EGFR-positive non-small cell lung cancer.

Fang Wu[1], Dan Fan[1], Yingzhe Zhang[1], Wenliang Liu[2], Fenglei Yu[2], Wen Hu[2], Yue Zeng[1], Yurong Peng[1], Chunhong Hu[1], Xianling Liu[1], Fang Ma[1], Chao Deng[1], Zhenhua Qiu[1], Shijiao Yao[1], Shuxing Wang[1], Xiaoqiao Lin[1], Aoxi Liang[1], Xinzhu Lin[1], Qian Guan[1], Han Yang[1], Yiyang Li[1]

[1]Department of Oncology, The Second Xiangya Hospital of Central South University, Changsha, China,[2]Department of Thoracic Surgery, The Second Xiangya Hospital of Central South University, Changsha, China

Background: Patients with EGFR-positive non-small cell lung cancer (NSCLC) do not respond as well to immunotherapy as patients without an EGFR mutation. Nevertheless, recent studies indicate that subsequent immunotherapy following EGFR-TKI treatment may be effective in EGFR-positive NSCLC. Given the critical role of the tumor immune microenvironment (TIME) in determining immunotherapy efficacy, understanding the influence of EGFR-TKI on the TIME in NSCLC remains an important yet unresolved area of research.

Methods: Single-cell RNA sequencing (scRNA-seq) was performed to investigate the TIME of NSCLC patients. Post-treatment samples were analyzed from three EGFR-positive NSCLC patients treated with neoadjuvant EGFR-TKI (Neo-TKI) and two EGFR-negative NSCLC patients treated with neoadjuvant immunotherapy (Neo-IO). The scRNA-seq datasets of seven EGFR-positive NSCLC patients undergoing surgery only (TN-TKI) from the National Genomics Data Center (CRA001477, CRA001963) and six EGFR-negative NSCLC patients received surgery only (TN-IO) from the Gene Expression Omnibus (GSE131907) were analyzed to assess the TIME in treatment-naïve conditions.

Results: A total of ~173,000 single cells were sequenced, revealing 6 subpopulations. Compared to TN-TKI samples, Neo-TKI samples showed a higher proportion of T and B cells, whereas the proportion of myeloid cells significantly decreased. Further analysis of T cell composition in Neo-TKI samples revealed a trend towards a higher prevalence of GZMK+CD8+T cells and enrichment of positive regulation of T cell activation pathway. The expression of TLS-associated genes in CD4+ T cells was significantly elevated, along with the upregulation of immune-related pathways, such as B cell activation signaling and IL-17-related signaling, underscoring the immunomodulatory role of EGFR-TKI. Regarding B cell composition, Neo-TKI samples showed a higher proportion of germinal center B cells with an enrichment in positive regulation of B cell signaling pathway compared to TN-TKI samples. Notably, a shift in tumor-associated macrophages from an M2 phenotype to a neutral phenotype was observed in Neo-TKI samples, supporting the notion that EGFR-TKI impacts the immune landscape. Further, we conducted an exploratory analysis comparing the effects of immunotherapy and EGFR-TKI treatment on the TIME. Distinct differences were observed in cellular subpopulation distribution, enriched genes, and activated pathways. Overall, EGFR-TKI therapy appears to have a more pronounced effect on the TIME of patients with NSCLC.

Conclusion: EGFR-TKI therapy alleviated the immunosuppressive TIME of EGFR-positive NSCLC, providing valuable insights for optimizing subsequent immunotherapy strategies in EGFR-positive NSCLC.

#3279 Smoking burden is associated with immunotherapy resistance in extensive stage small cell lung cancer.

Kyle Concannon[1], Benjamin Morris[1], Lixia Diao[1], Moushumi Sahu[2], Whitney Lewis[1], Xiaowen Sun[1], Simon Heeke[1], Bingnan Zhang[1], Hai Tran[1], Lingzhi Hong[1], Waree Rinsurongkawong[1], Minh Nguyen[1], Kang Qin[1], Hui Li[1], Jainjun Zhang[1], Jack Lee[1], Jing Wang[1], Robert Cardnell[1], Carl Gay[1], John Heymach[1], Lauren Byers[1]

[1]The University of Texas MD Anderson Cancer Center, Houston, TX,[2]Joe R. & Teresa Lozano Long School of Medicine, The University of Texas Health Science Center at San Antonio, San Antonio, TX

Small cell lung cancer (SCLC) remains the deadliest histologic lung cancer subtype with a median survival of only ~12 months among patients with extensive stage (ES) disease. SCLC is strongly associated with heavy tobacco use, yet the effect of tobacco use on therapeutic outcomes remains understudied. Recent data from our group showed that the subtype of SCLC with inflammatory gene signatures (SCLC-I) responds better to immunotherapy (IO) than the other subtypes. Given the association between smoking and inflammation, we hypothesized that heavy smoking may correlate with better IO responses and enrichment in the SCLC-I subtype. To investigate this, we evaluate the outcomes of ES-SCLC patients treated at MD Anderson between 2017-2024 (N=521) and compared those who received chemotherapy plus IO (N=263) to those who received chemo alone (N=258). Transcriptional changes were evaluated across different tobacco pack-year cohorts using the GEMINI bulk RNAseq database of MD Anderson SCLC tumors (N=81).

The median overall survival (mOS) for all ES-SCLC patients was 13.3 months. Immunotherapy provided an added 1-month benefit in mOS over chemotherapy alone, extending mOS from 12.1 to 13.1-months (HR=0.88; p=0.21); consistent with historic cohorts. Patients were then stratified by the cohort pack-year median of 40. For patients with ≤ 40 pack-year smoking histories, the addition of IO improved mOS by 3.7-months from 11.5 to 14.3-months (HR=0.74; p=0.03). However, those with >40 pack-year smoking histories demonstrated no benefit from added IO (13.0 to 12.2-months (HR=1.06; p=0.70). Further analysis by pack-year tertiles (0-24, 25-49, 50+) showed mOS benefits of 5.4 months (HR: 0.67, P=0.05), 1.6m (HR:0.91, P=0.62), and 0.7m (HR=1.01, P=0.679) respectively, for chemo plus IO vs chemo alone.

Despite better IO outcomes among patients with 0-40 pack-years, the SCLC-I subtype was underrepresented in the 0-40 pack-year group compared to expectation using the GEMINI RNAseq database (chi-squared 8.2; p=0.04). Tobacco exposure positively correlated with absolute immune cell infiltration by CIBERSORTx (R=0.24; p=0.03), although driven by higher immunosuppressive T cell signatures. Tumors from the 50+ pack-year (upper smoking tertile) group also demonstrated elevated chronic inflammatory GSEA signatures and genes associated with microenvironment immune suppression compared to the 0-24 (lower smoking tertile) pack-year group.

The discovery that smoking is linked to immunotherapy resistance in SCLC represents a novel contribution to our understanding of the disease and its treatment. By identifying immunosuppressive cellular infiltrates and immunosuppressive gene signatures among patients with heavy vs light smoking histories, we have identified potentially targetable mechanisms of immune evasion. This represents a new lens through which to study immunotherapy resistance in SCLC.

#3280 Type I IFN receptor signaling in myeloid and T cells drives antitumor immunity elicited by intratumoral delivery of immunogenic recombinant modified vaccinia virus Ankara.

Yueqi Wang[1], Shanza Baseer Tariq[1], Ning Yang[1], Shuaitong Liu[1], Bharath Salla[1], Zeda Zhang[1], Juan Yan[1], Weiyi Wang[1], Yi Wang[1], Gregory Mazo[1], Juan Angelo-Lozano[2], Jiahu Wang[3], Tuo Zhang[4], Jenny Zhaoying Xiang[4], Juan C. Osorio[2], Jeffrey V. Ravetch[2], Ming O. Li[1], Ping Chi[1], Scott W. Lowe[1], Charles M. Rice[2], **Liang Deng**[1]

[1]Memorial Sloan Kettering Cancer Center, New York, NY,[2]The Rockefeller University, New York, NY,[3]Genvira Biosciences, Ottawa, ON, Canada,[4]Weill Cornell Medical College, New York, NY

Type I interferons (IFNs) are critical in mediating antitumoral and antiviral responses. However, the roles of IFN and IFNAR signaling within the tumor microenvironment remain poorly understood. To address this, we utilized a Cre-loxP system to generate IFNAR1 conditional knockout mice, enabling us to dissect the role of IFNAR signaling in innate and adaptive immune cells during antitumor responses elicited by immune-stimulating vaccinia viruses. Our first-generation virus, MQ710, was developed by deleting *E5R*, which encodes a cGAS inhibitor, from the non-replicative modified vaccinia virus Ankara (MVA) and incorporating transgenes for membrane-bound Flt3L and OX40L. MQ710 has shown promising early results in a Phase I clinical trial for solid tumors. Building on this platform, the second-generation virus, MQ833, was engineered by deleting two additional viral immunosuppressive genes (*E3L* and *WR199*) and introducing extracellular matrix-anchored murine interleukin-12 (IL-12) as the third transgene. MQ833 was found to be more effective than its oncolytic vaccinia counterpart, OV-IL12, expressing the same transgenes in various tumor models, including murine ovarian cancer. The third-generation virus, MQ954, incorporated further modifications to MQ833, including deletion of *C12L* and insertion of human granulocyte colony-stimulating factor, G-CSF, also anchored to the extracellular matrix. Intratumoral (IT) administration of MQ954 elicited more potent antitumor effects than MQ833 in preclinical models of malignant peripheral nerve sheath tumor (MPNST) and bladder cancer. Using $Irf3^{-/-}Irf7^{-/-}$ and $Stat2^{-/-}$ mice, we found that type I IFN production and signaling are critical for the antitumor effects induced by these viruses. We evaluated the efficacy of MQ833 and MQ954 in $Lyz^{cre}Ifnar1^{fl/fl}$, $Fcgr^{cre}Ifnar1^{fl/fl}$, $MRP8^{cre}Ifnar1^{fl/fl}$, $Foxp3^{cre}Ifnar1^{fl/fl}$, and $CD4^{cre}Ifnar1^{fl/fl}$ mice, in which Ifnar1 gene is depleted exclusively in myeloid cells, monocytes/macrophages, neutrophils, and regulatory T cells, respectively, and compared with $Ifnar1^{fl/fl}$ controls. Our findings revealed that IFNAR signaling in myeloid cells, regulatory T cells (Tregs), and CD4/CD8 T cells is essential for the observed antitumor effects. Single-cell RNA sequencing of CD45+ cells isolated from MB49 tumors from conditional knock-out mice and controls treated with MQ954 twice three days apart further highlighted the pivotal role of type I IFN signaling in monocyte recruitment, macrophage and neutrophil activation and the differentiation of stem-like T cells into effector T cells. This study underscores the multifaceted role of type I IFN signaling across diverse immune cell types in the context of virus-based cancer immunotherapy and provides valuable insights into the intricate immune mechanisms driving antitumor responses.

#3281 CRISPR activation of endogenous STING as an innovative strategy for targeted immunotherapy.

Emil L. Lauridsen, Stine H. Godsk, Anders Etzerodt, Martin R. Jakobsen

Biomedicine, Aarhus University, Aarhus, Denmark

Background: Stimulator of Interferon Genes (STING) has long been of interest within the field of cancer immunology, as the cyclic GMP-AMP synthase (cGAS)-STING pathway can drive inflammation in the tumor microenvironment through the sensing of cytosolic DNA and production of 2'3'-cGAMP. Importantly, in cancer cells with high levels of chromosomal instability (CIN), we and others have observed selective suppression of STING expression, which we hypothesize benefit cancer cells to avoid activating an immune response and to promote immune escape.

Method: The murine triple-negative breast cancer model 4T1, which presents with CIN was explored. We conducted both *in vitro* and *in vivo* experiments to characterize cGAS-STING pathway signaling in response to exo- as well as endogenous DNA stimulation. Utilizing a CRISPR-dCas9 activation (CRISPRa) approach we selectively regulated STING expression in cancer cells and evaluated immune responsiveness *in vitro*. The anti-tumoral effect of activating the cGAS-STING signaling cascade was tested *in vivo* using aEpCAM-labelled lipid-nanoparticles (LNPs) for delivering mRNA to support selective uptake in 4T1 cells.

Results: Initially, 4T1 cellswere found to have low STING expression, in conjunction with high levels of micronuclei and cGAS activity, supporting endogenous accumulation of 2'3'-cGAMP. Using CRISRPa of STING, we observed a rapid cGAS dependent type-I interferon and inflammatory cytokine response correlating with STING expression in a time-dependent manner. Using EpCAM-targeted LNPs we enabled specific mRNA delivery to 4T1 cells *in vitro* and *in vivo*. Our current efforts focus on exploring the *in vivo* anti-tumoral effects of this STING-targeting immunotherapy which will be presented at AACR.

Conclusion: Our data reveal that reestablishing endogenous STING expression in cancer cells that exhibit elevated CIN, may result in an anti-tumoral inflammatory response. We believe that the altered immune profile determined by STING reactivation presents a therapeutic potential to promote tumor regression. Using this specifically targeted LNP-mRNA system, this type of epigenetic regulation may become a cornerstone of future personalized cancer therapies in addition to traditional immunotherapy.

#3282 Versican abundance/proteolysis as a biomarker for immunotherapy efficacy in intestinal cancers.

Elizabeth L. Field[1], Sean Kraus[1], Madeleine Buratti[1], Heidi Koehnke[1], Cheri A. Pasch[1], Fotis Asimakopoulos[2], Dustin A. Deming[1]

[1]University of Wisconsin-Madison, Madison, WI,[2]University of California San Diego, San Diego, CA

Background: The composition of the tumor microenvironment (TME) can regulate T cell infiltration and potentially immunotherapy efficacy. Versican (VCAN), an extracellular matrix proteoglycan, regulates the presence of tumor infiltrating lymphocytes (TILs) and their activation, while its proteolytic byproduct, versikine (Vkine), can stimulate an immune response. Here we aim to validate our prior findings that VCAN status correlates with CD8+ T cell infiltration in intestinal cancers and evaluate the predictive role of VCAN/Vkine for patients undergoing immunotherapy for microsatellite instability high (MSI-H) cancers.
Methods: A total of 28 consented subjects were identified with intestinal cancers that were MSI-H, high tumor mutation burden, or with alterations in mismatch repair genes as part of an IRB-approved protocol. Baseline characteristics, immunotherapy response, and survival data were collected. Cancer samples were obtained and stained for VCAN, Vkine, and CD8+ TILs. An intensity binning system was used to score VCAN and Vkine, ranging from 0-3. TILs were averaged across high power fields (HPF). Cancers with high VCAN (2-3) and any Vkine were categorized as VCAN proteolytic weak (VPW), cancers with low VCAN (0-1) and high Vkine (2-3) as VCAN proteolytic predominant (VPP), and cancers with both low VCAN (0-1) and low Vkine (0-1) as VCAN/Vkine low (VVL).
Results: Clinical characteristics of the 28 subjects studied: median age 62.5 years (32-90); 17 females; 19 colon cancers; six rectal cancers; one rectosigmoid cancer and two small intestinal cancers. Further, nineteen were stage 3, nine were stage 4 and 71% were MSI-H. Six were VVL, one was VPP and 21 were VPW. The VVL and VPP cancers had a median of 27 CD8+ TILs/HPF, while the VPW cohort had a median of 15.7 (p=0015). CD8+ TILs in the MSI-H VPW subset trended higher than the microsatellite stable VPW cancers (21.7 versus 8.5; p=0.35). Thirteen subjects with MSI-H cancers received immunotherapy (10 pembrolizumab (PEMBRO), three ipilimumab (IPI) and nivolumab (NIVO)). Of these cancers, six were VPW and completed PEMBRO. None of the VPW cancers achieved a complete response to PEMBRO alone with most developing progressive disease. An additional VPW subject is still receiving therapy with a partial response to PEMBRO to date. Two patients with VPW cancers received IPI and NIVO and had complete responses. The four subjects with VVL or VPP cancers have all achieved a complete response and are alive without cancer recurrence. Three were treated with PEMBRO and one with IPI and NIVO.
Conclusion: The VCAN status in the TME of intestinal cancers shows promise as a biomarker for T cell infiltration and response to immune checkpoint blockade. The ability of VCAN status to identify patients who are more likely to benefit from dual immune checkpoint blockade deserves further investigation.

#3283 RNAi mediated silencing of *STAT3 or PD-L1* in tumor-associated immune cells induces robust anti-tumor effects in immunotherapy resistant tumors.

Shanthi Ganesh[1], Minju KIm[1], Jenny Lee[1], Xudong Feng[1], Harini Krishnan[1], Amber Beaudry[2], Jennifer A. Lockridge[2], John Hanrahan[2], Sam Moskowitz[2], Vinita Uttamsingh[2]

[1]Pharmacology, Novo Nordisk, Lexington, MA,[2]Early Development, Novo Nordisk, Lexington, MA

Most refractory malignant solid tumors create an immunosuppressive tumor microenvironment (TME), rendering them resistant to standard-of-care immune checkpoint inhibitors (CPIs). We investigated the feasibility of applying systemically delivered RNAi agent to silence the mRNA of a historically undruggable target, that involved in mediating immune suppression in TME, directly in tumor-associated immune cells. In preclinical rodent tumor models, GalXC-Plus^{TM} conjugates selectively silenced the *Stat3* mRNA in multiple relevant cell types, reduced the protein levels, and increased cytotoxic T-cell infiltration. In immunotherapy resistant tumors, RNAi-mediated silencing resulted in tumor growth inhibition, which was further enhanced in combination with CPIs. We also demonstrated that silencing *Cd274* (PD-L1) in antigen-presenting cells using another GalXC-Plus^{TM} conjugate was effective in treating tumors that are resistant to PD-L1 antibody therapy. Currently, both human active STAT3 and PDL1 conjugates are in Phase 1 clinical trials for treating immunotherapy-refractory cancer types (NCT06098651, NCT06504368).

#3284 Dual blockade of EGFR and TGF-B with ficerafusp alfa has the potential to overcome resistance mechanisms in 1L R/M HNSCC in combination with pembrolizumab.

Brenda C. O'Connell[1], Shiv R. Krishn[2], Pradip Nair[2], John Kaczmar[3], Christine H. Chung[4], Dan Zandberg[5], Debora J. Wong[6], David Raben[1], Rachel Salazar[1]

[1]Bicara Therapeutics Inc., Boston, MA,[2]Syngene International Limited, Bengaluru, India,[3]Medical University of South Carolina, Hollings Cancer Center, Charleston, SC,[4]Moffitt Cancer Center, Tampa, FL,[5]UPMC Hillman Cancer Center, Pittsburgh, PA,[6]UCLA Medical Center, Los Angeles, CA

Objective: Resistance mechanisms, such as epithelial-mesenchymal transition (EMT) and hypoxia diminish the efficacy of standard treatments in head and neck squamous cell carcinoma (HNSCC), including anti-EGFR and anti-PD-1 therapies. TGF-β is a cytokine involved in these resistance pathways, promoting a mesenchymal tumor phenotype through EMT. TGF-β-expressing cancer-associated fibroblasts (CAFs) are associated with T cell exclusion and resistance to anti-PD-1/PD-L1, while EMT is linked to anti-EGFR resistance. Ficerafusp alfa, a bifunctional antibody targeting EGFR and TGF-β in the tumor microenvironment (TME), showed clinical activity in a Phase 1b study for 1L R/M HNSCC (NCT04429542), particularly among HPV-negative (neg) patients (IJROBP 2024). Analysis of paired biopsies from HPV-neg tumors highlight the effects of ficerafusp alfa in combination with pembrolizumab (P).
Methods: Paired tumor biopsies collected from the Ph1b 1L R/M HNSCC cohort (NCT04429542) were analyzed by immunohistochemistry for pSMAD2 and CD8 and for gene expression within regions of the TME by whole genome spatial transcriptomics. Cytokine analysis was performed on pre- and post-treatment plasma samples.
Results: Data from paired tumor biopsies demonstrated inhibition of TGF-β signaling within tumor cells and an increase in CD8+ T-cell infiltration (n=7), including in HPV-negative tumors with low PD-L1 (CPS 1-19). Spatial transcriptomics revealed down-regulation of genes and pathways associated with drug resistance including hypoxia and EMT in both tumor and stromal regions (n=8). Up-regulation of immune activation pathways such as interferon-gamma and interferon-alpha was also observed in both tumor and stromal regions. Plasma analyses revealed complete neutralization of TGF-β1 (0.5% of pre-dose at day 21; p<.0001) and increased pro-inflammatory cytokines CXCL9, CXCL10 and IFNG (p<.01) with the ficerafusp alfa combination (n=24).
Conclusion: Down-regulation of hypoxia and EMT pathways in both tumor and stromal regions with ficerafusp alfa and P treatment supports the potential role of TGF-β inhibition in preventing the mesenchymal phenotype associated with drug resistance. These findings provide proof of concept that ficerafusp alfa effectively blocks TGF-β signaling in both tumor cells and tumor supporting stromal cells. Association of translational findings with clinical data will be presented. This supports the rationale for combining ficerafusp alfa with P in HPV-negative R/M HNSCC and potentially in other settings where anti-EGFR and anti-PD-1 drug resistance is a factor.

#3285 Targeting interactions between tumor-associated macrophages and tumor cells to enhance chemotherapy response in a resection model of triple-negative breast cancer.

M. E. Fernandez[1], Y. Alshehry[1], R. R. Aldaqqa[1], H. D. Bear[2], D. H. Sweet[1], S. R. P. da Rocha[1];

[1]Virginia Commonwealth University - VCU, Richmond, VA, [2]Massey Comprehensive Cancer Center, Virginia Commonwealth University, Richmond, VA

Triple-negative breast cancer (TNBC) is the most lethal breast cancer subtype and lacks targeted treatment options. While immune checkpoint blockade leads to significant benefits when combined with chemotherapy, recurrence, metastasis, and chemoresistance remain major challenges. The purpose of this study was to assess the ability of a colony-stimulating factor 1 receptor inhibitor (CSF-1Ri) and an anti-CD47 (aCD47) monoclonal antibody to remodel the tumor microenvironment (TME) in a murine resection model of TNBC, and the benefit of such priming when administered with chemotherapy. We focused on targeting tumor-associated macrophages (TAMs) as they are the most abundant immune cell in the TME and are associated with worse metastasis free survival (MFS) and overall survival (OS). Targeting TAMs, specifically M2-like TAMs, has been shown to delay recurrence and prolong MFS and OS. We also sought to block the CD47-SIRPα interaction between TNBC cells and TAMs, because TNBC cells have higher levels of CD47 expression compared to other breast cancer subtypes, and high rates of CD47 expression are associated with worse MFS and OS and higher cancer stemness. We selected pexidartinib (PLX) as CSF-1Ri given its translational potential (FDA approved) and gemcitabine (GEM) as chemotherapy, given its immunomodulatory effects. To recapitulate the clinical setting, we utilized a survival resection model, allowing us to administer neoadjuvant and adjuvant therapy, and track the development of metastases. BALB/c mice were injected with 100,000 4T1 mammary carcinoma cells in the flank, and tumors established over the course of six days. Mice were then exposed to daily administrations of PLX (8 mg/kg), every other day administration of aCD47 (8 mg/kg) and weekly administrations of GEM (60 mg/kg). The primary tumor was resected on day thirteen and mice were then exposed to adjuvant therapy using the dosing regimen outlined previously. The TME of the resected tumors was characterized by flow cytometry, and MFS and OS were recorded over a ninety-day period. Both PLX+GEM and aCD47+GEM significantly reduced total TAMs (39% and 40% reduction, respectively). However, Only PLX+GEM significantly shifted the M1:M2 ratio towards the pro-inflammatory M1-like phenotype. Both combinations led to a significant prolongation of MFS and OS compared to GEM therapy alone. Triple therapy (PLX+GEM+aCD47) led to the most significant depletion of TAMs (62% reduction compared to vehicle), and a favorable M1:M2 shift, while reducing cancer stem cells and increasing dendritic cells. Triple therapy also had the greatest prolongation of MFS and OS (prolonged by 30% and 31% compared to GEM, respectively). Thus, the therapeutics investigated led to a remodeling of the TNBC TME towards a favorable phenotype, leading to enhanced chemotherapy efficacy and prolonged survival.

#3286 Targeting ALKBH5 to enhance the anti-tumor immunity of natural killer cells.

Yuan Che, Tingting Tang, Zunsong Hu, Chao Shen, Zhenhua Chen, Wei Li, Kitty Wang, Lillian Sau, Ying Qing, Dong Wu, Keith Leung, Zhaoxu Xu, Xiaolan Deng, Jianjun Chen

Department of Systems Biology and Center for RAN Biology and Therapeutics, Beckman Research Institute of City of Hope, Duarte, CA

Natural killer (NK) cell-based immunotherapy is emerging to be a promising strategy to treat cancers due to its high safety profile. Compared with traditional chimeric antigen receptor (CAR) T therapy, NK cell-based therapy has much lower side effects such as cytokine release syndrome (CRS) or neurotoxicity. However, the limited persistence and lower levels of infiltration to the tumor microenvironment has impeded the outcomes for NK cell-based clinical trials. How to genetically engineer NK cells to a better priming activation state has yet to be explored. Here, we identify ALKBH5, a well-established RNA N6-methyladenosine (m^6A) demethylase, as a key regulator that restricts NK cells cytotoxicity. Xenograft model studies using B16F10 and MC38 tumor cells demonstrated that tumor progression was dramatically inhibited upon Alkbh5 knockout ($Alkbh5^{-/-}$) in the recipient mice. Single-cell RNA sequencing (scRNA-seq) revealed the enriched abundance of NK cells among tumor-infiltrating lymphocytes in $Alkbh5^{-/-}$ mice. Also, NK cells extracted from $Alkbh5^{-/-}$ spleen are hyperactivated, exhibiting enhanced cytotoxic function and proliferation rate, facilitating robust tumor suppression. Using MeRIP-seq, RIP-seq and lipid metabolomics, we demonstrated that Alkbh5 deficiency in NK cells reprogramed lipid metabolism pathway, enhancing the conjugation rate between NK cells and tumor cells. This increased synapse formation leaded to elevated release of perforin and granzyme, further improving NK cell killing capacity. Based on these findings, we genetically reprogrammed NK cells by conjugating anti-NK1.1 antibodies to lipid nanoparticles (LNPs) embedding Alkbh5-targeting oligonucleotides. Using the in vivo LNPs target delivery system, we want to explore whether this NK-based immunotherapy could inhibit tumor growth/progression in mice. Altogether, our findings uncover a previously unrecognized role for ALKBH5 in regulating NK cell cytotoxicity and proliferation, providing a new therapeutic strategy by targeting ALKBH5 in NK cell-based immunotherapies for solid tumors.

#3287 TOX modulates methionine availability and enhances CD8$^+$ T cell anti-tumor function in colorectal cancer.

Yujie Chang, Zhao Hui

Shanghai Jiao Tong University Affiliated Sixth People's Hospital, Shanghai, China

Colorectal cancers (CRC) with high TOX expression exhibit greater infiltration of CD8$^+$ T cells, which display stronger tumor-killing capacity. This study investigates the metabolic mechanisms underlying the role of TOX in shaping the tumor microenvironment (TME) and its impact on CD8$^+$ T cell function. Using LC-MS/MS metabolomics, we found that methionine and its metabolites are enriched in the TME of TOX-high CRC tumors. Further analysis revealed that TOX-high tumor cells express lower levels of the methionine transporter SLC43A2, reducing their methionine uptake. This methionine pool supports CD8$^+$ T cell cytotoxicity and decreases apoptosis. In TOX-low tumors, we tested intratumoral methionine supplementation to assess its effect on tumor growth and CD8$^+$ T cell activity. Supplementing methionine in TOX-low CRC tumors led to a significant reduction in tumor size and an increase in the proportion and activity of infiltrating CD8$^+$ T cells. These results indicate that TOX modulates methionine metabolism by downregulating SLC43A2 in tumor cells, reducing competition with CD8$^+$ T cells and enhancing their anti-tumor function. Our findings highlight TOX as a critical regulator of tumor metabolism and immune cell function, with potential as a therapeutic target for both immunotherapy and metabolic intervention strategies in CRC.

#3288 Wildtype IDH1 blockade as a strategy to modulate the tumor microenvironment and boost immune responses in pancreatic cancer.

Priyashree Sunita[1], Soubhi Tahhan[1], Mehrdad Zarei[1], Christina S. Boutros[1], Omid hajjihassani[1], Hallie J Graor[1], Faith Nakazzi[1], Parnian Naji[1], Claudia Marcela Diaz[2], Jordan M Winter[1]

[1]Case Comprehensive Cancer Centre, Department of Surgery, Case Western Reserve University, Cleveland, OH,[2]Department of immunology, Cleveland Clinic, Cleveland, OH

Pancreatic ductal adenocarcinoma (PDAC) is an aggressive malignancy characterized by a dense tumor stroma and a five-year survival rate of less than 13%. Its poor prognosis arises from rapid progression, early metastasis, and resistance to therapy. Despite, advancements in chemotherapy and immunotherapy, outcomes remain dismal, largely due to the immunosuppressive tumor microenvironment (TME). Previous work in our lab demonstrated the efficacy of ivosidenib, an FDA-approved inhibitor of mutant isocitrate dehydrogenase 1 (IDH1), also inhibits wild-type IDH1(wtIDH1) under conditions mimicking the PDAC TME. Here we show that targeting wtIDH1 suppresses cancer cell proliferation by inducing apoptosis, increasing reactive oxygen species (ROS) levels, and enhancing antitumor immune responses by reducing immunosuppressive immune cell populations. In vitro studies were conducted using Miapaca-2, Panc-1 and KPC cell lines. Cells were cultured in low glucose (2.5mM) and low magnesium (0.08mM) media to mimic the TME. Cell viability was assessed using Titer-Glow, Pico Green and colony formation assays. Cellular and mitochondrial ROS levels were determined via DCFDA and Mito-SOX assays using colorimetric and flow cytometry analysis. The therapeutic potential of ivosidenib, was evaluated through cell proliferation (Cell Trace assay), cell cycle arrest (BrdU) assay via flow cytometry and immunofluorescence, and apoptosis detection (Annexin-V/PI staining). In vivo studies employed orthotopic and autochthonous murine models of PDAC to assess drug efficacy and its impact on immune cell infiltration in the TME. Our data revealed that targeting wtIDH1 suppress cell proliferation and DNA synthesis and elevated cellular and mitochondrial ROS levels leading to increased apoptosis. In orthotropic pancreatic murine models of pancreatic cancer, ivosidenib treatment significantly increased the infiltration of immune cells ($CD45^+$), and $CD4^+$ T cells in particular, including naïve T (CD45RA) and central memory T cells (CD45RO). Additionally CD127 expression was enhanced, promoting the survival and proliferation of naïve and memory T cells, potentially boosting anti-tumor immunity. Notably, treatment led to reduction of anti-inflammatory M2-like monocytes and adaptive immunity associated $CD8^+$T cells, suggesting reshaped immune landscape favoring antitumor responses. Wild-type IDH1 plays a critical role in tumorigenesis and chemoresistance in pancreatic cancer. Our data demonstrates that IDH1 inhibition not only reduces cancer cell proliferation in vitro but also
remodels the TME in in vivo, enhancing immune responsiveness. Modulation of the TME via IDH1 inhibition offers a promising avenue to improve efficacy of existing therapies, including chemotherapy and immune checkpoint inhibitors as a part of combination treatment strategies.

#3289 Radiation supports the polarization of M1 macrophages against triple-negative breast cancer cells via the IKZF1 - CCL5 axis.

Kuo Han-Hsi, Yu-Chan Chang

National Yang Ming Chiao Tung University, Taipei, Taiwan

Triple-negative breast cancer (TNBC), known for its therapeutic challenges and high metastatic potential, is commonly treated with ionizing radiation (IR). In the tumor microenvironment (TME) of TNBC, macrophages occupy a place and are reprogrammed into two main types, M1 and M2, in response to different stimuli such as IR or various cytokines. However, the detailed molecular mechanism remains to be elucidated. Using our cell model, we applied IR dose-dependently (0.5/8 Gy) to observe macrophage polarization and found that high-dose IR could increase the proportion of M1 macrophages. These trends are consistent with polarization by LPS (M1) and IL-4/IL-13 (M2), respectively. By integrating transcriptomics and cytokine array profiling, we demonstrated that IKAROS family zinc finger 1 (IKZF1), a transcription factor involved in DNA repair, downregulates secretion of the downstream target, CCL5, in macrophages under high-dose IR exposure. In the collected conditioned medium, the high-dose IR group could significantly inhibit the migration and proliferation of TNBC cells. Even, recombinant CCL5 protein was recruited to modulate the TME of TNBC, and the migration ability of TNBC cells was reversed. In the direct co-culture system, phagocytic event was enhanced by high-dose IR. In conclusion, under high-dose irradiation conditions, IKZF1 is inhibited and CCL5 secretion is reduced. The TME environment is conducive to polarization of the M1 subtype and enhances its ability to phagocytose TNBC cells, thereby inhibiting TNBC progression. This finding suggests that the benefits of radiotherapy in TNBC may also be linked to a new chapter in immunotherapy.

#3290 Targeting CREB reprograms the tumor immune microenvironment and enhances immunotherapy efficacy in smoking-associated pancreatic cancer.

Varunkumar Krishnamoorthy, Siddharth Mehra, Sudhakar Jinka, Haleh Amirian, Edmond Box, Chen Zheng, Jashodeep Datta, Nipun Merchant, Nagaraj Nagathihalli

Department of Surgery, University of Miami Miller School of Medicine, Sylvester Comprehensive Cancer Center, Miami, FL

Background: Smoking, a major risk factor for pancreatic cancer, significantly attenuates the survival benefits of standard therapies, contributing to poor clinical outcomes in this malignancy. Previously, we have identified that hyperactivation of cyclic AMP response element-binding protein (CREB) as driver of immunosuppressive tumor immune microenvironment (TME), which limits the therapeutic potential of immune checkpoint blockade (ICB) therapies. The present study explores the therapeutic strategy of targeting CREB to overcome TME associated immunosuppression and to enhance the efficacy ICB in smoking associated preclinical models of pancreatic cancer.

Methods: An *in vivo* smoking model was developed using syngeneic orthotopic tumor implantation in C57BL/6 mice and genetically engineered mouse model (GEMM) of pancreatic cancer, including *Creb* deleted ($Creb^{fl/fl}$, CREBcKO) $LSL\text{-}Kras^{G12D/+}$; $Trp53^{R172H/+}$; $Pdx1^{Cre/+}$ (KPC) mice. CRISPR/Cas9 technology was used to generate *Creb* knockout ($Creb^{KO}$) in KPC tumor cells, which were orthotopically implanted into the pancreata of C57BL/6 mice. Mice with established tumors were randomized and treated with CREB inhibitor (CREBi, 666-15) alone or in combination with anti-PD-1 monoclonal antibody. This combination therapy was further evaluated in $Ptf1a^{Cre/+}$; $LSL\text{-}Kras^{G12D/+}$;$Tgfbr2^{flox/flox}$ (PKT) GEMM. Multiplex immunophenotyping was performed on harvested tumors to assess immune subsets changes, along with histological analyses including H&E, immunohistochemistry (IHC) and Sirius red staining.

Results: Smoking-exposed KPC GEMM mice showed accelerated PDAC progression, characterized by increased high-grade PanIN lesions and an enhanced fibroinflammatory TME. CREB deletion (CREBcKO) significantly attenuated these effects, highlighting its role in smoking-induced tumorigenesis. Genetic ablation or pharmacological inhibition of CREB using 666-15 attenuated the immunosuppressive TME, promoted effector $CD4^+$ and $CD8^+$ T cell infiltration with elevated PD-1 expression on T cells. In combination with anti-PD-1 therapy, CREB inhibition enhanced the anti-tumor benefits in both PKT GEMMs and in KPC orthotopic models. Similarly, $Creb^{KO}$ tumor cells implanted in smoke-exposed C57BL/6 mice showed significant tumor suppression and modulates TME, with or without anti-PD-1 therapy.

Conclusions: This study demonstrates the therapeutic advantage of targeting CREB to reprogram the stromal immune microenvironment and improve the efficacy of immunotherapy in preclinical models of smoking-associated pancreatic cancer. These findings provide a strong rationale of integrating CREB inhibition into immunotherapeutic strategies for pancreatic cancer, particularly in high-risk smoking populations.

#3291 Development of anti-B7H3 CAR T cells for treatment of osteosarcoma in a canine model.

Theresa Higgins, Payal Agarwal

Auburn University, Auburn, AL

Characterized as a highly aggressive and metastatic solid bone tumor, osteosarcoma (OS) remains a difficult to treat cancer. Even with the current treatment options of chemotherapy, radiation, and tumor removal surgery there is poor patient prognosis and low survival rates, highlighting the need for novel treatments. Over the last decade, chimeric antigen receptor (CAR) T cells have shown promising results in the treatment of certain leukemias and lymphomas and are further being explored in solid tumor types. We aim to develop CAR T cells against the immune checkpoint cell surface receptor B7H3 (anti-B7H3 CAR T cells), which is over expressed in several cancers, including OS. We hypothesize that anti-B7H3 CAR T cells will be able to successfully lyse osteosarcoma in a canine model. We have verified that B7H3 is expressed and demonstrates significant antibody binding in four canine OS cell lines (D17, CF11, MCKOS, and D22). We have successfully isolated and activated T cells by incubating in CD3 and CD28 coated plates. We will transduce active T cells with anti-B7H3 encoding lentivirus. The cytotoxic effects of anti-B7H3 CAR T cells will be explored in both two-dimensional (2D) and three-dimensional (3D) cell cultures. Additionally, IFNγ, TNFα, and IL-2 cytokine levels will be measured and analyzed. We expect cell lysis and increased cytokine levels post-CAR T therapy in our canine OS cell lines.

#3292 Unraveling molecular mechanisms underlying the awakening of dormant melanomas.

Ianca R. Dias[1], Debora K. Alves-Fernandes[1], Lih Hongtao[2], Frank J. Slack[3], Gangning Liang[2], **Miriam G. Jasiulionis**[1]

[1]Pharmacology, Federal University of Sao Paulo (UNIFESP), Sao Paulo, Brazil,[2]Urology, University of Southern California, Los Angeles, CA,[3]Pathology, Harvard Medical School, Boston, MA

Tumor recurrence, which can occur many years after therapeutic intervention, represents the main challenge in clinical oncology. Clinically, this period between the "cure" of the primary tumor and its local or distal metastatic relapse is known as the "dormancy state." Tumor dormancy has been linked to therapeutic resistance and a high metastatic potential of malignant neoplasms. During tumor immunoediting, the immune response shapes the tumor to adapt and thrive within an immunocompetent host. Epigenetic modulation is an important way by which cells can quickly regulate gene expression and respond to environmental pressures. Another way of rapid modulation can be through regulatory RNAs, such as lncRNAs which can interact at the level of transcription and translation of other molecules, such as protein-coding genes, and regulate gene expression. To better understand the molecular basis of this tumor dormancy and awakening, we established a murine immune-mediated model of awakening of dormant melanoma cells. In this model, a large number of apoptotic cells are used to generate an acute inflammation process in C57BL/6 mice that promotes a permissive environment for a sub-tumorigenic dose of viable metastatic melanoma cells grown into a fully formed tumor, that would not be formed otherwise. Our study shows that the sub-tumorigenic dose of viable cells only generates tumors in immunosuppressed (NSG) mice (100% of animals), indicating that in immunocompetent animals, the primary defense system - T and B lymphocytes, and NK cells - appears to contain it. Considering the role of epigenetic modulation in rapid cell response to the pressure of the environment, we also show that treatment with the global demethylating agent 5-aza-2'-deoxycytidine causes delay and reduction of tumor mainly through immune activation. This suggests the need for future investigations regarding the epigenetic machinery in our model. Thereby, genome-wide DNA methylome analysis was conducted (EPICarray), and differential gene expression (RNA-seq) analysis of tumors from animals treated (or not) with the demethylating agent. Differentially expressed genes are being selected for further *in vitro* and *in vivo* studies. To elucidate this model, we are carrying on assays to understand the role of acute inflammation in the awakening of melanoma dormancy by analyzing the inflammatory profile of the defense system using flow cytometry meanwhile we are conducting other *in vivo* experiments to better characterize our model. Now, we investigated lncRNAs that are differentially expressed in tumors of animals treated with that drug aiming for new potential biomarkers, or regulators of important immune-response protein-coding genes. All *in vivo* data were statistically validated using the Student's t-test. We aim to discover potential therapeutic targets with a functional role in the immune-mediated progression of melanoma. Supported by CNPq, CAPES, FAPESP

#3293 Exploiting PEGylation of CCN5 for tumor immunity and therapy of triple-negative breast cancer: A new and effective approach for TNBC therapy.

Sunil P. Upadhyay[1], Axel H. Breier[2], Inamul Haque[2], Archana De[2], Snigdha Banerjee[3], Mohiuddin Quadir[4], Sushanta K. Banerjee[5]

[1]Cancer Research Unit, Kansas City VA Medical Center, Kansas City, MO,[2]Kansas City VA Medical Center, Kansas City, MO,[3]Pathology and cancer Research unit, University of Kansas Medical Center and Kansas City VA Medical Center, Kansas City, MO,[4]Coatings and Polymeric Materials, North Dakota State University, Fargo, ND,[5]University of Kansas Medical Center, Kansas City, MO

Triple-negative breast cancer (TNBC) is defined by a lack of expressions of three receptors. These include estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor rector 2 (HER2). TNBC accounts for ~15-17% of all breast cancers (BC) and is the most aggressive subtype of metastatic BC. TNBC incidence is high among BRCA1 mutation carriers, women with the age of 50 or below, and African American descent. The therapeutic opportunities for TNBC are limited to chemotherapy as targeted options are deficient, resulting in elevated risk of recurrence and mortality risk. Over the last five years, new strategies for treating TNBC have transformed significantly by introducing PD-1/PD-L1-immune checkpoint inhibitors (ICIs) and others. However, only eighteen-20% of PD-L1 positive TNBC patients with metastasis respond to ICIs with or without chemotherapy and enhance the antitumor response of therapeutic CD8+ T cells. The low overall response rate of ICIs in TNBC patients is due to insufficient PD-L1/PD-1 interaction blockade. Consequently, an unmet need exists to revolutionize treatment regimens by replacing or modifying them with ones that are more effective and less toxic. Previous studies demonstrate that CCN5 (also known as WISP-2), which is family of cellular communication Network (CCN) factors, is considered a tumor suppressor and anti-invasive protein as it promotes the growth arrest and progression of TNBC cells. Our previous studies showed that recombinant CCN5 (hrCCN5) therapy is weak for systemic delivery due to poor bioavailability. Thus, only intratumoral injection of CCN5 was considered and found effective with no toxicity in animal studies, but this is not an ideal therapeutic strategy for progressive BC therapy. To overcome this limitation, we implemented the protein PEGylation/PEG conjugation technique that increased the bioavailability and activities of CCN5 and reverses tumor growth and metastasis and increases prolonged overall survival in an MDA-MB-231tumor xenograft model. Further, we found that ^{PEG}CCN5 significantly increased CD8+ T cells decreased myeloid infiltration and PD-L1 expression in tumor cells. Thus, we consider ^{PEG}CCN5 can emerge as a new, beneficial immunotherapeutic drug for TNBC treatment alone or in combination with αPD-1, chemotherapy, or both.

#3294 Subtype-specific genetic drivers of immune evasion in breast cancer.

Otilia Menyhart, **Balazs Gyorffy**

Semmelweis University, Budapest, Hungary

Introduction: Immune evasion is a hallmark of cancer and a significant driver of therapeutic resistance. While immunotherapy has shown promise in highly immunogenic cancers, its efficacy in breast cancer (BC) remains limited, particularly in less immunogenic subtypes. We aimed to investigate the prognostic relevance of two immune-related gene signatures—106 genes associated with evasion of immune destruction (EID) and 182 genes linked to evasion of killing by cytotoxic T lymphocytes (ECTL)—across distinct BC subtypes.

Methods: Transcriptomic and clinical data from three integrated datasets (GEO, n=1,965; TCGA, n=1,069; and GSE96058, n=2,976) were analyzed. Expression of immune evasion-related genes was stratified by BC subtype using PAM50 classification. Survival analysis was conducted using Kaplan-Meier curves and Cox regression models, stratifying gene expression into high- and low-expression groups. A False Discovery Rate (FDR) correction was applied to ensure statistical robustness. Subtype-specific survival associations were further evaluated with individual gene-level analyses.

Results: High mean expression of the ECTL signature was significantly associated with improved overall survival (OS) in triple-negative BC (TNBC) patients (HR = 0.25, 95% CI = 0.16-0.4, p = 8.6e−10, FDR < 1%). Similar trends were observed in HER2-enriched BC but were less pronounced after FDR correction. For the 106 EID genes, high mean expression correlated with favorable OS in TNBC (HR = 0.3, 95% CI = 0.18-0.49, p = 3.4e−7). Gene-level analysis identified essential immune evasion genes, including *CXCL10*, *CXCL9*, *CXCR4*, and *JAK3*, as robust predictors of survival in TNBC, validated across independent datasets. The new, combined four-gene signature showed significant predictive power for response to immune checkpoint inhibitors (ICI), with an AUC of 0.722 (p = 1.3e−7).

Conclusions: Immune evasion-related gene signatures exhibit subtype-specific prognostic value, particularly in TNBC and HER2-enriched BC. A signature based on genes within these signatures represent potential biomarkers for predicting survival outcomes and guiding immunotherapy.

#3298 LRP12 promotes triple-negative breast cancer metastasis via recruiting the activation of β-catenin and PI3K/AKT signaling pathways.

Kung-Ju Chen, Yuan-Feng Lin

Graduate Institute of Clinical Medicine, College of Medicine, Taipei Medical University, Taipei, Taiwan

Background: Triple-negative breast cancer (TNBC) metastasis is the major cause of failure in TNBC therapy. The challenges in treating TNBC may stem from their heightened cellular plasticity, and characterized by significant heterogeneity at the molecular level. As a result, understanding the molecular mechanism for TNBC metastasis is urgently needed for the precise management of TNBC clinically. Low-density lipoprotein receptor-related proteins (LRPs) are the multifunctional transmembrane proteins involved in receptor endocytosis and signal transduction and associated with tumor progression. The aim of this study was made to delineate the role of LRP12 in the metastatic progression of TNBC.
Methods: The transcriptional profile of normal tissues and primary tumors derived from TNBC patients obtained from The Cancer Genome Atlas (TCGA) database was used to examine the expression of LRPs. Kaplan-Meier analysis was performed to estimate the prognostic significance of LPRs. Trans-well migration and lung colony-forming assays were established to evaluate the metastatic potentials of TNBC cell variants. RNA-sequencing was employed to generate differentially expressed genes (DEGs) followed by the prediction of possibly activated pathways by pathway enrichment analysis after LRP12 knockdown in the tested TNBC cells. Cycloheximide-chased assay was used to measure the degradation of β-catenin in response to LRP12 knockdown in TNBC cells.
Results: Transcriptional profiling and Kaplan-Meier analysis demonstrated that LRP12 upregulation is commonly found in primary tumors compared the normal adjacent tissues and highly associates with the poor prognosis in TNBC patients. LRP12 knockdown predominantly suppressed the cellular migration and lung colony-forming abilities. Pathway enrichment analysis against DEG result from RNA-sequencing indicated that LRP12 knockdown dramatically suppresses the activity of β-catenin and PI3K/AKT signaling pathways in Hs578T cells. Western
blot analysis conformed that LRP12 knockdown predominantly reduced the phosphorylated/active β-catenin and PI3K/AKT protein in Hs578T cells. Cycloheximide-chased assay further showed that LRP12 knockdown significantly accelerates the protein degradation of β-catenin in Hs578T cells.
Conclusion: These findings highlight the potential role of LRP12 as a prognostic biomarker but also a therapeutic target in metastatic TNBC.

#3299 Anti-FRα antibody-drug conjugate luveltamab tazevibulin for the treatment of FRα-expressing non-small cell lung cancer.

Robert Yuan, Andrew McGeehan, Sihong Zhou, Mark Armanini, Jennifer Smith, Millicent Embry, Rhoneil Pena, Danielle K. Lewis, Krishna Bajjuri, Cuong Tran, Gang Yin, Xiaofan Li, Hanspeter Gerber, Alice Yam, Helena Kiefel, **Genevive Hernandez**

Sutro Biopharma, Inc., South San Francisco, CA

Luveltamab tazevibulin (luvelta; STRO-002) is a novel antibody-drug conjugate (ADC) designed to target folate receptor alpha (FRα)-positive cancers across a broad range of expression levels. It is composed of an anti-FRα antibody conjugated to a tubulin-directed hemiasterlin payload via a protease-cleavable linker. The linker-payload is site-specifically conjugated via non-natural amino acids incorporated into the antibody sequence using Sutro's Xpress CF+® system, yielding a homogenous ADC with a drug-antibody ratio of four (DAR4). Preliminary results from Phase 1 and 2/3 studies in endometrial and ovarian cancer, respectively, show robust clinical activity and enhanced tolerability of luvelta as a single agent and in combination with bevacizumab. Here, we report preclinical data to support therapeutic targeting of advanced non-small cell lung cancer (NSCLC), for which there remains an unmet medical need, with luvelta.

IHC staining of NSCLC patient tumor microarrays shows a prevalence of 48% and 14% FRα-positive tumors in non-squamous and squamous NSCLC tumors, respectively, as defined by ≥1% tumor cells with FRα membrane staining at any intensity. In NSCLC patient-derived xenograft (PDX) models, luvelta treatment resulted in robust tumor growth inhibition, with best responses strongly correlating with FRα levels. The majority of PDX models evaluated were EGFR wild type, but responses were also observed in some EGFR mutant models.

An existing standard-of-care option for NSCLC is immunotherapy. ADCs and chemotherapeutic drugs have been shown to promote an inflamed tumor environment by triggering immunogenic cell death (ICD), which can synergize with immune checkpoint blockade. We provide evidence that luvelta is a potent inducer of ICD. In *in vitro* assays, luvelta induced all three hallmarks of ICD: HMGB1 release, ATP release, and surface expression of calreticulin. Furthermore, in *in vivo* vaccination studies, injection of luvelta-treated tumor cells established protective immunity against subsequent tumor challenge. Consistent with ICD induction, luvelta treatment in combination with anti-PD-1 or anti-PD-L1 immune checkpoint inhibitors resulted in enhanced *in vivo* efficacy in syngeneic mouse tumor models. Luvelta treatment in tumor-bearing mice also altered tumor immune cell infiltration and activation, demonstrating its ability to modulate the tumor immune microenvironment.

In conclusion, the work presented here provides support for luvelta as a promising targeted therapy for NSCLC, either as monotherapy or in combination with immune checkpoint blockade. Luvelta is now being evaluated in a Phase 2 study in patients with advanced or metastatic NSCLC (NCT06555263).

#3300 A longitudinal, circulating tumor molecular response biomarker as a predictor of clinical outcomes in a real-world cohort of patients with advanced solid tumors treated with tyrosine kinase inhibitors.

John Guittar[1], Akash Mitra[1], Rossin Erbe[1], Shannon Mulmat[1], Michelle Stein[1], Xifeng Wang[1], Seung Won Hyun[1], Chithra Sangli[1], Halla Nimeiri[1], Rotem Ben-Shachar[1], Wade T. Iams[2], Charu Aggarwal[3]

[1]Tempus AI, Inc., Chicago, IL,[2]Tennessee Oncology, Nashville, TN,[3]University of Pennsylvania, Philadelpha, PA

Studies have shown that early changes in quantitative measures of circulating tumor DNA (ctDNA) in response to immunotherapy can predict clinical outcomes and may be useful for identifying molecular responders (MRs) and molecular non-responders (nMRs) who may benefit from a change in therapy. Yet few studies have evaluated treatment with tyrosine kinase inhibitors (TKis).

The cohort consisted of deidentified patients from the Tempus clinicogenomic database with stage IV solid tumors who underwent ctDNA NGS. Patients who had a pre-treatment baseline liquid biopsy (T0) and a longitudinal sample 21-180 days after initiating TKi therapy (T1) were included. TKis were classified by the Tempus Medical Ontology, which was validated using the NCI Metathesaurus TKi concept (NCI Code C1967). xM for treatment response monitoring estimates tumor fraction (TF) via an ensemble algorithm that incorporates pathogenic variant allele frequencies, copy number information, and germline information. Evaluable patients had at least one blood sample with a TF ≥ limit of blank of 0.09%. MR was quantified as a ≥ 50% decrease in TF from T0 to T1. Patients with consistently low TF < 1% at both T0 and T1 were also classified as MRs given previous data demonstrating that baseline low TF is correlated with prolonged clinical outcomes. All other patients were classified as nMRs.

Real-world overall survival (rwOS) was defined from T1 to death or last known clinical record in event-free patients. Stratified Cox proportional hazards models were used to estimate the hazard ratio (HR) for MR status (MR vs. nMR), stratified by line of therapy (LOT, first line, 1L vs. ≥ second-line, 2L+). A 1-sided Wald test was conducted using a 5% significance level. Predicted rwOS estimates were obtained from the Cox models.

The evaluable cohort consisted of 109 patients (1L=62, 57%, 2L+=47, 43%). Cancer types included non-small cell lung cancer (NSCLC, n=52, 48%), breast cancer (BC, n=35, 32%), and 10 other cancer types each comprising < 5% of the patient cohort. The most common therapies were osimertinib in NSCLC patients (n=34) and alpelisib + fulvestrant in BC patients (n=11). Median time from the start of TKi therapy to T1 was 93 days and median follow-up was 10.3 months. Sixty patients had MR and 49 patients were classified as nMRs.

MR was significantly associated with longer rwOS than nMRs (HR = 0.45; P = 0.006). Median predicted rwOS among MRs receiving TKis in 1L (n=43) was 28.4 months vs. 16.5 months for nMRs (n = 19). The HR for death between MR vs nMR was consistent across different cancer subgroups and LOT: HR=0.38 for NSCLC patients, HR=0.57 for BC patients, HR=0.46 for 1L patients and HR=0.44 for 2L+ patients.

These data demonstrate that longitudinal molecular treatment response can stratify rw-outcomes to TKi therapy in a heterogeneous, real-world pan cancer cohort.

#3301 A sequential treatment strategy for ex vivo profiling of live tumor fragments that mitigates tumor heterogeneity and tissue scarcity from core needle biopsies to characterize response to immunotherapies.

Christina Scribano[1], Pichet Adstamongkonkul[1], **Sean Caenepeel**[2], Nicholas Dana[1], Jackie Derrick[1], Evan Flietner[1], Hilary Hernan[1], Christin Johnson[1], Nathan Marhefke[1], Payton McDonnell[1], Betsy Mulligan[1], Amreen Nasreen[1], Josh Porter[1], Jordyn Richardson[1], Sidney Schneider[1], Mikaela Schultz[1], Mike Smith[1], Chetan Sood[1], Aishwarya Sunil[1], Lindsey Vedder[1], Ellen Wargowski[1], Hinco Gierman[1], Andreas Friedl[3], Laura Hrycyniak[1], Michael Korrer[1], T.S. Ramasubramanian[1]

[1]Elephas, Madison, WI,[2]Elephas, Thousand Oaks, CA,[3]University of Wisconsin, Madison, WI

Immunotherapies are highly effective treatment options for cancer; yet they do not work in all patients, and current companion diagnostic (CDx) biomarkers do not always align with response. Ex vivo profiling of live tumor samples provides the ability to measure T cell activity in response to treatment and is a potential means of improving response prediction. The limited amount of tumor tissue available from core needle biopsies (CNBs) presents a challenge when split into control and treatment groups for ex vivo profiling, as tumor heterogeneity causes increased variability and sampling errors. Elephas has developed a treatment strategy where control (IgG) and immune checkpoint inhibitor (ICI) treatments are performed sequentially on the same tissue within a single well. Changes in the rate of cytokine secretion are then compared between ICI and IgG treatment to characterize response to therapy. For these experiments, human CNBs (n>150) were collected from diverse tumor types during standard of care diagnostic procedures and sliced using a proprietary cutting instrument. Each biopsy was profiled for response to ICI using a multiplexed cytokine immunoassay. Sequential aliquots of conditioned media were collected from cultured biopsy slices at three time points: ~4 hrs post-encapsulation with a proprietary hydrogel, following ~16 hrs of IgG treatment and following ~28 hrs of treatment with ICI. Cytokine results were assessed for data quality to inform inclusion/exclusion of data points for analysis/algorithm development. CDx biomarker status (PD-L1, MMR/MSI and TMB) for individual biopsies was obtained from medical records. Our results show live tumor fragments, obtained from resections where tumor tissue amount was sufficient to address inter-well heterogeneity, exhibit comparable cytokine response profiles when stimulated with CD3/CD28 at experiment start vs. following 20 hrs of IgG treatment. An algorithm to define ex vivo response to ICI treatment in CNBs was then developed using tissue viability measurements and treatment-induced changes in cytokines. Response on the Elephas platform was subsequently compared to CDx biomarker status and clinical response from patient medical records. A sequential treatment strategy for the assessment of response to immunotherapy is an effective approach to capture treatment-induced changes in cytokine response. Sequential treatment of CNBs circumvents issues of tumor heterogeneity inherent to cross-well comparison in settings of limited tissue availability. Implementation of this strategy enables the Elephas platform to differentiate potential responder and non-responder CNB specimens to immunotherapy ex vivo.

#3302 Comprehensive analysis of B7-H7/HHLA2 expression in pan-solid tumors and its potential significance in anti-tumor immunity.

Yasmin L. Hashambhoy-Ramsay, Karishma Vekaria, Emilien Loeuillard, Melissa A. W. Hayes, Emma Ya-Ting Wang, Matthew Rausch, Tatiana Novobrantseva, Katalin Kis-Toth, Leena Gandhi

NextPoint Therapeutics, Inc., Cambridge, MA

BACKGROUND: B7-H7/HHLA2 is a B7 family member expressed on select normal epithelium and upregulated in many tumors. B7-H7 suppresses T and NK cell function through an inhibitory receptor, KIR3DL3, and stimulates lymphocyte activation through a distinct receptor, TMIGD2. High levels of B7-H7 expression in tumor cells are frequently associated with poor prognosis and it may represent a novel target for therapeutic interventions. We have previously demonstrated that higher levels of B7-H7 are associated with increased tumor cell killing by a B7-H7-targeting T cell engager. Here, we systematically characterized B7-H7 expression across solid tumor histologies to assess the potential of B7-H7 as a biomarker for use in therapeutic targeting of B7-H7.
METHOD: B7-H7 protein expression was assessed by immunohistochemistry (IHC) using a monoclonal antibody that has been widely used in the literature (566.1). Hundreds of tumors across many indications and select normal tissues were characterized for B7-H7 expression. To develop a B7-H7 IHC assay that could be used for patient selection for B7-H7 targeting therapeutics including NPX887, a monoclonal antibody currently in clinical trials, the performance of 566.1 and a commercially available monoclonal antibody (E1U6X) were compared. Quantitative flow cytometry (qFC) was used to measure the number of molecules per cell across cell lines displaying different levels of B7-H7, and concordance of qFC and IHC measurements by E1U6X was established. To investigate the effects of B7-H7 levels on immunomodulation and cell killing, *in vitro* tumor and immune cell co-culture systems were used.
RESULTS: Tumor cells from colorectal, non-small cell lung, pancreatic, renal and gastric cancer displayed the highest protein levels of B7-H7 and defined patient populations of interest for NPX887. Normal B7-H7 expression was restricted to substructures of intestine and lung and showed only faint cytoplasmic staining in the kidney. There was no detectable B7-H7 expression on any circulating immune cells. During assay development, similar patterns of B7-H7 expression were detected using the two monoclonal antibodies, however the optimized assay using E1U6X displayed superior performance. The levels of B7-H7 expression on tumor samples were comparable to tumor cell lines effectively killed by immune cells in the presence of anti-B7-H7 therapeutic antibodies *in vitro*.
CONCLUSION: We demonstrated that normal tissue expression of B7-H7 is restricted to organ substructures within the intestine, lung, and kidney. We observed significant expression of B7-H7 across tumor cells of varying histologies, highlighting patient populations for B7-H7 targeting therapies. The IHC assay using E1U6X was selected for investigational use in ongoing (NPX887-001; NCT06240728) and potential future clinical studies of therapeutic molecules targeting the B7-H7 axis.

#3303 Standardizing peripheral blood mononuclear cells processing for *ex vivo* evaluations to predict response to immunotherapy.

Katelyn Jansen[1], Farah Sagin[2], Claire Girten[2], Joanna Khoury[2], Tyler Hendrickson[2], Kelsey Dillehay McKillip[2], Dalia El-Gamal[1], Trisha Wise-Draper[1]

[1]Hematology and Oncology, University of Cincinnati College of Medicine, Cincinnati, OH,[2]University of Cincinnati College of Medicine, Cincinnati, OH

In many cancers, including head and neck squamous cell carcinoma (HNSCC), expression of programmed death ligand-1 (PD-L1) is upregulated, which inhibits the anti-tumorigenic immune response of cytotoxic T-cells. Immune checkpoint inhibitors (ICIs) targeting the PD-1/PD-L1 axis has greatly enhanced survival rates in these patients, but many progress and/or relapse due to other immunosuppressive factors. Therefore, predicting patient response to current ICIs and identifying new biomarkers is imperative to advance tailored therapeutics. The current "gold standard" for diagnosing and assessing treatment response and tumor progression is tumor biopsy, however, it is not always feasible, safe, or sufficient for additional molecular testing. While research into alternative methods such as circulating tumor cells (CTCs) are ongoing, these methods are expensive and lack standardization. As a result, our laboratory is investigating a liquid biopsy approach utilizing peripheral blood mononuclear cells (PBMCs) as a surrogate for tumor biopsy, as longitudinal peripheral blood sampling of patients is safe and more readily available in patients before, during, and following treatment. Previous work has demonstrated that preanalytical variables affect PBMC viability and suitability for functional assays. The purpose of our work so far has been to elucidate the optimal collection tube condition and timing of blood processing to standardize the collection and mitigate pre-analytical bias of PBMC processing for downstream critical functional analyses. Peripheral blood samples from eligible HNC patients were collected in EDTA or sodium heparin (SH) tubes and either processed for isolation of PBMCs immediately or at delayed timepoints (8- and 24-hours post-collection) at room temperature (22-30°C) to account for same-day and overnight processing delays. Additionally, the delayed (8 and 24 hour) timepoint samples were diluted 1:1 with sterile PBS immediately following collection and compared to matched undiluted specimens to assess the effects of granulocyte contamination on PBMC viability and functionality following cryopreservation. Functional tests included cytotoxicity assays with patient-derived CD8+ T-cells or NK cells that were co-cultured with HN5 target tumor cells at a 1:5 target to effector cell ratio and stained with 7AAD Viability Solution for flow cytometry analysis. NK or T cell-killed HNC cells are calculated by dividing the percent dead (7AAD-positive) in co-culture and the basal cell death. Preliminary findings suggest that dilution enhances cell recovery but may slightly reduce NK cell cytotoxicity, while the blood collection tube type has no significant influence on recovery or cytotoxicity. Although this research is focused on one solid tumor class, our rigorous approach and findings could be readily expanded to other solid tumors.

#3304 HCAR2 activation limits tumor growth by the activation of p53 signaling in breast cancer.

SONIA BATAN, Nanditi Thangaraju, Jabuneesa Khanom, Kunal Kumar, Snigdha Ganjikunta, Subash Sundaram, Nikhil Patel, Santhakumar Manicassamy, Puttur D. Prasad, Muthusamy Thangaraju

Augusta University, Augusta, GA

Breast cancer (BC) is the most common cause of cancer-related death in women. BC affects ~2.3 million women worldwide, with ~685,000 deaths every year. Therefore, a clear understanding of the molecular mechanism(s) associated with BC formation and the development of more effective therapeutic strategies for the prevention and treatment of this disease are sorely needed. The p53 tumor suppressor protein, encoded by the TP53 gene, prevents multicellular organisms from developing cancer. However, p53 mutations occur in almost all tumors, emphasizing its role as a formidable barrier that must be breached to allow oncogenic transformation. *p53* is the most frequently mutated gene in BC, especially in triple-negative breast cancer (TNBC). Although *p53* mutation has been seen in 18-25% of primary BC, about 80% of TNBC is associated with *p53* mutation or inactivation. p53 is a multi-functional protein that controls the cell cycle, cell proliferation, DNA repair, senescence, and apoptosis, thereby blocking the proliferation of damaged cells and preventing tumor formation. Therefore, the development of therapeutic strategies that will rejuvenate wild-type p53 (*WTp53*) function or target mutant *p53* (*p53α*) should have a high clinical impact on the prevention and treatment of BC. We found that HCAR2 (Hydroxycarboxylic acid receptor 2) or NIACR1 (Niacin receptor 1) or HM74A or GPR109A, a G-protein coupled receptor for the vitamin B3 Niacin (NA), the bacterial fermentation product butyrate (BTR), and the ketone body β-hydroxybutyrate (BHB), activates WTp53 and also destabilizes *p53*α in BC cells. p53 is an NAD^+-dependent molecule, and deficiency of NA, the precursor of NAD^+ and HCAR2 agonist impairs p53 function. NA- and BTR-induced HCAR2 activation can enhance p53 function by decreasing cAMP, thereby attenuating the binding of MDM2 to p53 and the resulting proteasomal degradation and inhibiting SIRT1, a p53 deacetylase. Similarly, BHB, an HCAR2 agonist and the primary ketone body in mammals, potentiates p53 function by increasing p53 acetylation. Further, HCAR2 activation induces cytotoxicity in *p53*α BC cells via inhibition of HSP90-HDAC chaperone, which stabilizes the transcription of p53α in the mammary epithelium**.** Therefore, HCAR2 activation should have a high clinical translational potential for the prevention and treatment of BC by rejuvenating *WTp53* and destabilizing p53α in BC cells. Overall, our study provides preclinical evidence to show the functional implication of ketogenic signaling in the regulation of p53 and its relevance to BC prevention and treatment.

#3305 Notch mutations in subjects with recurrent or metastatic adenoid cystic carcinoma treated with rivoceranib from study RM-202.

Ari Rosenberg[1], James Bugni[2], Lissa Nazal[2], Chris Galloway[2], Kristin Ryan[2]

[1]Department of Medicine, Hematology and Oncology, University of Chicago, Chicago, IL,[2]Elevar Therapeutics, Fort Lee, NJ

Background: Activating *NOTCH* mutations are present in approximately 20% of metastatic adenoid cystic carcinomas (ACC) leading to an aggressive tumor phenotype and poor clinical prognosis, yet less common pathogenic *NOTCH* mutations are poorly characterized. RM-202 was an international, single-arm, open-label phase 2 trial of oral VEGFR-2 tyrosine kinase inhibitor, rivoceranib, in patients with histologically confirmed recurrent or metastatic (R/M) ACC (Hanna *et al.* 2023 Clin Cancer Res 29(22): 4555). Herein, we report the mutational analysis *NOTCH* genes 1-4 *(NOTCH1-4)* in a subset of ACC samples from RM-202.
Methods: Patients (n=72) enrolled in RM-202 received oral rivoceranib 700 mg once daily for a 28-day cycle. The co-primary endpoints were objective response rate (ORR) assessed by both investigator and a blinded independent review committee (BIRC). RNA seq was performed on ACC tumor samples from 27 patients. Complete coding sequences were analyzed with *NOTCH1-4* variants identified and cross-referenced with Tempus and public databases to categorize mutations according to pathogenicity.
Results: The investigator and BIRC assessed objective response rates were 15.3% (95%CI, 7.9-25.7) and 9.7% (95% CI, 4.0-19.0), respectively. The median duration of response was 14.9 months (95% CI, 4.9-17.3) and median progression free survival was 9.0 months (95% CI, 7.3-11.5). Grade 3 treatment related adverse events occurred in 70% of patients, with hypertension (42.5%) and stomatitis (7.5%) being the most common. A total of 477 variants were identified in *NOTCH1-4* from 27 RM-202 ACC tumor samples, of which 463 (97%) mutants had been previously reported by Tempus DNA sequencing of germline and somatic variants across multiple tumor types. Three pathogenic *NOTCH1* mutations (two nonsense mutations and 1 in-frame deletion) were identified across 2 tumor samples. Two of these mutations had not been previously reported in ACC. Forty-five additional non-synonymous variants were identified in *NOTCH1-4*. Of those, *NOTCH4* L16 mutations occurred in 17/27 (63%) of tumors, with 12/27 (44%) tumors harboring L16 deletions, 4/27 (15%) of tumors with L16 duplications, and 1/27 (4%) that had both an L16 deletion and an L16 duplication. The frequency of L16 mutant sequences in tumors ranged from 8%-67% suggesting subclonal variation and potential pathogenicity.
Conclusions: Previously unreported pathogenic *NOTCH1-4* mutations were identified in ACC tumor samples from the RM-202 phase II trial. High rates of *NOTCH4* L16 mutations suggest a novel mechanism of Notch pathway activation in ACC and represents a potential therapeutic target in this rare disease.

#3306 Comprehensive plasma profiling in NSCLC patients undergoing IO- and chemotherapy identifies potential proteomic signatures for progression-free survival.

A. Rigutto[1], S. Schaer[2], P. Shichkova[2], L. Raess[2], A. Viode[2], C. Below[2], R. Bruderer[2], M. Joerger[3], J. Musilova[3], S. Hayoz[3], V. Somasundaram[3], N. Nunez[4], N. Fournier[5], J. Lourenco[5], R. Gottardo[5], B. Becher[4], A. Addeo[6], A. Gupta[1], **Y. Feng**[2], A. Curioni-Fontecedro[7];

[1]University of Fribourg, Fribourg, Switzerland, [2]Biognosys AG, Schlieren, Switzerland, [3]Swiss Group for Clinical Cancer Research (SAKK), Bern, Switzerland, [4]University of Zurich, Zurich, Switzerland, [5]Agora Cancer Research Center, Swiss Institute of Bioinformatics, Lausanne, Switzerland, [6]University Hospital Geneva, Geneva, Switzerland, [7]HFR Hospital Fribourg, Fribourg, Switzerland

In NSCLC, the identification of circulating predictive biomarkers is critical to improve patient selection. Circulating biomarkers have the advantage of accessibility of samples but challenges arise in detecting disease-relevant biomarkers in plasma, where low-abundance circulating analytes are often obscured by highly abundant proteins. This underlines the need for highly sensitive, reproducible assays to detect subtle changes. Therefore, developing a sensitive, reproducible method for biomarker discovery in plasma could significantly enhance clinical outcomes for patients with NSCLC.

To address this need, we developed a novel workflow combining particle enrichment (P2) and quantitative mass spectrometry (DIA-MS). We deployed this method on plasma samples from a multicentric phase II clinical trial (SAKK17/18)[1] in patients with NSCLC. Longitudinal plasma samples were collected at baseline (n=33) and at two post-dose time points (C1D8, n=31 and C2D1, n=31). The samples were subjected to the developed P2 workflow and unbiased mass spectrometry analysis, leading to the quantification of 9283 proteins across all 95 samples. With this depth at plasma proteome profiling, we could cover up to 12 orders of magnitude, detecting low-abundance tissue/cell proteins from leakage events as well as proteins from extracellular vesicles[2].

We conducted weighted gene correlation network analysis (WGCNA) incorporating plasma protein expression and clinical outcome measures. This analysis identified a cluster of key proteins significantly associated with progression-free survival (PFS), including DERL1 and SEPRB, both known to be upregulated in NSCLC, as well as MOSPD1, which has been previously reported to promote epithelial-mesenchymal transition (EMT). To enhance our understanding of the biological context surrounding these plasma proteomic findings, we also incorporated data from two orthogonal methods: 1) the characterization of circulating immune cells from blood samples taken from patients at the same time points, performed using high-dimensional spectral flow cytometry; and 2) the integration of information on cell type markers from published single-cell datasets to delineate potential sources of plasma proteomic signatures.

In conclusion, this integrated proteomics approach provides a powerful platform for identifying predictive biomarkers, enabling more precise patient stratification and potentially improving clinical outcomes in NSCLC treatment.

#3307 Utilizing endocytosis as a predictive biomarker for ADCs.

Anette Weyergang[1], Astrid Medhus[1], Kay Oliver Schink[2], Kristian Berg[1], Olav Engebraaten[1]

[1]Oslo University Hospital, Institute for Cancer Research, Oslo, Norway,[2]University of Oslo, Institute of Basic Medical Sciences, Oslo, Norway

Antibody drug conjugates (ADCs) consist of an antibody conjugated to a chemotherapeutic drug. These therapeutic compounds are designed to exert improved targeted toxicity as compared to conventional chemotherapy. However, variable therapeutic outcome has been experienced and predictive markers for response are warranted. ADCs are dependent on endocytosis to exert their effect, and we have hypothesized that proteins regulating the endocytic machinery can be utilized as predictive biomarkers. We have shown, for the first time, that the expression level of Rab5A, a protein regulating endocytosis correlates to the efficacy of Trastuzumab Emtansine, a HER2 targeted ADC. Furthermore, we have documented Rab5A as a predictive biomarker for Trastuzumab emtansine in three independent clinical cohorts. We are currently investigating the interplay between different ADCs and the endo/lysosomal machinery, and aim to develop this concept to a diagnostic tool for patients to be treated with ADCs. We use Trastuzumab emtansine, Trastuzumab deruxtecan and Sacituzumab Govitecan as model ADCs and evaluate the impact of different Rab GTPases on their mechanism of actions in cell lines from breast- and lung-cancer.

#3308 Use of biosimulation to predict immune checkpoint inhibitor resistance in patients with high microsatellite instability.

Adity Ghosh, Mamatha Patil, Anuj Tyagi, Ansu Kumar, Chandan Kumar, Muthiyah MR, Rahul KR, Swati Khandelwal, Jyoti Chauhan, Michael Castro, Shweta Kapoor, **James Wingrove**

Cellworks Group, Inc, South San Francisco, CA

Background: Immune checkpoint inhibitors (ICI) have become a standard treatment option in patients with high microsatellite instability (MSI-H). Although immune checkpoint inhibitors are largely effective in these patients, MSI is an imperfect biomarker and other therapies may be warranted. A mechanistic Computational Biology Model (CBM) was developed by Cellworks that can be personalized based on a patient's tumor-based genomic profile, revealing signaling pathway dysregulation and patient-specific drug response. Model output was used to identify MSI-H patients who may have a poorer response to ICIs.
Design: Computational biosimulation was performed using real-world retrospective cohorts of 423 STAD patients and 534 CRC patients (TCGA). MSI measurements were provided by TCGA. Efficacy scores (ES) based on biosimulated composite cell growth in response to disease and therapy were generated on all patients for pembrolizumab. Molecular rationales for ICI resistance were identified for MSI-H patients with low pembrolizumab ES (ES-L).
Results: Model efficacy scores for pembrolizumab were significantly higher in MSI-H patients for both STAD (average ES 20.5 vs 3.2 respectively, $p\text{-value} < 0.001$) as well as CRC (average ES 13.4 vs 2.4 respectively, $p\text{-value} < 0.001$). Of the MSI-H patients, 59% and 81% were ES-L (STAD and CRC respectively) MSI-H/ES-L STAD patients showed a significantly higher percentage of NOTCH2, EGFR, and EZH2 amplifications as well as a higher percentage of TP53-SOF mutations, whereas MSI-H/ES-L CRC patients showed a significantly higher percentage of MYC amplifications ($p\text{-value} < 0.05$)
Conclusions: In this study, a therapy efficacy score produced through biosimulation was significantly associated with microsatellite instability levels, and markers of ICI resistance were identified in MSI-H/ES-L patients. Future studies will be performed to confirm the hypothesis that biosimulation has utility in deciding which MSI-H patients might benefit from therapies other than ICI.

#3309 Characterization of long non-coding RNAs in ependymomas: Uncovering potential biomarkers and therapeutic targets.

R. Malik, D. Kumar, D. Suri, D. C. Sharma;
All India Institute of Medical Sciences (AIIMS) New Delhi, New Delhi, India

Introduction: Ependymomas (EPNs), accounting for 5-6% of glial tumors, arise from radial glial cells and exhibit significant heterogeneity, leading to variable prognosis. Despite their clinical significance, the oncogenic drivers and potential therapeutic targets for EPNs remain poorly understood. Long non-coding RNAs (lncRNAs) are emerging as crucial regulators in many cancers, influencing tumorigenesis and therapeutic resistance. However, their role in EPN pathobiology has not been explored. This study aims to unravel the lncRNA landscape in EPNs to identify novel diagnostic biomarkers and therapeutic targets, improving patient stratification and treatment outcomes.

Methods: 38 EPN tumor samples were classified into 21 supratentorial (ST), 13 posterior fossa (PF), and 4 spinal (SP) subtypes based on WHO 2021 criteria and subjected to RNA sequencing to map their RNA landscape, using 6 normal brain tissue samples as control. Raw data was normalized to identify significantly deregulated genes (padj < 0.05, -1 ≤ log2 fold change ≥ 1). qPCR validated the top deregulated lncRNAs (n = 60 extended cohort, $p < 0.05$). Pan-cancer analysis, functional annotation, target prediction, co-expression network construction, and prognostic relevance were assessed using ECORI, LncExplore, LncHub2, RNAInter, and Prognoscan respectively.

Results: RNA sequencing identified 2,271 upregulated and 1,728 downregulated lncRNAs in EPN sub-groups, with 108 commonly upregulated and 187 downregulated across subtypes. qPCR confirmed LINC01971 overexpression in ST-EPNs ($p < 0.001$), FAM74A7 upregulation in PF and SP subtypes ($p < 0.0001$, $p < 0.001$), and LINC00320 downregulation in all subgroups ($p < 0.001$). Pan-cancer analysis revealed high LINC01971 in uterine endometrial and lung carcinoma, slightly increased FAM74A7 in kidney clear cell carcinoma, and low LINC00320 across all cancers. LINC01971, co-expressed with RELA, is involved in NF-kB-driven tumorigenesis and immune modulation. Pathway analysis associated with transcription factors (ESR1, SOX2, TP53, FOXA1) and chromatin modifiers (H3K27me3, H3K4me3), indicating a role in epigenetic reprogramming. FAM74A7, correlated with transcription factors (EOMES, SOX2, NANOG, FOXA1), is linked to tumor progression and epigenetic regulation, with disease associations (papillary, cellular, and myxopapillary EPNs) supporting its potential as a diagnostic and therapeutic target. LINC00320, reduced in malignant gliomas, regulates FOXA1 and H3K4me3, affecting metabolism and protein lipidation. Co-expression patterns in EPNs and gliomas highlight their role in tumor progression and neurodegenerative diseases Prognoscan links RELA, FOXA1, and SOX2 overexpression to poor prognosis in various cancers. This comprehensive transcriptomic analysis of EPNs unveils novel lncRNAs, as potential prognostic biomarkers and therapeutic targets.

#3311 Uncovering methylation signatures and pathways associated with resistance to anti-EGFR therapy in colorectal cancer.

A. de Abreu[1], Y. Heylen[1], J. Ibrahim[1], M. Peeters[2], G. Van Camp[1], K. Op de Beeck[1];
[1]University of Antwerp, Edegem, Belgium, [2]Antwerp University Hospital, Edegem, Belgium

Background: Although anti-epidermal growth factor receptor (EGFR) therapy has established efficacy in *RAS*/*BRAF* wild type (WT) metastatic colorectal cancer (mCRC), a significant proportion (30-50%) of WT patients exhibit primary resistance to this treatment. Existing biomarker discovery has predominantly focused on tumor-specific DNA mutations, which suffer from variable mutation frequencies among patients. In contrast, DNA methylation represents a common and early event in carcinogenesis. For this reason, methylation markers hold great promise for detecting resistance mechanisms in primary tumors. Several studies have shown an association between DNA methylation patterns and resistance to anti-EGFR therapy in CRC. To validate and build upon these findings, we investigated the methylomes of primary tumors with resistant and responsive phenotypes.
Material and Methods: We isolated DNA from FFPE tissue of 40 primary CRC tumors. DNA was subjected to bisulfite conversion and Infinium MethylationEPIC v2.0 BeadChip (Illumina). Subsequently, ChAMP was used to determine the methylation values (β values) and perform differential methylation analysis. The CpG sites were ranked based on the largest Δβ values and the significance of p-values across the patient groups. To ensure the reliability of our findings, we performed a false discovery rate (FDR) evaluation using the Benjamini-Hochberg method, which led to the selection of a subset of differentially methylated CpG sites (DMCs) with the highest likelihood of being genuine associations. Additionally, a gene set enrichment analysis (GSEA) was performed with methylGSA.
Results: 48 DMCs were identified with adjusted p-values < 0.05. The affected genes are involved in cancer progression and invasiveness, suggesting a role in a yet-to-be discovered resistance mechanism. The GSEA revealed significant enrichment in 53 KEGG and 33 Reactome pathways, including MAPK-related and Akt signaling pathways. There were 470 significant gene ontology (GO) pathways: 347 in biological processes, 71 in cellular components and 52 in molecular functions.
Conclusion and future work: We have found methylation sites associated with resistance to anti-EGFR therapy in CRC patients. In addition to identifying critical DMCs, the pathways uncovered hold potential as a rich source of predictive biomarkers. Next, we will include 24 additional patients. When increasing the sample size, we expect a higher statistical power and an enrichment of CpGs with significant p-values. Afterwards, we will independently validate the most significant CpG sites in a follow-up study using a highly sensitive multiplexed droplet digital PCR assay on additional tissue biopsies.

#3313 GenialisTM Supermodel: A large molecular model enabling monotherapy and combination therapy selection in KRAS-mutated cancers.

Josh Wheeler, Luka Ausec, Miha Stajdohar, Rafael Rosengarten, Mark Uhlik

Genialis, Inc., Boston, MA

KRAS mutations drive approximately 25% of human cancers, resulting in 3.9 million new cases annually. Recently approved KRAS inhibition (KRASi) monotherapies demonstrate limited efficacy and durability. Diverse combination therapies are under investigation. This necessitates biomarker strategies for identifying patients most likely to respond to KRASi monotherapy or combination therapy.The Genialis™ Supermodel is a foundation model of cancer biology that can be used to derive novel biomarkers for diagnosis, clinical development, and treatment decision-making in oncology. Trained on nearly 1 million harmonized transcriptomic samples, this large molecular model (LMM) maps individual patient RNA-seq samples into biologically meaningful spaces defined by distinct combinations of biological signatures. Each biological subspace reflects mechanisms relevant to a specific therapeutic class. These mappings enable the selection of core biological features, which are then used in downstream machine-learning models to predict therapeutic response and stratify patients.The Supermodel captures biology linked to responses to KRASi, EGFR inhibitors, ICI (immune checkpoint inhibitors), and standard-of-care chemotherapy, among other therapeutic mechanisms, generating classifiers that predict monotherapy responses in diverse preclinical and clinical cohorts. We further demonstrate that the intersection of these individual classifiers identifies clinical contexts where monotherapy is sufficient and where combination therapies may provide additional benefit. These results refine patient stratification and guide clinical decision-making by aligning treatment selection with the underlying tumor biology and therapeutic context.The Genialis™ Supermodel establishes a novel and robust framework for precision oncology, enhancing patient stratification, optimizing clinical decision-making, and expanding opportunities for effective KRAS-driven cancer treatments.

#3314 AML patients characterized by BH3 profiling and the response to venetoclax-based regimen.

Qi Tatarata[1], Zhe Wang[2], Lina Han[2], Tapan Kadia[2], Courtney DiNardo[2], Marina Konopleva[3]

[1]Internal Medicine, SUNY Downstate Health Sciences University, Brooklyn, NY,[2]Leukemia, The University of Texas MD Anderson Cancer Center, Houston, TX,[3]Medical Oncology, Albert Einstein College of Medicine, Bronx, NY

Venetoclax (VEN), a selective BCL-2 inhibitor, has dramatically changed acute myelogenous leukemia (AML) treatment. The AML patient respond heterogenous to VEN-based therapy and frequently require additional conjugated treatment.

BCL-2 family, crucial in apoptosis regulation, comprises three categories: anti-apoptotic protein, pro-apoptotic protein, and BH3-only sensitizers which bind to specific anti-apoptotic proteins at resting state. By exposing cells to various synthesized BH3-only peptides and measuring cytochrome c release, we are able to detect the cells dominate anti-apoptotic proteins, namely BCL-2 family dependency. This method, known as BH3 profiling, has been validated by multiple studies as a way to correlate the cells response to different BH3 inhibitors in cell lines and primary samples (*Bhatt et al. Cancer Cell 2020*). In this study, we performed BH3 profiling on samples collected from 52 patients on VEN-based treatments, including 40 patients achieved response (28 CR, 7 CRi, 2 CRp, 1 CR with MRD, 2 CR then relapse), 12 non-response (NR). We exposed the primary cells to peptides of hBIM and PUMA (general priming, all anti-apoptotic proteins), HRK-Y (priming BCL-XL), mBAD (priming of BCL-W in addition to BCL2- and BCL-XL), MS-1 and mNoxaA (priming MCL-1), FS-1 (priming of BFL-1), and BCL-2 inhibitor Veneotoclax (priming BCL-2) for 1 hour, and then measure the cytochrome C by flow cytometry. The priming was defined as CytC loss by median fluoresce intensity relative to Alamethicin and DMSO controls. AML dependency on anti-apoptotic proteins is heterogenous, as reflected by varying responses to BH3-only peptides. 69.23% (36 out of 52) of the samples showed intact apoptotic capacity with more than 50% priming to hBIM. 43.15% (24/52) of samples depended on BCL-2, as indicated by more than 40% priming to VEN, while 34.62% (18/52) depended on BCL-XL, as indicated by more than 40% priming to HRK-Y. In addition, 51.92% (27/52) had a dependency on MCL-1 (more than 40% priming to MS-1), and 25.00% (13/52) were dependent on BFL-1 (more than 40% priming to FS-1). Overlapping co-dependencies were also observed. Among the 24 samples with BCL-2 dependency, 16 also depended on MCL-1, 10 on BCL-XL, 9 on BFL-1, and 6 were co-dependent on BCL-2, MCL-1, BCL-XL and BFL1.

Comparing the samples from patients who achieved response with who did not, response samples had higher priming capacity, as shown by greater median CytC release in response to hBIM (p=0.0378). Non-CR samples exhibited higher dependency on non-BCL-2 proteins, with greater priming to peptides mNoxaA (p=0.0893), MS-1 (p=0.0153), and FS-1 (p=0.0147).

In summary, AML shows heterogenous and co-dependent relationships withc multiple anti-apoptotic proteins. Patients who responded to VEN-based therapy typically retain the apoptotic capacity and show lower co-dependency on MCL-1 and BFL-1.

#3315 Unveiling a protective role of B-cells in classical Hodgkin lymphoma progression through gene expression signatures.

Stefano Pozzi[1], Francesca Reggiani[2], Tanja Lazic[2], Nizzoli Maria Elena[2], Alberto Bavieri[2], Benedetta Donati[2], Durmo Rexhep[2], Riccardo Valli[2], Attilio Gennaro[2], Cristian Ascione[2], Alessia Ruffini[2], Annibale Versari[2], Francesco Merli[2], Massimo Dominici[3], Alessia Ciarrocchi[2], Stefano Luminari[2]

[1]University of Modena and Reggio Emilia, Clinical and Experimental Medicine PhD Program, Modena, Italy,[2]AUSL-IRCCS Reggio Emilia, Reggio Emilia, Italy,[3]University of Modena and Reggio Emilia, Modena, Italy

Background: Classical Hodgkin Lymphoma (cHL) is considered highly curable, but identifying patients at risk of relapse or progression after initial treatment remains a challenge. Disease progression may involve biological factors not accounted for by current prognostic models, which could potentially be revealed by molecular analysis. In this study, we performed comprehensive gene expression profiling to identify molecular markers that could help to develop new prognostic tools in cHL patients.
Patients and Methods: We conducted a retrospective review of local clinical records to identify patients with confirmed cHL diagnosed between 2004 and 2019, aged 18-65, at any disease stage, and treated with systemic chemotherapy. Gene expression analysis using nCounter Nanostring Technology with the PanCancer Immune Profiling Panel was performed on baseline diagnostic biopsies. Genomic data were correlated with clinical, laboratory, and radiomic information. Progression-Free Survival (PFS) was the primary endpoint. Immunohistochemistry was used for validation.
Results: We identified 185 patients with classical Hodgkin lymphoma (cHL), of whom 155 had available formalin-fixed paraffin-embedded (FFPE) tissue samples. Of these, 32% were aged over 45 years, 46% had stage III-IV disease, and 10% presented with bulky disease. After a median follow-up of 72 months (range, 6-171 months), 31 PFS events occurred, with a 4-year PFS rate of 80.4% (95% CI 74.1-87.3). Through Cox Proportional Hazards modeling, we identified 66 genes that were significantly associated with PFS ($p<0.05$). Of these, 41 genes were positively associated with better PFS, suggesting a protective effect, while 25 genes were linked to a reduced probability of survival.
Through correlation analysis and gene ontology, we were able to identify a 7-gene signature associated with B-cell signaling pathways. An unsupervised analysis on the entire cohort based on the expression of the identified B cell signature has allowed us to define two main patient clusters: low- B cell and high- B cell. The former cluster displayed a significant increase in the incidence of clinical events ($p=0.03$) and worse PFS compared to the high B-cell cluster ($p=0.007$). Additionally, elevated expression of PAX5, a key regulator of B-cell differentiation, was significantly associated with better PFS, with a 4-year PFS rate of 90% (95% CI 82.7-97.3) compared to 71% (95% CI 61.3-82.4) in patients with lower expression levels. Immunohistochemical evaluation of PAX5 in the tumor microenvironment further supported its potential as a prognostic marker.
Conclusion: These results suggest that gene expression analysis may assist in the early detection of disease relapse and highlight the immune-modulatory role of B-cells in cHL progression.

#3316 Comparative analysis of Ki67 and BCI for risk of recurrence and prediction of extended endocrine therapy benefit in the BCI Registry study.

Sami Diab[1], Natalia Siuliukina[2], Brandon O'Neal[2], Amanda K. L. Anderson[2], Yi Zhang[2], Kai Treuner[2]

[1]Intermountain Health, Denver, CO,[2]Biotheranostics, a Hologic Company, San Diego, CA

Background: The BCI Registry study is an ongoing trial with over 3000 enrolled patients diagnosed with HR+ early-stage breast cancer to assess long-term outcomes as well as the overall impact of BCI in treatment decisions. The BCI (H/I) ratio has been validated to predict benefit from extended endocrine therapy (EET) in the MA.17, Trans-aTTom, IDEAL and B-42 trials. The BCI score is prognostic for the risk of distant recurrence. Ki67 is a well-known prognostic marker for invasive breast cancer disease. A high expression of Ki67 relates to a higher proportion of actively dividing cells within the tumor, which is associated with more aggressive behavior and poorer prognosis. Conversely, low Ki67 expression indicates a lower proliferation rate and may be associated with a less aggressive tumor phenotype and better prognosis. This analysis investigates the relationship between BCI (H/I) and BCI score against Ki67 score in patients enrolled in the BCI Registry study.

Methods: BCI Registry patients with available BCI and Ki67 results were incorporated in this study (n=1872), consisting of 1483 node negative and 389 node-positive patients. BCI (H/I)-Low and BCI (H/I)-High groups were derived from a pre-specified cut-point. Ki67 score was stratified into the following risk groups: Low risk (Ki67 < 10%), Intermediate risk (Ki67: 10 to 25%), and High risk (Ki67 > 25%). Kendall correlation (R) was used to examine the correlation between BCI (H/I), BCI score and Ki67 score as continuous variables. Descriptive statistics were used to summarize the distribution of BCI (H/I) categories and BCI prognostic groups across all Ki67 risk categories for all patients and subsets based on nodal status.

Results: In the overall cohort, 37.2%, 27.2% and 35.6% patients were classified by Ki67 as Low, Intermediate and High Risk, respectively. In addition, 61.5% of patients were classified as BCI (H/I)-Low and 38.5% as BCI (H/I)-High. Continuous analysis of BCI (H/I) versus Ki67 revealed a weak correlation (R= 0.14), but a positive correlation for BCI score versus Ki67 (R= 0.46). Within Ki67 Low Risk patients, 27.4% were classified as BCI (H/I)-High, and 48.1% of Ki67 High Risk patients were classified as BCI (H/I)-Low. The prognostic analysis identified 28.6% of Ki67 Low Risk patients classified as BCI high risk and 17.3% of Ki67 High Risk patients classified as BCI low risk. In addition, 51.8% and 48.2% of Ki67 Intermediate Risk patients were classified as BCI low risk and high risk, respectively.

Conclusions: These results confirm only a weak correlation between BCI (H/I) and Ki67 but a moderate correlation between the BCI score and Ki67. These findings further highlight the important distinction between prognostic and predictive biomarkers, where prognostic risk assessment by Ki67 does not predict the likelihood of benefit from extended endocrine therapy.

#3317 IFITM3: A predictive biomarker for therapeutic outcomes in advanced hepatocellular carcinoma.

Yinchao Zhang[1], Linze Xu[1], Jin Zhang[1], Dandan Wu[1], Huikai Li[1], Yueguo Li[2], Yang Liu[1]

[1]Tianjin Medical University Cancer Institute & Hospital, National Clinical Research Center for Cancer, Key Laboratory of Cancer Prevention and Therapy, Tianjin's Clinical Research Center for Cancer, Tianjin, China,[2]Tianjin Medical University Cancer Institute and Hospital, National Clinical Research Center for Cancer, Tianjin Key Laboratory of Digestive Cancer, Key Laboratory of Cancer Prevention and Therapy, Tianjin's Clinical Research Center for Cancer, Tianjin, China

Background: Hepatocellular carcinoma (HCC) is a major global health challenge, with China bearing a significant burden due to its high incidence and mortality rates. Vascular invasion (VI), particularly microvascular invasion (MVI), is a critical prognostic factor in HCC , profoundly influencing treatment decisions. Despite its clinical importance, reliable and non-invasive biomarkers for stratified prediction and therapeutic response remain scarce. Extracellular vesicles (EVs) are emerging as promising tools in cancer progression and therapy assessment.

Methods: Sixty-five patients with China Liver Cancer (CNLC) stage III HCC treated with hepatic artery infusion chemotherapy (HAIC) plus sintilimab and a bevacizumab biosimilar (IBI305) were stratified based on RECIST criteria and surgical status for survival analysis and Kaplan-Meier (KM) curve construction. Univariate and multivariate regression analyses were employed to identify independent predictors of surgical eligibility. Cellular and molecular investigations followed to uncover potential biomarkers. scRNA-seq data (GEO: GSE242889), bulk RNA-seq data (GEO: GSE19977, TCGA), and hdWGCNA analysis were utilized to identify hub genes linked to MVI. TCGA data were divided into training and validation sets at a 7:3 ratio. Machine learning algorithms (LASSO regression, SVM-RFE, random forest) identified high-risk MVI genes. A prognostic nomogram model was constructed and significant predictors were explored with its performance assessed via ROC curves. Immunohistochemical staining and exosomal IFITM3 analysis were applied to evaluate gene expression across treatment stages.

Results: Data from 65 patients (April 2021 to July 2023) with a median age of 57 years, predominantly male (83.1%), were analyzed. Patients who underwent surgery (30.8%) or achieved partial response (PR) per RECIST (38.5%) demonstrated significantly improved overall survival. Multivariate regression indicated that patients with VI, distant metastasis, ascites, and Child-Pugh grade B as factors reducing surgical eligibility, with VI as an independent predictor. Six MVI high-risk genes (VTN, DYNC1I2, HABP2, IFT43, IFITM3, NDUFS4) were identified, among which IFITM3 emerged as a key prognostic marker. High IFITM3 expression was associated with shorter survival ($P < 0.001$). The nomogram model showed strong predictive accuracy for survival (AUC1=0.641, AUC2=0.613, AUC2.5=0.579). Immunohistochemical analysis and exosomal analysis further validated IFITM3's role in influencing therapeutic outcomes.

Conclusions: In summary, IFITM3 levels are closely linked to therapeutic outcomes in HCC patients. Non-invasive blood-based detection of IFITM3 holds promise for enhancing therapeutic stratification. Further research may refine prediction models and deepen understanding of IFITM3's role in poor therapeutic outcomes in cancer.

#3318 Serum Insulin-Like Growth Factor-1 levels predict outcomes in patients with advanced hepatocellular carcinoma receiving immunotherapy.

Tsung-Che Wu[1], Ching-Tso Chen[1], Chien-Huai Chuang[2], Ann-Lii Cheng[2], Chih-Hung Hsu[3], Yu-Yun Shao[3]

[1]Department of Oncology, National Taiwan University Hospital, Hsinchu Branch, Hsinchu, Taiwan,[2]Department of Medical Oncology, National Taiwan University Cancer Center, Taipei, Taiwan,[3]Department of Oncology, National Taiwan University Hospital, Taipei, Taiwan

Background: The combination of immune checkpoint inhibitors (ICIs) with antiangiogenesis agents or another ICI has become the standard of care for advanced hepatocellular carcinoma (HCC). Elevated serum levels of insulin-like growth factor-1(IGF-1) levels have been previously associated with better outcomes of patients with advanced HCC treated with sorafenib or atezolizumab plus bevacizumab. However, the prognostic value of serum IGF-1 level for other immunotherapy regimens remains unexplored.
Methods: Patients with advanced HCC who received anti-PD-1/anti-PD-L1 monoclonal antibody monotherapy or combinations were enrolled. Serum samples were collected prior to initiating immunotherapy, and serum IGF-1 levels were quantified using enzyme-linked immunosorbent assay (ELISA). Based on prior findings from our group, a cutoff value of 63.6 ng/mL was used to stratify patients into high and low serum IGF-1 groups. Patient demographics, tumor characteristics, treatment responses, and survival outcomes were analyzed.
Results: From August 2015 to July 2024, 111 patients were enrolled. Baseline characteristics were as follows: 90% male, 71% HBsAg-positive, 18% anti-HCV-positive, Child-Pugh scores: 72% (5 points)/23% (6 points)/5% (7 points), 43% with macrovascular invasion (MVI), 72% with extrahepatic involvement (EHI), and 46% treated with antiangiogenic-containing regimens. Patients with higher serum IGF-1 levels demonstrated fewer adverse clinical features, including lower Child-Pugh scores, ALBI grades, and MVI rates. Patients who achieved an objective response to therapy had significantly higher IGF-1 levels compared to those who did not (57.2 vs. 46.2 ng/mL, $p = 0.037$). Additionally, patients with high IGF-1 levels exhibited improved overall survival (OS) compared to those with low IGF-1 levels ($p = 0.024$). When stratified by regimen types, the prognostic value of high IGF-1 levels was maintained in patients treated with antiangiogenic-containing regimens ($p = 0.001$) but was not observed in patients treated without antiangiogenic agents ($p = 0.967$).
Conclusions: High serum IGF-1 levels are associated with improved OS in patients with advanced HCC, but this prognostic value is confined to regimens containing antiangiogenic agents. These findings underscore the potential of IGF-1 as a biomarker for optimizing immunotherapy strategies in advanced HCC.

#3319 Evaluating and targeting DNA repair defects in pediatric high grade glioma.

Evan Savage[1], Ke Xu[2], Miaomiao Li[3], Jason Myers[2], Evadnie Rampersaud[2], Rebekah DeVries[1], Kamran Mohammad Zahid[3], Krista Millican[1], Yawei Hui[2], Ti-Cheng Chang[2], Gang Wu[2], Anang Shelat[1], Christopher Tinkle[3]

[1]Chemical Biology and Therapeutics, St. Jude Children's Research Hospital, Memphis, TN,[2]Center for Applied Bioinformatics, St. Jude Children's Research Hospital, Memphis, TN,[3]Radiation Oncology, St. Jude Children's Research Hospital, Memphis, TN

Homologous recombination deficiency (HRD) has been extensively studied in breast cancer and ovarian cancer given its correlation with sensitivity to Poly (ADP-ribose) polymerases (PARP) inhibitors. In these cancers, HRD is most frequently caused by biallelic inactivation of BRCA1/2 and these tumors often exhibit ‘genomic scars’ (Nik-Zainal, 2016; Telli, 2016; Davies, 2017). Our group profiled a cohort of 255 pediatric high-grade glioma (pHGG) patient samples for DNA damage response (DDR) gene variants and genomic scars. We found no evidence of BRCA1/2 loss in any sample, but we did detect evidence for HRD-associated genomic scars in 30% of our samples. Interestingly, we also detected biallelic loss of ATM, which is reported to be synthetically lethal with ATR inhibition (Marwan, 2016). Given these findings, our group set out to answer the following questions: 1) Does the presence of BRCA deficiency or HRD-related genomic scars predict sensitivity to PARP inhibition in pHGG tumors? 2) Do the ATM mutations we found impair ATM pathway activation and confer radiosensitivity, and do they induce synthetic lethality with ATR inhibition? Overall, this work underscores the importance of looking beyond simple mutation status to identify robust biomarkers of drug response in pHGG tumors.

#3320 A comprehensive pan-cancer analysis of BCOR as a promising biomarker for immune checkpoint inhibitor therapy.

C. Li[1], S. Sun[2], K. Dong[2], Y. Zhu[1], X. Zhong[3];

[1]Dali Bai Autonomous Prefecture People's Hospital (The Third Affiliated Hospital of Dali University), Dali, Yunnan, China, [2]The first Affiliated Hospital of Dali University, Dali, Yunnan, China, [3]3D Medicines Inc., Shanghai, China

Background: *BCOR* is a gene that encodes an epigenetic regulator, which is indispensable for guiding cell differentiation and body structure development. While immune checkpoint inhibitors (ICIs) have emerged as a significant therapeutic option for tumor patients, the correction between *BCOR* mutations and the efficacy of ICIs in solid tumors remains uncertain.

Methods: Next-generation sequencing (NGS) and clinical data of pan-cancer patients were sourced from two MSK-IMPACT cohorts: MSK-2017, comprising 10336 patients, and MSK-2019, consisting of 1661 patients. The MSK-2019 cohort treated with ICIs underwent analysis to investigate the correlation between *BCOR* mutations and the therapeutic efficacy of ICIs. mRNA expression data of 10228 pan-cancer patients were retrieved from the TCGA database, aiming to explore the relationship between BCOR expression levels and immune cell infiltration.

Results: Totally, 2.9% (304/10336) of pan-cancer patients in the MSK-2017 cohort and 3.9% (64/1661) in the MSK-2019 cohort harbored *BCOR* mutations. In the MSK-2017 cohort, the top three tumor types with the highest frequency of *BCOR* mutations were endometrial cancer (28/218, 12.8%), adrenocortical carcinoma (3/25, 12.0%), and salivary gland cancer (9/114, 7.9%), respectively. Differently, the MSK-2019 cohort showed the highest frequency of *BCOR* mutations in colorectal cancer (11/110, 10.0%), whereas in the MSK-2017 cohort, *BCOR* mutations were only observed in 3.5% (35/1007) of colorectal cancer patients. The most common types of *BCOR* mutations in both cohorts were missense and truncating mutations. In the MSK-2019 cohort, the *BCOR*-mutated group exhibited a significantly higher tumor mutational burden (TMB) compared to the *BCOR*-wild group (median TMB: mutated-type vs. wild-type = 36.7 vs. 5.9 Muts/Mb, $P<0.0001$). Additionally, the overall survival (OS) of the BCOR-mutated group was significantly longer than that of the wild-type group (median OS: 36.0 vs. 15.0 months; hazard ratio [HR]=0.5, 95% confidence interval [CI]: 0.6-0.7, $P=0.003$). However, in MSK-2017 cohort treated without immunotherapy, there was no difference in OS between *BCOR*-mutated group and *BCOR*-wild group (median OS, 30.0 vs. 26.0 months; HR=0.9, 95%CI: 0.7-1.1, $P=0.3$). The immuno-correlation analysis showed that across most tumor types, the infiltration levels of CD4+ memory resting T cell, plasma B cell, and naive B cell exhibited a positive correlation with BCOR expression. Conversely, the infiltration levels of regulatory T cells, gamma delta T cells, and follicular helper T cells exhibited a negative correlation with BCOR expression.

Conclusion: The results indicated that the *BCOR* mutation frequency varied across different tumor types and cohorts. Notably, in patients treated with ICIs, *BCOR* mutations were associated with higher TMB and improved OS, suggesting its potential as a biomarker in immunotherapy response.

#3321 Real-world clinical outcome analyses in head and neck squamous cell carcinoma (HNSCC) to uncover TIGIT biology in patients treated with first-line immune checkpoint inhibitors.

Meghna Das Thakur, Xiaoyong Fu, Shahed Iqbal, Joon Rhee

Gilead Sciences, Inc., Foster City, CA

Introduction: ICIs are approved for HNSCC. T-cell immunoreceptor with immunoglobulin and immunoreceptor tyrosine-based inhibition motif domain (TIGIT) is a potential ICI anti-tumor target. Understanding how effector T cell (Teff) and *TIGIT* expression levels in tumors correlate with real-world outcomes of 1L treatment can highlight the role of TIGIT as a potential target.

Methods: Deidentified real-world pt data, including whole-transcriptome RNA sequencing (RNA-seq) and progression-free survival (PFS), were acquired from Tempus AI, Inc. Data from pts with metastatic HNSCC (mHNSCC) who received 1L therapy with ICI, ICI + chemotherapy (chemo), or chemo were analyzed. Gene expression correlations, including between *TIGIT* and a Teff gene set (geometric mean of: *CD8A, GZMA, GZMB, IFNG, EOMES, and PRF1*) were assessed by Pearson correlation coefficients. Human papilloma virus (HPV) status was extrapolated by an HPV gene signature (*GGA2*, *SPIB*, *CD200*, *ADAM28, BCL2*, *VCAM1*, *ICOSLG*, *STAG3*). Real-word PFS (rwPFS) was assessed using the Kaplan-Meier method and compared by expression level (high vs low) of *TIGIT*, Teff gene set, and *TIGIT* normalized by Teff gene set.

Results: The cohort included pts with 1L ICI (n = 27), ICI + chemo (n = 62), and chemo (n = 159). At baseline, *TIGIT* expression (N = 276 biopsies with RNA-seq) was highly correlated with Teff gene set ($R = 0.852$, $P < 0.001$) and *FOXP3* expression ($R = 0.853$, $P < 0.001$). Correlations were consistent when stratified by HPV status (HPV+ or HPV−) or programmed death-ligand 1 (PD-L1) status (combined positive score: < 1, 1-19, and ≥ 20). Higher immune marker expression and numerically improved rwPFS for ICI + chemo were observed for HPV+ vs HPV− status. High vs low *TIGIT* expression was associated with numerically improved rwPFS for ICI (n = 13 vs 14; HR [95% CI], 0.86 [0.23-3.22]) or ICI + chemo (n =31 each; HR [95% CI], 0.4 [0.18-0.9]; $P = 0.023$). Similar results were observed for high vs low Teff gene set expression (ICI: HR [95% CI], 0.54 [0.13-2.16]; ICI + chemo: HR [95% CI], 0.66 [0.3-1.42]). When *TIGIT* expression was normalized to Teff gene set expression, rwPFS was numerically shorter for high vs low expression in ICI (HR [95% CI], 1.25 [0.33-4.8]) or ICI + chemo (HR [95% CI], 1.37 [0.64-2.95]).

Conclusions: *TIGIT* expression was highly correlated with Teff gene set expression and *FOXP3* in HNSCC tumors. Improved rwPFS with HPV+ status was likely due to a more immunogenic tumor microenvironment. High Teff or *TIGIT* expression in tumors was associated with improved rwPFS with 1L ICI-containing regimens. However, after normalization of *TIGIT* expression by Teff infiltration, the presence of TIGIT-high tumors was associated with worse rwPFS with ICI-based treatment. Thus, combining anti-TIGIT and anti-PD-1 treatments could bring more benefit in a 1L mHNSCC setting to pts with TIGIT-high tumors.

#3322 Comprehensive genomic profiling (CGP)-informed circulating tumor DNA analysis for postoperative monitoring of non-small cell lung cancer: BEACON study.

Guanggui Ding[1], Jinquan Yuan[2], Peikun Ding[1], Xiaoxiang Huang[1], Junjun Li[3], Hongsheng Xie[1], Yuxin Wen[1], Jiaochun Shi[3], Shihua Dou[1], Wohua Han[2], Xuning Fan[3], Yuan Sun[3], Zhihong Zhang[3], Bing Li[3], Zhou Zhang[3], Jianping Zhou[2], **Lin Yang**[1]

[1]Department of Thoracic Surgery, Shenzhen People's Hospital（The Second Clinical Medical College，Jinan University；The First Affiliated Hospital, Southern University of Science and Technology）, Shenzhen, China,[2]Department of Thoracic Surgery, Dongguan People's Hospital, Dongguan, China,[3]Burning Rock Biotech, Guangzhou, China

Background: Detection of circulating tumor DNA (ctDNA) after surgery in early-stage non-small cell lung cancer (NSCLC) is associated with poorer outcomes. The previous MEDAL study (PMID: 37683638) demonstrated that PROPHET, a whole-exome sequencing (WES)-based, individualized ctDNA detection assay, outperformed fixed-panel assays in a direct comparison for NSCLC. However, WES requires high-quality tissue samples and is associated with high costs. Here, we further aim to validate CGP sequencing-based individualized ctDNA assay for minimal residual disease (MRD) detection in NSCLC.

Methods: The BEACON study is a multicenter, prospective cohort study that collected plasma samples at pre-surgery, 30 days post-surgery, and at longitudinal time points from patients with early-stage NSCLC between February 2022 and September 2024. A 520-gene panel sequencing-based personalized tumor-informed technology known as PROPHET_lite was used, which employs deep sequencing up to 25 patient-specific variants. PROPHET_lite was developed to detect MRD with a limit of detection (LoD) of 0.01% and a sample-level specificity exceeding 99%, as established during analytical validation.

Results: In our cohort, excluding two patients with no detectable mutations, 130 patients successfully underwent ctDNA assays, with a median of five tumor-specific tracking variants. Of these, 77.7% had stage I NSCLC, and 86.2% had adenocarcinoma. ctDNA was detected pre-surgery in 129 patients, with a 31% positivity rate. Among patients with stage I NSCLC, this rate was comparable to the PROPHET assay in the MEDAL study. After a median follow-up of 445 days (95% CI: 376-536), 18 patients experienced distant recurrence. Landmark MRD status was significantly associated with DFS (HR 3.36, 95% CI: 1.3-8.71, $p = 0.008$); the negative predictive value (NPV) and positive predictive value (PPV) for recurrence were 88.3% and 53.8%, respectively. Longitudinal MRD status was also significantly associated with DFS (HR 15.1, 95% CI: 4.33-52.61, $p < 0.001$); the NPV and PPV for recurrence were 95.8% and 66.7%, respectively. Among the 18 patients with recurrence, MRD was positive in 14 cases at or before recurrence, with a median lead time of 295 days before CT detection. The remaining four MRD-negative cases were associated with brain metastases or prolonged intervals without ctDNA detection. Multivariate Cox analysis further revealed that longitudinal MRD status (HR 52.28, 95% CI: 7.37-370.8, $p < 0.001$) was an independent predictor of recurrence.

Conclusion: Our study demonstrated that the MRD approach, with its high clinical accessibility, broad applicability, and good sensitivity, enables prognostic predictions and supports disease monitoring during surveillance in NSCLC patients.

#3323 nELISA high-throughput protein profiling applied to the RADIOHEAD cohort: Insights from the largest plasma proteomics study of patients receiving checkpoint inhibitor therapy.

Nathaniel Robichaud[1], Samantha I. Liang[2], Grant Ongo[1], Enjun Yang[2], Kiran Edwardson[1], JiaMin Huang[1], Andy Lee[1], John E. Connolly[2], Milad Dagher[1]

[1]Nomic Bio Inc, Montreal, QC, Canada,[2]Parker Institute for Cancer Immunotherapy, San Francisco, CA

Proteomics holds great promise for cancer immunotherapy, with intensive efforts being exerted for early disease identification, patients selection, and adverse event prediction. Despite this potential, the high cost and low throughput of existing tools to profile circulating proteins render such studies prohibitively slow and costly, limiting their wide-spread application. As a result, proteomics studies in the field have been constrained to sample sizes in the 10s and 100s , restricting the power to discover key biomarkers. Here, we leverage a novel proteomics tool, the nELISA, to quantify ~600 circulating proteins across ~3000 samples from the RADIOHEAD (Resistance Drivers for Immuno-Oncology Patients Interrogated by Harmonized Molecular Datasets) cohort, a prospective study of 1070 immunotherapy naive pan-tumor patients on standard of care immune checkpoint inhibitor (ICI) therapy regimens from community oncology clinics.

The nELISA is a highly multiplexed immunoassay platform that enables the profiling of hundreds of proteins across 1536 samples per instrument daily, at significantly reduced costs. The method miniaturizes sandwich immunoassays by pre-packaging antibody pairs on the surface of color-coded microparticles, which can then be analyzed via high-throughput flow cytometry. Using this technology, our preliminary data identified several markers of response to treatment; for example, PD-1 inhibitors resulted in increased circulating levels of soluble PD-1, and ICIs increased levels of several chemokines including CXCL9 and CXCL10, as seen in several other small-scale studies. We also identified potentially novel markers associated with response to treatment and irAEs, requiring a much larger dataset for validation.

The scalable nature of the nELISA platform now allows us to validate these findings in a large longitudinal cohort, providing the power needed for such a broad biomarker discovery effort. In this presentation, we share the results of applying nELISA to the RADIOHEAD serum samples from pretreatment, early on-treatment, 6-month, and 12-month timepoints. For participants who experienced immune-related adverse events, additional samples were collected upon presentation and in follow-up visits - these samples were also analyzed in this study. Pairing nELISA protein profiling of these longitudinal samples with associated demographic metadata and clinical outcomes provides an opportunity to identify clinically actionable mechanisms for ICI resistance and adverse events, discover targets for combination therapies and post-ICI treatment, and inform system biology approaches to elucidate disease pathways. Such identified biomarkers and protein signatures are expected to further accelerate research and improve clinical decision making in the field of cancer immunotherapy.

#3324 Co-occurrence of gene fusions with SNV/Indels and with CNVs on solid tumors in a cohort of 795 patients from the community setting.

Chaugiang Duong, Nathan Montgomery, Derek Lyle, Fernando Lopez-Diaz

NeoGenomics, Aliso Viejo, CA

Background: Co-occurrence of gene alterations often plays a relevant role in the selection of potential targeted therapies for a cancer patient. It has been reported that patients with fusions respond to fusion-targeted therapy regardless of the tissue type. Less is known about the co-occurrence of SNVs and Indels with gene fusions and copy number variation.
Methods: Data from 795 patients tested with a CGP assay that interrogated SNVs/Indels on 517 genes, fusions of 59 genes, and CNV on 55 genes were included in the study. Variant clinical significance was determined as described by the FDA-recognized OncoKB database or the National Comprehensive Cancer Network, NCCN. The study was performed with an IRB approved research protocol.
Results: We examined the co-occurrence of copy number variation, RNAseq fusion detection, and actionable SNV and Indel mutations in community care settings to understand their combined potential clinical implications. We analyzed the co-occurrence of fusion events with targetable mutations, the overlap of fusions with copy number variation detection, and simultaneous copy number variation and actionable SNV/Indels. Roughly 5.3% (38/ 713) of tumors with pathogenic/likely pathogenic OncoKB gene mutation also had a fusion event. Conversely, 80.9% (38/47) of patients harboring a gene fusion had pathogenic OncoKB mutation(s). When analyzed alone, amongst the 40 fusions, the most frequent were SDCCAG8::AKT3 (n=5), TMPRSS2::ERG (n=4), ESR1::CCDC170, and ROS1 fusions (n=3). Fifteen (15) of these fusions have a potentially actionable fusion as defined by NCCN and/or OncoKB database. ROS1 fusions most commonly had TP53 mutations (66.66%), with equal detection of other pathogenic oncoKB co-mutations in BRCA2, EGFR, and BRAF. Meanwhile, 6 of the patients had PIK3CA oncogenic mutations with an available therapeutic selection, and 2 had a fusion that offers additional clinical implications. Additionally, ESR1 was the most frequent fusion partner with PIK3CA co-mutation with OncoKB described actionability. The most common SNV/Indel mutation observed was TP53, with 31 unique tumors bearing co-occurring TP53 mutation with a fusion. In addition, 36.2% (17/47) of fusion positive tumors had concurrent copy number variation, whereas 6.9% (17/245) of tumors with copy number alteration detection (n=245) concurrently had a fusion. Moreover, 32.0% (228/713) of samples with pathogenic gene mutation also had copy number variation(s). Conversely, 93.1% (228/245) of tumors with copy number variation had pathogenic OncoKB mutation.
Conclusion: Genomic rearrangements, albeit relatively infrequent, can often be concomitantly expressed in the context of other actionable DNA mutations or CNVs, which can lead to better understanding of tumorigenesis and improve clinical care as tumors are tested with comprehensive genomic profiling assays.

#3325 PELO is a synthetic lethal target in FOCAD deleted cancers.

Michelle Patricia Cicchini[1], Yang Peng[2], Yanhua Rao[1], Biju Mangatt[1], Benjamin Schwartz[1]

[1]Intracellular Targeted Cancer Therapeutics, GlaxoSmithKline, Collegeville, PA,[2]Synthetic Lethality, GlaxoSmithKline, Collegeville, PA

During protein translation, ribosomes may stall for a number of reasons including the presence of mRNA defects, cell stress, nonoptimal codon clusters, ribosome collisions, etc. One mechanism of resolving these stalled ribosomes is to extract the mRNA using the SKI complex. Focadhesin (FOCAD) provides an essential function to the SKI complex by stabilizing and protecting SKI proteins from degradation, but it is also a common collateral deletion with CDKN2A- and MTAP-loss in many cancers. In the absence of a functional SKI complex, stalled ribosomes are resolved via the No-go decay (NGD) pathway which leverages PELO (protein pelota homolog), HBS1L (HBS1-like protein), and ABCE1 (ATP-binding cassette sub-family E member 1) . Together PELO and HBS1L recognize stalled ribosomes and recruit ABCE1 to split and recycle ribosomal subunits. Consistent with the NGD pathway compensating for the loss of a functional SKI complex in normal cells, unbiased whole-genome knockout screens identify FOCAD-deleted cell lines to be dependent on PELO for their survival. In this work, PELO-dependency is validated in FOCAD-deleted cancer cell lines and it is demonstrated that FOCAD-deletion drives PELO-dependency. Furthermore, it is shown that PELO-knockout induces ribosomal readthrough, GCN2 activation, and EIF2α induction in FOCAD-deleted cell lines prior to the robust anti-proliferative and apoptotic readouts observed at longer timepoints. Together, these data support that loss of PELO in FOCAD-deleted cancer cells is synthetic lethal due to the persistence of stalled ribosomes that initially activate cell survival pathways but ultimately lead to cell death.

#3326 Putative value of HLA-neoantigen-TCR interactions as a response biomarker to neoadjuvant chemoradiotherapy in locally advanced rectal cancer.

R. Torreglosa do Carmo[1], V. Lira[2], F. Hinterholz Knebel[1], F. Bettoni[1], G. Pagin Sao Juliao[3], N. M. Felicio[3], L. Corbi[3], A. Habr-Gama[4], A. Aranha Camargo[1], C. Masotti[1], R. Oliva Perez[2];

[1]Hospital Sirio-Libanes, Sao Paulo, Brazil, [2]Hospital Beneficencia Portuguesa de Sao Paulo, Sao Paulo, Brazil, [3]Hospital Alemao Oswaldo Cruz, Sao Paulo, Brazil, [4]Instituto Angelita e Joaquim Gama, Sao Paulo, Brazil

The standard initial treatment for locally advanced rectal cancer (LARC) is neoadjuvant chemoradiotherapy (nCRT), which aims to reduce tumor size before total mesorectal excision. A notable proportion of patients (10-30%) achieve a complete pathological response (pCR) post-nCRT, allowing organ-preserving approaches, such as the Watch and Wait protocol. However, predicting pCR and differentiating between responders (nCRT-R) and non-responders (nCRT-NR) remains challenging, as current clinical, radiological, and molecular tools lack sufficient accuracy. Identifying predictive biomarkers for nCRT response could thus transform LARC clinical management. Research consistently highlights that tumor-infiltrating lymphocytes (TILs), especially those enriched with cytotoxic CD8+ T-cells, correlate with improved outcomes across various cancers and treatments. Recent findings indicate that some LARC tumors exhibit “hot” immune microenvironments, which may be associated with enhanced nCRT responses. Furthermore, an immunohistochemistry-based scoring system that evaluates CD3+ and CD8+ T-cell enrichment in LARC TILs is being explored as a potential preoperative predictor of response. This study assesses whether elements of the anti-tumor immune response, such as the antigen-presentation pathway, might serve as viable molecular biomarkers for response. We conducted exome and T-cell receptor (TCR) sequencing on 69 LARC tumors (15 nCRT-R and 37 nCRT-NR) to investigate possible associations between HLA, neoantigens, and TCR genetic diversity and nCRT response. Results showed that the neoantigen load, a measure of tumor immunogenicity, was significantly higher in nCRT-NR patients (Wilcoxon test, p=0.03). HLA somatic mutations, however, had no significant impact on antigen presentation or drug resistance, with only 8 mutations identified in 8 patients (6 nCRT-NR and 2 nCRT-R; Pearson’s Chi-squared, p=0.76). HLA polymorphism did not reveal significant differences between response groups, showing no enrichment for specific HLA alleles or loss of heterozygosity (Pearson’s Chi-squared, p=0.64). TCR diversity also showed no association with response (Wilcoxon test, p=0.25), and no differences were detected in TCR gene composition between nCRT-NR and nCRT-R. Notably, we could not quantify the specific repertoire of anti-tumor CD8+ T-cells. Finally, we estimated the probability of HLA-neoantigen-TCR interactions through a machine-learning algorithm and observed that they are more frequent in nCRT-R patients (Wilcoxon test, p&lt0.001). This is the first time that the anti-tumor adaptative immune response was associated with nCRT response based on tumor and host immunogenetic data (tumor-specific neoantigen, HLA, and TCR sequences from TILs), corroborating the growing evidence of the predictive value of the basal immune repertoire.

#3327 Obesity-mediated extracellular vesicle secretion: A potential target for preventing endometrial hyperplasia and cancer initiation.

Lakshmi Narasimhan Chakrapani[1], Kalpana Deepa Priya Doraiyappan[1], Ganesh Yadagiri[1], Jessica Velasquez[1], Shyam Sundaram[1], Takahiko Sakaue[2], Casey Cosgrove[1], George Larry Maxwell[3], David M. O'Malley[1], David E. Cohn[1], Selvendiran Karuppaiyah[1]

[1]Obstetrics and Gynecology, The Ohio State University, Columbus, OH,[2]Gastroenterology, Kurume University, Kurume, Japan,[3]Gynecology, Inova Fairfax Hospital, Falls Church, VA

Introduction: Endometrial cancer (EC) is the most common gynecologic malignancy in the U.S., with obesity contributing to 57% of cases. This study investigates the molecular mechanisms linking obesity to EC, focusing on extracellular vesicle (EV) secretion and oncogenic protein regulation in adipose and uterine tissues. Understanding these pathways could lead to innovative preventive and therapeutic strategies for obesity-related EC.

Methods: Endometrial hyperplasia and cancer were induced in immunocompetent mice using high-fat diets (HFD; 45% or 60% kcal from fat) for 25 weeks. Molecular profiling was performed using LC-MS/MS, while EV quantification and size analysis were conducted via nanoparticle tracking analysis (NTA) and transmission electron microscopy (TEM), respectively. The expression of TMEM205, STAT5, FAS, and PIAS3 was assessed using immunohistochemistry (IHC), ELISA, and RT-PCR in patient and HFD-treated mouse adipose and uterine tissues.

Results: EV secretion and the regulation of oncogenic proteins were significantly elevated in adipose and uterine tissues from obese EC patients compared to non-obese controls. In mice fed a 45% or 60% kcal HFD for 25 weeks, we observed increased body weight, abdominal adipose tissue, uterine horn enlargement, and heightened inflammation, correlating with endometrial hyperplasia and cancer initiation. This was associated with increased EV secretion, upregulated TMEM205, FAS, and STAT5 expression, and downregulation of the tumor suppressor PIAS3. Furthermore, HFD-induced EV secretion carrying oncogenic proteins were linked to elevated serum glucose, lipid and Free fatty acid levels. A small-molecule inhibitor, DAP-5, selectively targeting EV secretion, significantly reduced body weight and adipose tissue accumulation in HFD-treated mice. DAP-5 treatment also restored normal uterine morphology and reduced the expression of EV-related oncogenic proteins.

Conclusion: This study highlights obesity-mediated EV secretion as a key contributor to the pathogenesis of EC and identifies it as a potential target for prevention. Preclinical findings support further investigation into EV-targeted therapies, including initiating first-in-human trials to prevent obesity-driven EC.

CLINICAL RESEARCH: Prognostic Biomarkers 2
Poster Session

#3331 Genomic landscape and prognostic indicators in Taiwanese high-grade glioma.

Chun-Yu Liu, Ji-Lin Chen, Chun-Fu Lin, Jui-To Wang, Wei-Hsin Wang, Cheng-chia Lee, Hsin-Hung Chen, Yi-Wei Chen, Shih-Chieh Lin, Chih-Chun Wu, Chi-Cheng Huang, Sanford P. C. Hsu

Taipei Veterans General Hospital, Taipei, Taiwan

Purpose: High-grade gliomas, including glioblastoma (GBM), are characterized by aggressive phenotypes and a high recurrence rate. Molecular subtyping within high-grade gliomas has advanced diagnostic precision and opened pathways for personalized medicine. IDH mutation status, a critical determinant of high-grade glioma subtypes, reflects distinct patterns in genetic profiles and treatment responses. Given the poor prognosis of high-grade gliomas, there is an urgent need for developing diagnostic tools and therapeutic strategies.
Experimental Design: In this VGHTPE cohort, we recruited 192 patients diagnosed with high-grade glioma/GBM between 2009 and 2024. Tumor samples were collected for genomic DNA extraction and analyzed using the FoundationOne CDx test. We assessed the association between genomic alterations and clinical outcomes.
Results: Tumor samples from 192 patients (ages 4-82) included 134 IDH-wildtype glioblastomas (69.8%) and 58 IDH-mutant high-grade gliomas (30.2%) based on IDH1/2 status. In the VGHTPE cohort, 21 genes displayed genomic alterations in at least 5% of cases. Over 50% of IDH-wildtype glioblastoma patients exhibited TERT promoter or CDKN2A/B mutations, while over 50% of IDH-mutant glioma patients had TP53 and ATRX mutations. Notably, genes predominantly altered in recurrent tissues were linked to Rap1 signaling. Our analysis showed that IDH1 mutations co-occurred with ATRX and CIC alterations but were mutually exclusive with CDKN2A/B, EGFR, MTAP, and PTEN alterations. Alterations in CDKN2A/B, MTAP, EGFR, PTEN, PIK3CA, and KIT were associated with unfavorable outcomes, whereas patients with IDH1, ATRX, and CIC alterations demonstrated better progression-free survival.
Conclusion: This study provides a comprehensive genomic profile of Taiwanese patients with high-grade glioma or GBM, supporting the identification of potential prognostic biomarkers.

#3332 Cancer organoid growth rate as a phenotypic marker to predict adjuvant chemotherapy outcomes in ovarian cancer patients.

Dong Woo Lee[1], Sang-Yun Lee[2], Sung Hun Ju[2], Bosung Ku[3], Yongmun Choi[3], Jeong Woo Lee[4]

[1]Gachon Univ. of Medicine and Science, Suwon-si, Korea, Republic of,[2]Gachon Univ. of Medicine and Science, Seongnam-si, Korea, Republic of,[3]Medical & Bio Decision (MBD) Co., Ltd, Suwon-si, Korea, Republic of,[4]Sungkyunkwan University School of Medicine, Suwon-si, Korea, Republic of

Background: Patient-derived organoid (PDO)-based drug sensitivity tests have been utilized to predict patient outcomes, such as recurrence after adjuvant chemotherapy, by assessing the drug response of patient-derived organoids. This study introduces a multi-parameter assay platform called Organoid Growth-based Oncological Sensitivity Test (OncoSensi) for predicting recurrence of adjuvant therapy in patients with Epithelial Ovarian Cancer (EOC). Patient-derived organoid (PDO)-based drug sensitivity tests have been utilized to predict patient recurrence after adjuvant therapy by assessing the drug response of PDOs. However, we found that PDO growth rates vary among individuals, and it is a very important factor in predicting patient recurrence.
Methods: Among 135 patients, 95 ovarian cancer patients were followed up for recurrence over a 2-year period after receiving adjuvant chemotherapy (Paclitaxel/Carboplatin). PDOs derived from these 95 patients were utilized to measure growth rates and drug responses without subculturing. Recurrence-free survival rates were compared between responders and non-responders identified by OncoSensi.
Results: In this study, we propose an organoid growth-based Oncological Sensitivity Test (OncoSensi) that utilizes the PDO growth rate-based approach to specifically improve the prediction of adjuvant therapy outcomes (recurrence) in patients with EOC. Comparing conventional drug sensitivity tests that considered only single parameters such as the area under the curve (AUC), the proposed OncoSensi algorithm showed improved 6-month, 1-year, 1.5-year recurrence prediction performance in patients with EOC. The recurrence rate within one year for responder groups in OncoSensi is 4.76 %, which is three times lower than the 14.29 % recurrence rate of the previous sensitivity test. For non-responder groups, the recurrence rate within one year for OncoSensi is 41.51 %, which is higher than the 33.96% of the previous sensitivity test. In addition, the responder and non-responder groups were statistically well distinguished (P-value < 0.0001) under OncoSensi index-based analysis conditions. Thus, the good recurrence prediction performance was confirmed using the OncoSensi algorithm. The recurrence rate within one year for responder groups in OncoSensi is 4.76 %, which is three times lower than the 14.29 % recurrence rate of the previous sensitivity test. For non-responder groups, the recurrence rate within one year for OncoSensi is 41.51 %, which is higher than the 33.96% of the previous sensitivity test.

#3333 Ultra-sensitive detection of KRAS mutations in circulating tumor DNA predicts survival in pancreatic adenocarcinoma.

Madison Cox[1], Amy Wells[1], Dominic Vitello[1], Larissa Masnyk[1], Chengwei Peng[2], John Abad[1], Qiang Zhang[2], Pan Du[3], Shidong Jia[3], Akhil Chawla[1]

[1]Department of Surgery, Division of Surgical Oncology, Northwestern University Feinberg School of Medicine, Chicago, IL,[2]Department of Medicine, Division of Medical Oncology, Northwestern University Feinberg School of Medicine, Chicago, IL,[3]Predicine, Inc., Hayward, CA

Introduction: The Kirsten rat sarcoma viral oncogene homolog (*KRAS*) gene is mutated in over 90% of pancreatic adenocarcinoma (PDAC). These mutations are predominantly single-base missense variants, 98% of which are found at codon 12 (*G12*), codon 13 (*G13*), or codon 61 (*Q61*). Numerous studies have demonstrated the clinical utility of these *KRAS* mutations in PDAC, more recently employing liquid biopsy technology as a preferred method to analyze mutations non-invasively. This study aimed to investigate the prognostic potential of pathogenic *KRAS G12*, *G13*, or *Q61* mutations harbored by circulating tumor DNA (ctDNA) in resectable PDAC prior to treatment initiation using an ultra-sensitive liquid biopsy panel.
Methods: Plasma samples for patients at our institution with resectable disease at diagnosis were collected prior to chemotherapy initiation. This study cohort included 45 patients (median age 73; 42% male and 58% female; 86.7% Non-Hispanic White, 2.2% Non-Hispanic Black, 8.9% Hispanic White, 2.2% American Indian). At diagnosis, 68.8% had resectable disease (Stage IA-IIA), 15.6% had borderline resectable disease (Stage IIB), and 15.6% had locally advanced disease (Stage III). 38 patients received 3-12 cycles of neoadjuvant chemotherapy with modified FOLFIRINOX and/or Gemcitabine/Abraxane, 27 patients received 1-8 cycles of adjuvant chemotherapy, and 29 patients underwent upfront or interval surgery with Whipple procedure or distal pancreatectomy. Baseline ctDNA was analyzed for *KRAS G12*/*G13*/*Q61* mutations using the PredicineCARE liquid biopsy assay (20,000x sequencing depth) and the PredicineCARE Ultra assay (>100,000x sequencing depth), providing full *KRAS* gene coverage.
Results: The PredicineCARE assay identified pathogenic *KRAS* mutations (*G12*/*G13*/*Q61)* in 11 patients. Of these, 8 had co-occurring *G12* and *Q61* mutations. Presence of any *KRAS* mutation determined by CARE assay at baseline was not significantly associated with overall survival (OS) (HR 2.96, 95% CI 0.85-10.29), however, detection of a *G12* mutation was significantly predictive of worse OS (HR 4.93, 95% CI 1.39-17.44). Co-occurrence of *KRAS G12* and *Q61* mutations in baseline ctDNA was also predictive of worse OS (HR 3.89, 95% CI 1.12-13.54). The PredicineCARE Ultra assay identified KRAS mutations in an additional 7 patients who were mutation-negative by the standard CARE assay. Baseline *KRAS G12/G13* mutations detected with the Ultra assay were predictive of OS (HR 3.71, 95% CI 1.04-13.28), in addition to demonstrating 100% concordance with CARE assay results for overlapping mutations.
Conclusion: Ultra-sensitive liquid biopsy assays such as the PredicineCARE Ultra panel demonstrate robust detection of pertinent KRAS mutations that significantly improves prognostic stratification for PDAC patients, demonstrating the potential of advanced liquid biopsy technology in improving outcomes in PDAC.

#3334 Expression analyses of SLC3A2 and its associated genes in glioma progression.

Birnur Sinem Karaoglan[1], Ozan Topcu[1], Ecren Ecem Uzlu[1], Osman Aliskan[1], Thomas Mohr[2], Nazli Cakici[3], Ahmet Tulgar Basak[3], Asli Cakir[4], Nihal Karakas[5]

[1]Cancer Research Center, Research Institute for Health Sciences and Technologies (SABITA), Istanbul Medipol University, Istanbul, Turkey,[2]Center of Cancer Research, Department of Medicine, Medical University of Vienna and Comprehensive Cancer Center, Vienna, Austria,[3]Department of Neurosurgery, Istanbul Medipol University School of Medicine, Istanbul, Turkey,[4]Department of Pathology, Istanbul Medipol University School of Medicine, Istanbul, Turkey,[5]Department of Medical Biology, Istanbul Medipol University International School of Medicine, Istanbul, Turkey

High grade gliomas (grade III and IV) including glioblastomas (GBM, grade IV, IDH wild type), are highly aggressive brain tumors with limited treatment options and poor prognosis. Tumor recurrence is inevitable with standard methods including surgical debulking, radio- and chemotherapies. For this reason, a broad range of studies focus on the discovery of diagnostic and therapeutic markers to cure the malign disease. SLC3A2, a polyamine transporter, has been implicated in chemoresistance of tumors and identified as a prognostic marker in renal cell carcinoma. Accordingly, in this study, we examined i) the prognostic impact of SLC3A2 expression in gliomas, ii) its association with differentially expressed gene networks, and iii) its molecular characteristics to elucidate its role in glioma biology. Immunohistochemical and western blot analyses revealed significant overexpression of SLC3A2 in high grade glioma tissues compared to controls. Robust SLC3A2 expression was also observed in a pannel of GBM cell lines. Cohort analysis of the TCGA French glioma patient dataset (n=264) stratified patients by SLC3A2 expression, showing a significant survival advantage for low expressors across glioma grades (p=.0021). This survival benefit was particularly pronounced in high-grade gliomas, underscoring the link between SLC3A2 expression and tumor aggressiveness. Differentially expressed gene analysis identified several druggable genes co-regulated with SLC3A2. Differential expression of VEGFA and ADM in SLC3A2 high-expressors suggests a potential role of Slc3a2 in tumor angiogenesis, while links to CHI3L1 and CXCL14 imply roles in enhancing tumor invasiveness and immune modulation. In contrast, TOX3 and SNAP91 were enriched in SLC3A2 low-expressors, pointing to suppression of neuronal differentiation and maintenance of glioma stem-like properties. Weighted gene co-expression analysis linked SLC3A2 to genes involved in cytoskeletal remodeling (DMPK), and chromatin regulation (RNF40), reinforcing its role in tumor plasticity. Negative correlations with SIRT1 and KAT6B suggest a metabolic shift favoring tumor-specific survival and growth. These findings lay the groundwork for exploring SLC3A2 as a therapeutic target and its potential in personalized therapies. Further studies will clarify its mechanistic role in gliomagenesis and its utility in clinical applications. This study was supported by The Scientific Research Commision of İstanbul Medipol University with project number 2023-66.

#3335 Non-tumor-bearing tissue: A prognostic biomarker for cancer.

Ji Hye Choi[1], Yeong Hak Bang[2], YeonJu Lee[1], Woong-Yang Park[2]

[1]Samsung Advanced Institute of Health Sciences and Technology, Sungkyunkwan University, Seoul, Korea, Republic of,[2]Samsung Genome Institute, Samsung Medical Center, Seoul, Korea, Republic of

Background: We hypothesized that distinct microenvironments either support or inhibit the growth of cancer cells, and that the non-tumor bearing tissue (NBT) reflects these microenvironments. Additionally, we assumed that the more closely the characteristics of the NBT resemble those of the tumor, the greater the likelihood of supporting cancer cell progression and promoting disease recurrence.
Method: We investigated TCGA dataset with more than 20 samples of NBT and paired tumors. We employed a scoring system using the top 10-50 DEGs with high fold-change values in tumors. We scored the expression of the tumor-supportive signature genes in the NBT using single-sample gene set enrichment analysis (ssGSEA). We evaluated the mean score derived from the top 10-50 in the NBT to categorize the patients into two groups that most effectively facilitated prognostic differentiation. The groups were defined as follows: patients showing relatively high tumor supportive signatures in NBT (patients with tumor-supportive microenvironment in NBT; TSM), and patients showing relatively low supportive signatures in NBT (patients with healthy microenvironment in NBT; HM).
Results: Among the 12 cancers, the significantly poorer overall survival (OS) in TSM were identified in head and neck cancer squamous cell carcinoma (HNSC; hazard ratio [HR]: 2.06 [1.03 - 4.10]), lung squamous cell carcinoma (LUSC; hazard ratio [HR]: 3.87 [1.69 - 8.90]), kidney renal cell carcinoma (KIRC; hazard ratio [HR]: 2.85 [1.31 - 6.21]). In other cancer types, there are no prognostic differentiations. The 3-year overall survival in the TSM group compared to the HM group were markedly lower: HNSC (0.569 vs. 0.813), LUSC (0.242 vs. 0.492), and KIRC (0.250 vs. 0.689). Pathway analysis suggested that leukocyte-mediated immunity and inflammatory pathways were upregulated, whereas the maintenance of epithelial barriers was decreased in the NBT of the TSM group in HNSC, LUSC and KIRC. Immune cell deconvolution analysis revealed that the TSM group had a significantly higher proportion of neutrophils compared to that of the HM group in HNSC and LUSC. In KIRC, significantly higher proportion of CD8+ T cells and memory CD4+ T cells were observed in the NBT of the TSM group.
Conclusions: Our findings suggest that NBT serves as a prognostic biomarker that effectively predicts cancer invasiveness and tumor-promoting inflammation, particularly in HNSC, LUSC, and KIRC. This also highlights the importance of maintaining a healthy microenvironment.

#3336 Early detection of tumor relapse, racial disparity, and treatment resistance in triple negative breast cancer.

Amy H. Tang[1], Richard A. Hoefer[2], Mary L. Guye[3], Billur Samli[4], Janet S. Winston[4], Jennifer Koblinski[5], Valentina Robila[6], Michael O. Idowu[7], Rick J. Jansen[8], Harry D. Bear[9]

[1]Biomedical and Translational Sciences, Macon & Joan Brock Virginia Health Sciences at Old Dominion University, Norfolk, VA,[2]Sentara Surgery Specialists, Sentara CarePlex Hospital, Sentara Cancer Network, Sentara Healthcare, Norfolk, VA,[3]Sentara Cancer Network, Sentara Healthcare, Sentara Surgery Specialists, Sentara CarePlex Hospital, Newport News, VA,[4]Pathology Sciences Medical Group, Sentara Norfolk General Hospital, Norfolk, VA,[5]Massey Cancer Center, Virginia Commonwealth University, Richmond, VA,[6]Department of Pathology, Division of Anatomic Pathology, Virginia Commonwealth University, Richmond, VA,[7]Pathology, Virginia Commonwealth University, Richmond, VA,[8]Masonic Cancer Center, University of Minnesota, Minneapolis, MN,[9]Departments of Surgery and Microbiology & Immunology, Massey Comprehensive Cancer Center, Virginia Commonwealth University/VCU Health, Richmond, VA

Introduction: Triple-negative breast cancer (TNBC) is an aggressive breast cancer subtype that disproportionately affects BRCA1 mutation carriers and young Black/white women. Black/AA patients have the highest mortality and the shortest survival of any racial/ethnic group in the US. Pembrolizumab and neoadjuvant chemotherapy (NACT) has become the standard of care (SOC) for high-risk early-stage TNBC. Pathologic complete response (pCR) predicts good outcome, whereas pathologic incomplete response (pIR) with high residual cancer burden (RCB) is correlated with early tumor relapse, treatment resistance, and poor survival. Many similarly treated patients with identical TNM and RCB classifications experience treatment disparity, distinct relapse rates, and disparate survival. Current methods fall short in predicting early tumor relapse/chemo-resistance/patient survival with high accuracy in the clinic.

Methods: We have conducted IHC staining of EGFR, Ki67, SIAH and PD-L1 expression in a large cohort of TNBC patients (> 1,000 patients), of which 48% patients are Black/AA and 48% patients are white patients, from the Sentara Cancer Network and VCU Massey Comprehensive Cancer Center, both of which serve socio-economically-disadvantaged, medically underserved, and underinsured racial/ethnic minorities in low-income communities in Virginia.

Results: We found that high SIAH expression in residual tumors reflects ineffective therapy and persistent EGFR/K-RAS/SIAH pathway activation (ON) and predicts early relapse, chemo-resistance, and poor survival. Conversely, low SIAH expression in residual tumors reflects effective therapy and EGFR/K-RAS/SIAH pathway inactivation (OFF) and predicts tumor remission and good survival. We detected a major racial disparity in the large TNBC cohort. Black/AA breast cancer patients suffer a higher MBC mortality and reduced survival compared to their white counterparts in our clinical studies similar to the SEER/CDC databases.

Conclusions: We found that persistent EGFR/RAS/SIAH pathway activation is a major driving force in TNBC malignancy. As an evolutionarily conserved RING-domain E3 ligase, SIAH is a new prognostic biomarker for patient risk stratification, tumor relapse prediction, and racial disparity detection in TNBC. We aim to validate the prognostic power of SIAH and develop a SIAH-centered biomarker panel for patient risk stratification and relapse/resistance/survival prediction in TNBC.

#3337 Unveiling m6A epitranscriptome-related genomic variations in bladder cancer: predictive biomarkers for disease progression and treatment outcome towards tailored therapeutics.

A. Scorilas[1], K.-M. Pilala[1], P. Tsiakanikas[1], K. Panoutsopoulou[1], M.-A. Papadimitriou[1], K. Soureas[1], G.-C. Giagkos[1], P. Levis[1], G. Kotronopoulos[1], Z. Kanaki[2], I. Prassas[3], L. Dimitrakopoulos[3], G. Yousef[3], K. Stravodimos[1], S. Koroneou[1], M. Avgeris[1];
[1]National and Kapodistrian University of Athens, Athens, Greece, [2]Biomedical Research Foundation Academy of Athens, Athens, Greece, [3]University of Toronto, Toronto, ON, Canada

Due to its highly heterogenous molecular landscape, bladder cancer (BlCa) is still characterized by non-personalized prognosis and treatment decisions. N6-methyladenosine (m6A) has emerged as the most common and conserved internal mRNA modification, regulating RNA metabolism and translation. Herein, we have profiled mutations and copy number variations (CNVs) within m6A RNA machinery genes and assessed their clinical relevance in BlCa patients' prognosis and treatment outcome. DNA-seq libraries were prepared from 96 bladder specimens (tumors: n=87; normal urothelium: n=9) using a custom-designed panel of enrichment probes for m6A writers (*METTL3, METTL14, METTL16, VIRMA, WTAP, RBM15, RBM15B*, *ZC3H13*), erasers (*FTO, ALKBH5*) and readers (*YTHDF1, YTHDF2, YTHDF3, YTHDC1, YTHDC2, IGF2BP1, IGF2BP2, IGF2BP3*). *METTL3* methyltransferase expression was quantified by RT-qPCR. Mutational and CNV analyses of DNA-seq data were performed by SNPNexus and CNVkit, respectively. Kaplan-Meier curves and Cox regression analysis were implemented for patient's survival analysis. Internal validation was performed by bootstrap analysis. DNA-seq on DNBSEQ-G400 revealed that ~30% of bladder tumors (25/87) harbored deleterious mutations in m6A writers, while m6A erasers (3,2%) and readers (5,3%) were less mutated. CNVs were found in ~60% of tumors (52/87), with *VIRMA* frequently amplified (22%) in superficial (TaT1) tumors. Reduced *METLL3* expression was detected in muscle-invasive tumors (p=0.009) and associated with increased risk for NMIBC relapse (p=0.002) and progression (p=0.028) to MIBC. Moreover, MIBC patients with deleterious mutations in m6A writer's complex presented significantly higher progression risk (p=0.036) and worse survival (p=0.010), while *VIRMA* copy-number gain/amplification was associated with significantly increased risk of short-term relapse (p=0.019) in NMIBC. Finally, multivariate Cox regression confirmed m6A writer complex mutations as independent marker for patients' progression (HR=3.242, p=0.021) and death (HR=5.388, p=0.006) in MIBC, and of *VIRMA* gain/amplification as an independent indicator of NMIBC relapse risk (HR=3.564, p=0.010).Genomic variations in m6A machinery emerge as modern molecular markers to address BlCa clinical heterogeneity and guide personalized prognosis and treatment/monitoring decisions. *Acknowledgements:* The research project was supported by the Hellenic Foundation for Research and Innovation (H.F.R.I.) under the "2nd Call for H.F.R.I. Research Projects to support Faculty Members & Researchers" (Project Number: HFRI-FM20-3765)

#3338 A CpG methylation based epigenetic signature for recurrence prediction in stage II/III colorectal cancer: *The CENSURE Study*.

Caiming Xu[1], Silei Xu[1], Joan Maurel[2], Man Li[3], Ajay Goel[1]

[1]Beckman Research Institute of The City of Hope, Monrovia, CA,[2]Department of Medical Oncology, Hospital Clinic of Barcelona, Barcelona, Spain,[3]Department of Oncology, The Second Affiliated Hospital of Dalian Medical University, Dalian, China

Introduction: Adjuvant chemotherapy (ACT) is the standard of care for patients with stage III or high-risk stage II colorectal cancer (CRC) following curative-intent resection. However, over 30% of these patients experience recurrence despite treatment, highlighting the urgent need for developing predictive biomarkers of response to ACT. This study sought to identify epigenetic biomarkers for predicting recurrence in stage II/III CRC.

Patients and Methods: This study included three phases: discovery, training, independent testing. In the discovery phase, we performed genomewide methylation profiling analysis between recurrent (recurrence-free survival, RFS < 5 years) and non-recurrent patients with CRC. A LASSO-based machine learning algorithm was employed to refine and optimize the candidate CpG sites. Subsequently, we developed and tested a methylation biomarker panel by quantitative pyrosequencing assays, followed by eXtreme Gradient Boosting (XGB) machine-learning algorithm in both the training (n = 236) and testing (n = 175) cohorts. Finally, we established the CENSURE (***C****pG m****E****thylatio****N****-based epigenetic ****S****ignat****URE***) model, which combined the CpG methylation panel and carcinoembryonic antigen (CEA) levels, to predict recurrence in stage II/III CRC.

Results: A panel of 8 CpG candidates identified in the discovery phase was refined to 6 using XGB in the training cohort. The 6-CpG panel demonstrated robust ability to predict recurrence, with AUC values of 91.2% and 79.3% in the training and testing cohorts, respectively. Multivariate Cox regression analysis revealed that CEA ≥ 5 ng/mL (HR 2.92; 95% CI: 1.81-4.70) and the CpG panel (HR 19.5; 95% CI: 8.78-43.1) were independent predictors of recurrence. Building on this, we developed the CENSURE model, which integrates the CpG panel with CEA. The CENSURE model achieved AUC values of 95.2% and 86.1%, with sensitivities of 83.9% and 83.3% in the training and testing cohorts, respectively. CENSURE high-risk patients exhibited significantly higher 5-year (71.5% vs 8.0%) and 2-year recurrent rates (48.0% vs 5.4%). Notably, the CENSURE model outperformed CEA risk stratification alone, correctly predicting an additional 46.5% (40 out of 86) of recurrence cases in the entire study cohort.

Conclusions: In conclusion, the CENSURE assay represents a novel potential advance with a significant clinical impact for postoperative recurrence prediction in stage II/III CRC.

#3339 Evaluation of GATA6 and KRT17 immunostaining for subtype classification in pancreatic ductal adenocarcinoma.

Ruomeng Fang[1], Joan Miguel Romero[1], Yifan Wang[2], Alicia Gomez Mendez[3], Adeline Cuggia[3], George Zogopoulos[3]

[1]Clinical and Translational Research, McGill University, Montreal, QC, Canada,[2]Surgical Oncology, MD Anderson Cancer Center, Houston, TX,[3]Research Institute of the McGill University Health Centre, Montreal, QC, Canada

Pancreatic ductal adenocarcinoma (PDAC) is a highly lethal malignancy with poor survival outcomes. Transcriptomic profiling has identified distinct PDAC subtypes associated with survival, highlighting their clinical relevance. However, reliance on RNA sequencing for subtype classification is not feasible in routine clinical practice, underscoring the need for surrogate biomarkers that are both effective and practical for predicting patient outcomes. This study evaluated GATA6 and KRT17 as multiplex immunohistochemistry (IHC) biomarkers to develop a prognostic model for PDAC subtype classification. Using a tissue microarray (TMA) comprising 130 patient-derived xenografts (PDXs), we quantified cell IHC positivity and stratified samples into subtypes based on GATA6 and KRT17 expression. Whole-slide staining of representative patient tumors validated the consistency of subtype classifications between PDXs and corresponding patient tumors. Patient TMAs (224 cores from 82 tumors) were subsequently analyzed to refine the classification system, incorporating GATA6 and KRT17 positive cell percentages, staining intensity (H-scores), and clinical variables into a comprehensive prognostic model. Initial classification based on PDX models demonstrated non-significant distinct survival trends ($p=0.14$), likely due to sample size limitations. However, a refined model applied to patient TMAs that incorporated additional parameters effectively stratified patients into prognostic groups with significantly different overall survival ($p=0.042$). These findings highlight the utility of GATA6 and KRT17 as surrogate classifiers for PDAC subtype classification and prognostication, offering a practical alternative to transcriptomic sequencing in HR-proficient PDAC.

#3340 A miRNA based signature for the individual assessment of the prognosis of patients with seminoma.

Farzaneh Zohari[1], Lea Eckhart[2], Hiresh Ayoubian[1], Hans-Peter Lenhof[2], Rainer Bohle[3], Felix Bremmer[4], Fabian A. Gayer[5], Yue Che[6], Marieke Vermeulen-Spohn[6], Tim Nestler[7], Michael Stockle[8], Julia Heinzelbecker[8], Kerstin Junker[8]

[1]Department of Urology and Pediatric Urology, Saarland University, Homburg/Saar, Germany,[2]Saarland Informatics Campus, Saarland University, Center for Bioinformatics, Saarbrucken, Germany,[3]Institute of Pathology, Saarland University Medical Center and Saarland University, Homburg/Saar, Germany,[4]Institute of Pathology, University Medical Center Gottingen, Gottingen, Germany,[5]Department of Urology, University Medical Center Gottingen, Gottingen, Germany,[6]Department of Urology, Heinrich-Heine University, Medical Faculty, Dusseldorf, Germany,[7]Department of Urology, Bundeswehr Central Hospital Koblenz, Koblenz, Germany,[8]Department of Urology and Pediatric Urology, Saarland University Medical Center and Saarland University, Homburg/Saar, Germany

Introduction: Due to the risk of long-term toxicities in young seminoma patients, surveillance regimens nowadays are the standard of care in patients without metastases. Nevertheless, up to 20% will relapse with the necessity of definitive treatment exposing them to an even higher amount of therapy compared to in the adjuvant setting. This study seeks to establish a prognostic miRNA profile on primary tumors utilizing bioinformatics tools to differentiate between metastatic (m) and non-metastatic (nm) seminomas.
Materials and methods: MiRNA was extracted from formalin-fixed paraffin-embedded sections. Two cohorts of patients with seminoma (each 24 patients, each 12 nm and 12 m) were investigated by microarray analysis. Validation was performed in 103 patients (47 nm and 56 m) through quantitative PCR (qPCR) using the TaqMan® assay, with RNU48, miR-191-5p, and miR-361-5p serving as references. Statistical and bioinformatics analyses were performed by using the Mann-Whitney U test and machine learning algorithms.
Results: The bioinformatics analysis of microarrays identified 16 miRNAs exhibiting an accuracy >70% in differentiating m tumors from nm ones. qPCR analysis of seven selected miRNAs demonstrated significant expression differences between m and nm tumors for miRNA-371a-5p, miR-512-3p and miR-517a-3p ($p<0.05$), contingent upon the reference used. Analyzing metachronous and synchronous m tumours separately, all 3 miRNAs showed significantly different expression only in synchronous m, although a trend was observed in metachronous m.
Conclusions: By employing machine-learning on microarray data, we established a miRNA signature that differentiates metastatic from non-metastatic seminomas with high accuracy. The findings have been validated for 3 miRNAs in independent cohorts by qPCR, reinforcing the potential of miRNAs as prognostic markers in seminomas. Ongoing validation efforts are currently being conducted in independent cohorts to define a robust miRNA signature.

#3341 The co-expression and prognostic significance of the HER-family members, EGFRvIII, CD44, CD109 and Claudin 18.2 in patients with stomach adenocarcinoma.

Tina Al-Janaby[1], Izhar Bagwan[2], Said Khelwatty[1], Helmout Modjtahedi[3]

[1]Kingston Univ. London School of Life Sci., Kingston, United Kingdom,[2]Royal Surrey Hospital, Guildford, United Kingdom,[3]Kingston Univ. London School of Life Sci., Kingston upon Thames, United Kingdom

Stomach cancer remains a major cause of death worldwide. While targeted therapies with anti-HER2 monoclonal antibodies (mAbs) such as trastuzumab, antibody-drug-conjugate trastuzumab deruxtecan, and more recently zolbetuximab, an anti-claudin 18.2 (CLDN 18.2) mAb, have been approved for the treatment of stomach cancer, many patients may not respond or have a response of short duration to such treatments. Therefore, there is an urgent need for identification of novel biomarkers for the response to therapy, and the development of more effective therapeutic interventions. In the past few decades, the crosstalk between the HER-family and other biomarkers such as cancer stem cells have been proven to promote tumorgenicity, metastasis and resistance to anti-HER2 therapy. Therefore, in this study, for the first time, we examined the relative expression levels, and prognostic significance of all members of the HER-family, the type-III EGFR mutant (EGFRvIII), CD44, CD109, and CLDN 18.2 in patients with stomach cancer by immunohistochemistry. The staining was scored at different cut off values (i.e. >5%, 10%, 20% and 50% of tumours with positive staining), the cellular location, and the intensity of staining. In addition, the prognostic significance of the expression and co-expression of these biomarkers were also investigated. We found the expression of wild-type EGFR (12.8%), HER2 (82.1%), HER3 (9.0%), HER4 (33.3%), EGFRvIII (33.3%), CD44 (41.0%), CD109 (60.3%) and CLDN 18.2 (39.7%) in tumour specimens from 78 patients. Furthermore, the expression of HER2 was accompanied with the co-expression of EGFR (9%), HER3 (8%), HER4 (27%), EGFRvIII (28%), CD44 (33%), CD109 (49%) and CLDN18.2 (32%) in the cases examined respectively. [SK1] [SK2] Interestingly, at a cut-off value of >5% of tumour cells with positive staining, the co-expression of HER2/EGFRvIII (7.26 vs 4.43 years, P=0.028), EGFRvIII/CD44 (7.02 vs. 2.17 years, P=0.003) HER2/EGFRvIII/CD44 (6.93 vs. 2.33 years, P=0.011), and CD109/CLDN 18.2 (7.01 vs 3.99 years, P= 0.021) were associated with a poorer overall survival. Moreover, the membranous expression of CD109 (7.06 vs. 3.93 years, P=0.028), and its co-expression with EGFRvIII/CD44 were also associated with a poorer overall survival (7.01 vs 1.65 years, P=0.0009) and a higher risk of poor overall survival [SK3] (HR=4.21, P=0.0009) as well as CLDN 18.2 immunostaining of intensity of 3+ (6.83 vs. 3.50 years, P=0.032). All these remained as independent prognostic factors for overall survival in multivariate analysis. Taken together, our results suggest co-expression of HER-2 with other members of the HER family, EGFRvIII, CD44, CD109 and CLDN 18.2 occurs in patients with stomach cancer and warrants further investigation on the predictive value of such biomarkers for the response to therapy with inhibitors to HER family members and CLDN 18.2.

#3342 Congruence of tumor-specific ctDNA and radiographic recurrence in high-risk sarcoma.

Chahat Rana, Daniel Y. Wang, Amanda M. Dann, Nissy A. Alex, **Sanjay Chandrasekaran**

Harold C. Simmons Comprehensive Cancer Center, Dallas, TX

Background: Surveillance imaging remains the best method for detecting recurrence of high-risk sarcoma in patients off therapy. Whether tumor-specific ctDNA (circulating tumor DNA, Signatera) adds prognostic value to radiography remains unknown. We hypothesize that ctDNA conversion from negative to positive (mean tumor molecules per milliliter [MTM/ml]) will correlate with radiographic recurrence.

Methods: We retrospectively assessed congruence of tumor-specific ctDNA and radiographs at serial timepoints in high-risk sarcoma patients 1) off therapy and on surveillance, with 2) scans showing no evidence of disease (NED) and a negative ctDNA +/- 28 days of those scans, and 3) ≥ 1 follow-up data point. Congruence was achieved if ctDNA and scans remained negative or if ctDNA conversion to positivity occurred prior to or ≤ 21 days post imaging recurrence.

Results: 16 patients (9 male/7 female; median age 57yrs, Range 39-77) treated from 9/2021-9/2024 with bone or soft tissue sarcoma (STS) met study criteria. Histologies included 3 ewing sarcoma, 3 leiomyosarcoma (LMS), 3 liposarcoma (LPS), 1 each for osteosarcoma, sclerosing epithelioid fibrosarcoma (SEF), malignant pecoma, clear cell, undifferentiated pleomorphic, and other (2). 3 patients with metastatic disease (LMS, ewing, osteosarcoma) met study criteria. Prior therapies included surgery (14/16), radiation (7/16), and chemotherapy (4/16, 3/3 metastatic). Median follow-up time was 330.5 days (range 73-810) with 6 median assessments per patient (2-11). The median interval between the initial negative ctDNA and NED scan was 10 days (1-28) and 16 days (1-63) across all assessments. 10/16 patients (62.5%) remained NED on scans and 6 (37.5%) recurred, with ctDNA congruence in 9/10 (90%) and 5/6 (83.3%), respectively. 1/10 (10%) NED patients with myxoid LPS had a single positive ctDNA event (0.18 MTM/mL) with 2 subsequent negative events. All 3 metastatic patients recurred along with 1 SEF, 1 LMS, and 1 pleomorphic LPS. 5/6 positive ctDNA levels were detected 66 (pleomorphic LPS), 49, and 14 (both LMS) days before scans and 8 days post scans (ewing & SEF). An osteosarcoma patient with progression in pulmonary metastasis had 2 negative ctDNA levels before conversion (13.94 MTM/mL, 158 days) and required 2 lung biopsies prior to pathologic confirmation. Altogether, ctDNA was congruent in 14/16 (87.5%) cases, with sensitivity of 83.3% (35.9-99.6%) and specificity of 90% (55.5-99.8%). PPV and NPV were 83.3% (42.9-97.1%) and 90% (59.8-98.2%).

Conclusions: Our findings show that tumor-specific ctDNA may be a useful prognostic sarcoma surveillance tool in high-risk bone and STS patients with local or metastatic disease. ctDNA positivity in 2 cases >6 weeks prior to scans suggests potential to detect early DNA shedding and the need to further examine temporal associations between ctDNA and scans in surveillance patients.

#3343 Centrosomal and mitotic gene expression profiles across cancer types: Implications for tumor progression and survival outcomes.

Christopher L. Farrell, Amy Turner, Alex Feltus, Victoria Cipollino

Clemson University, Clemson, SC

Introduction: Genes involved in centrosome function, microtubule dynamics, and mitotic regulation are critical for normal cell division. In cancer, dysregulation of these processes can lead to chromosomal instability and tumor progression. The genes CEP72, HAUS4, TUBGCP4, HAUS2, PLK1, and OFD1 play essential roles in cell cycle regulation, mitosis, and microtubule dynamics, particularly in spindle assembly and centrosome function. These genes are involved in interconnected cellular processes related to mitotic progression, and their altered expression may be linked to cancer progression and survival outcomes.
Objective: This study analyzes the expression profiles for these six genes across thirteen cancer types, aiming to identify associations between dysregulation of these genes and cancer progression, as well as their impact on survival outcomes.
Methods: We analyzed the expression of these six genes and the tumor suppressor genes APC and PTEN using RNA sequencing data from TCGA cancerous tissues and normal control tissues from GTEx for the thirteen cancer types. Differential gene expression was assessed using the DESeq2 R package, which models RNA sequencing data using a negative binomial distribution. Results:
Our analysis identified significant changes in gene expression across cancers, including bladder (BLCA), colon (COAD, READ), esophagus (ESCA), kidney (KICH, KIRC, KIRP), liver (LIHC), prostate (PRAD), stomach (STAD), and thyroid (THCA). Elevated CEP72 expression was associated with lower progression-free survival (PFS). We observed consistent downregulation of CEP72, HAUS2, and PLK1 across several cancers, with significantly adjusted p-values (padj < 1E-5). OFD1, HAUS4, and PTEN showed tissue-specific expression patterns, with upregulation in cancers such as prostate (padj = 1.1E-11) and thyroid (padj = 8.5E-5). We further identified cancer-specific expression profiles for these six genes involved in cell division. These findings suggest complex regulatory mechanisms influencing tumor progression and metastasis. Further analysis of these mitotic and centrosomal proteins revealed significant cancer-specific correlations between gene expression levels of CEP72, HAUS4, TUBGCP4, HAUS2, PLK1, OFD1 and patient outcomes, including PFS, disease-specific survival, and overall survival.
Conclusion: This study underscores the interconnectedness of centrosomal and mitotic genes, suggesting that downregulation of key proteins like CEP72, HAUS2, and PLK1 disrupts essential cell migration, proliferation, and adhesion pathways. Conversely, upregulation of HAUS4 may enhance tumor suppressor functions and immune modulation. Analyzing these genes within their broader biological networks provides valuable insights into their roles in cancer progression, offering potential as cancer-specific biomarkers or therapeutic targets.

#3344 The 31-gene expression profile identifies patients at risk of developing early distant metastases and can guide risk-appropriate surveillance strategies.

Merve Hasanov[1], Elshad Hasanov[1], David Pariser[2], Sonia Morgan-Linnell[3], Samuel Dierks[3], Brian Martin[3], Abel Jarell[4]

[1]Comprehensive Cancer Center, The Ohio State Univeristy, Columbus, OH,[2]Pariser Dermatology, Norfolk, VA,[3]Research and Development, Castle Biosciences, Inc., Friendswood, TX,[4]Northeast Dermatology Associates, Portsmouth, NH

Introduction: Up to 20% of patients with stage I-II cutaneous melanoma (CM) will develop distant metastases (DMs), with the most frequent DM sites being the liver, lungs, bone, and brain. Although patients who develop DM have poor prognosis, trials of new immunotherapies in patients with DM have reported 5-year survival rates as high as 50%. Critically, early detection of DM, when tumor burden is lower, tends to lead to better treatment responses. Thus, it is important to identify patients at the highest risk of developing DM so clinicians can recommend risk-appropriate surveillance and treatment plans. We previously assessed the ability of the 31-gene expression profile (31-GEP) to predict CNS metastases, and here we expand our analysis to assess 31-GEP risk prediction for DMs to the lung, liver, and bone.

Methods: We conducted a retrospective analysis of patients with stage I-II CM clinically tested with the 31-GEP from 2013-2017 (n=1,661). Differences in DM rates between groups were assessed with Chi-squared test. Survival estimates (DM-free survival, DMFS) were estimated using Kaplan-Meier and compared using the log-rank test. (*, $p<0.05$; **, $p<0.001$).

Results: Among patients with stage I-II CM, a total of 90 DMs developed in 67 (4.0%) patients to the liver (n=48), lung (n=22), and/or bone (n=20). A higher percentage of patients with Class 2B than Class 1A developed DM to the liver (7.4% vs. 1.2%, **), lung (4.5% vs. 0.6%, **), and bone (3.0% vs. 0.8%, *). A 31-GEP Class 2B result was associated with significantly lower 5-year DMFS than Class 1B/2A or Class 1A for liver (91.7%, 92.2%, vs. 98.9%, **), lung (95.0%, 97.6%, vs. 99.4%, **), and bone (96.4%, 98.0%, vs. 99.2%, *). Of those with DM, the median time to develop DM (Class 1A, 1B/2A, vs. 2B) was 2.43, 2.22, vs. 2.27 years for liver; 1.74, 3.20, vs. 1.10 years for lung; and 3.2, 2.05, vs. 1.30 years for bone.

Conclusion: Among patients with stage I-II CM, a greater percentage of those with a Class 2B 31-GEP developed DM at all studied sites, and 5-year DMFS was significantly lower for those with a Class 2B result. Thus, including 31-GEP testing with AJCC staging can allow clinicians to identify patients at higher risk of DM and recommend risk-appropriate surveillance modalities and frequency for early detection and treatment of DM.

#3345 Application of cGAS-immunopositive micronuclei as an indicator of tumor aggressiveness in liposarcoma.

Kiyota Kato[1], Toru Motoi[1], Yu Naito[2], Masumi Ogawa[1], Chihiro Onda[1], Hideo Arai[1], Shin-ichiro Horiguchi[1], Toshihide Hirai[3], Tsunekazu Hishima[1]

[1]Pathology, Tokyo Metropolitan Cancer and Infectious Diseases Center Komagome Hospital, Tokyo, Japan,[2]Nagoya University Graduate School of Medicine, Nagoya, Japan,[3]Musculoskeletal Oncology, Tokyo Metropolitan Cancer and Infectious Diseases Center Komagome Hospital, Tokyo, Japan

Background: Recent molecular biological studies have revealed that chromosomal instability (CIN) promotes the malignant phenotype of tumors. CIN causes chromosomal segregation errors, leading to micronuclei (MN) formation. Ruptured MNs activate the cGAS-STING pathway, an intracellular DNA sensor, and induce metastasis and invasion. Histological confirmation of MNs is thought to be uncertain and not reproducible. On the other hand, cGAS is localized in a subset of MN by immunohistochemistry, so we attempted to apply cGAS-positive MN as an indicator of CIN and tumor aggressiveness in liposarcoma, which is reported as one of the tumors with the highest frequency of CIN among various malignant tumors.
Study Design: Formalin-fixed paraffin-embedded biopsy and surgical specimens of liposarcoma of four histological types, namely well-differentiated (WLPS) (n=18), dedifferentiated (DLPS) (n=32), myxoid (MLPS) (n=6), and pleomorphic liposarcoma (PLPS) (n=7) were examined. In addition, benign lipomatous tumors (n=17) were also tested. Ten cases of non-lipomatous high-grade sarcoma were used as controls. Because DLPS results from the dedifferentiation of WLPS, it comprises differentiated (W) and dedifferentiated (D) components. Immunohistochemical staining for cGAS was performed, and the number of cGAS-positive micronuclei in 500 tumor cells of each tumor was counted. For DLPS, dedifferentiated cells (D cells) in the D component and lipogenic cells (L cells) and non-lipogenic cells (N cells) in the W component were evaluated separately.
Results: cGAS immunostain highlighted a subset of micronuclei, as well as mitotic figures, and some small punctate structures within the main nuclei. The average number of cGAS-positive MNs was 1.2 for benign lipomatous tumor (n=17), 1.0 for myxoid liposarcoma (MLPS, n=6), 34.1 for pleomorphic liposarcoma (PLPS, n=7), 23.2 for D cells in (DLPS, n=32), 3.1 for L cells and 3.6 for N cells in WLPS / W-component (n=43), 24.2 for referenced sarcomas, respectively. The number of cGAS-positive micronuclei was significantly higher in aggressive sarcomas (PLPS and D components of DLPS) than in translocation-associated sarcoma (MLPS), WLPS / W-component, and benign tumors. Although the D-component and W-component / WLPS share a similar complex karyotype, the number of c-GAS positive MNs was significantly higher in D cells rather than L cells (t-test, p=0.0001) and N cells (t-test, p=0.0002).
Conclusion: MNs can be visualized by cGAS immunostain. Significant increases in cGAS-positive MNs were observed in aggressive liposarcomas with complex karyotypes. Furthermore, increased cGAS-positive MNs are associated with malignant progression in DLPS. cGAS-positive MNs may be applicable as an objective indicator of tumor aggressiveness and CIN.

#3346 CD44 is an independent predictor of lymph node metastasis in differentiated thyroid cancer.

Syed Zeeshan Qadri, Abdul K. Siraj, Sandeep K. Parvathareddy, Nabil Siraj, Padmanaban Annaiyappanaidu, Khawla S. Al-Kuraya

King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia

Background: Differentiated Thyroid Carcinoma (DTC), a common endocrine malignancy, has witnessed a significant rise in global incidence over the past few decades. Despite its indolent nature and favorable prognosis, the clinical course of DTC varies extensively, with lymph node metastasis being an important risk factor in prognosis. CD44 has been shown to be associated with prognosis in various cancers. However, its role in DTC is not well explored.
Methods: A total of 1703 DTC cases of Middle Eastern ethnicity were included in the study. CD44 expression was evaluated by immunohistochemistry using tissue microarray to analyze the clinico-pathological associations. Univariate and multivariate logistic regression analysis was used to determine the predictors of lymph node metastasis.
Results: CD44 over-expression was noted in 69.7% (1187/1703) of DTC cases and was significantly associated with younger age (< 55 years; $p < 0.0001$), multifocality ($p < 0.0001$), lymphovascular invasion ($p = 0.0007$) and lymph node metastasis ($p < 0.0001$). Interestingly, on multivariate logistic regression analysis, CD44 was found to be an independent predictor of lymph node metastasis (Hazard ratio = 1.79; 95% confidence interval = 1.40 - 2.30; $p < 0.0001$).
Conclusion: Our study showed that CD44 expression was an independent predictive biomarker of lymph node metastasis in Middle Eastern patients with DTC. Detection of CD44 expression could help identify patients at risk for developing lymph node metastasis and help in individualization of clinical management for DTC patients.

#3347 Developing a prognostic biomarker of EGFR/RAS/SIAH pathway activation/inactivation following neoadjuvant chemotherapy to risk stratify patients, detect racial disparity, and predict relapse and survival in triple-negative breast cancer in Hampton Roads, Virginia.

Z. Bouker[1], A. H. Tang[1], C. B. Piatak[1], T. N. Drake[1], C. D. Lee[1], E. L. Breeding[1], J. S. Winston[2], B. Samli[2], R. J. Jansen[1], M. Danso[3], R. A. Hoefer[2];

[1]Eastern Virginia Medical School, Norfolk, VA, [2]Sentara Health, Norfolk, VA, [3]Virginia Oncology Associates, Norfolk, VA

Background: Triple-negative breast cancer (TNBC) is an aggressive breast cancer subtype that disproportionately affects BRCA1 mutation carriers and young Black/white women. Hampton Roads, Virginia is a major cosmopolitan area with 1.8 million population, in which 30% are Black/African Americans. TNBC is highly prevalent in our area where high mortality and racial disparity are reported by CDC/SEERS databases. Supported by strong evidence in developmental, evolutionary, and cancer biology, we hypothesize that persistent EGFR/K-RAS/SIAH pathway activation is a major driving force of TNBC malignancy, and a new prognostic biomarker of racial disparity, early tumor relapse, and high mortality in the clinic.

Methods: Chart review was conducted using Sentara MD Office/EPIC and VOA iKnowMedicine portals to update tumor relapse and survival of 535 TNBC patients. In a sub-cohort study, we focused on 183 high-risk TNBC patients who received neoadjuvant chemotherapy (NACT). We will determine if 5-year TNBC survival is associated with $SIAH^{High/Low}$ expression pre- and post-NACT, race, and/or other clinicopathological parameters.

Results: We report that a higher SIAH expression in residual tumors post-NACT was associated with lower 5-year survival rates. In a cohort of 48 incomplete responders (pIR) post-NACT, the 5-year survival rate was 2.25-fold higher in patients whose residual tumors had a lower SIAH expression (< 50%) than those with a higher SIAH expression (> 50%) (61.5% vs 27.3%; p=0.02). Similarly, the 5-year survival rate was 3-fold higher in 18 pIR patients with stage 2 residual tumors that had a lower SIAH expression (<50%) than those with a higher SIAH expression (> 50%) post-NACT (100% vs 37.5%, p=0.01). A significant racial disparity in 5-year survival was detected between Black/white TNBC patients with stage 2 diseases post-NACT (95 vs 74%; p=0.005).

Conclusion: A persistent high SIAH expression post-NACT was associated with reduced survival in high-risk TNBC patients. Encouraged by the preliminary data, we aim to develop a SIAH-centered biomarker panel, $SIAH^{High\ (>\ 50\%)}/SIAH^{Low\ (<50\%)}$ by measuring the EGFR/K-RAS/SIAH pathway activation (ON)/inactivation (OFF) to risk stratify TNBC pIR patients, detect cancer racial disparities, forecast early tumor relapse, and predict survival at 1st-line neoadjuvant settings. We aim to delineate the molecular underpinning of the Black/white racial disparity in TNBC so that we can provide better, more equitable, and effective therapies to more high-risk TNBC patients with residual diseases in our local communities.

#3348 Clinical relevance and tumor microenvironment characteristics of SMARCD3 expression in gastric cancer.

K. Yuza[1], M. Oshi[2], Y. Takeshita[1], T. Takahashi[1], S. Sato[2], T. Kosaka[2], T. Kumamoto[1], T. Sato[1], K. Takabe[3], I. Endo[2];
[1]Yokohama City University Medical Center, Yokohama City, Japan, [2]Yokohama City University School of Medicine, Yokohama City, Japan, [3]Roswell Park Comprehensive Cancer Center, Buffalo, NY

Background: SMARCD3, a member of the SWI/SNF family, plays a role in chromatin remodeling and gene transcription. Although its involvement in mesenchymal-epithelial transition in breast cancer cells has been reported, its clinical significance in gastric cancer (GC) remains unclear. This study aims to investigate the clinical relevance of SMARCD3 expression in GC and its impact on the tumor microenvironment, survival outcomes, and tumor biology.
Methods: We analyzed clinical and gene expression data from 807 GC patients in The Cancer Genome Atlas (TCGA) and GSE57495 cohorts. SMARCD3 high expression was defined as the top tertile in each cohort. Gene set enrichment analysis (GSEA) was performed to explore biological pathways, while the xCell algorithm was used to evaluate immune and stromal cell infiltration in the tumor microenvironment.
Results: High SMARCD3 expression was significantly associated with worse overall survival in both cohorts ($p = 0.044$, and $p = 0.005$, respectively), underscoring its potential as a prognostic marker. Tumors with elevated SMARCD3 expression exhibited deeper invasion and more aggressive pathological features (all $p < 0.001$). SMARCD3-high tumors showed lower tumor mutation burden but higher intratumoral heterogeneity, indicating a complex genomic landscape. Immune profiling of SMARCD3-high GC revealed reduced infiltration of both anti- and pro-tumor immune cells, including CD4+ memory T cells, Th1, Th2, and NK cells (all $p < 0.001$). Conversely, these tumors demonstrated increased infiltration of stromal cells, including fibroblasts, adipocytes, microvascular endothelial cells, lymphatic endothelial cells, and pericytes (all $p < 0.001$), reflecting a distinct tumor microenvironment. GSEA revealed significant enrichment of pro-cancerous pathways, including the epithelial-mesenchymal transition, the Hedgehog signaling, the Apical Junction, and Myogenesis, while proliferation-related pathways were inversely correlated with SMARCD3 expression.
Conclusions: SMARCD3-high GC is associated with poor prognosis, characterized by aggressive tumor behavior, distinct immune and stromal profiles, and activation of pro-cancerous pathways compared to SMARCD3-low GC. These findings suggest that SMARCD3 is a potential prognostic biomarker, aiding in the stratification of GC patients and informing personalized treatment strategies. Further validation in clinical settings may establish its utility in guiding therapeutic decisions.

#3349 Loss of GATA2 promotes invasion and predicts cancer recurrence and survival in FIGO stage I uterine serous carcinoma.

Usha S. Polaki[1], Trey E. Gilpin[1], Apoorva T. Patil[1], Emily Chiu[2], Paula M. Manan Mejias[2], Pei Hui[3], Maria Virumbrales-Munoz[2], Lisa Barroilhet[2], Stephanie M. McGregor[1], Emery H. Bresnick[4], Daniel R. Matson[1]

[1]Pathology and Laboratory Medicine, University of Wisconsin - Madison, Madison, WI,[2]Obstetrics and Gynecology, University of Wisconsin - Madison, Madison, WI,[3]Pathology, Yale University School of Medicine, New Haven, CT,[4]Cell and Regenerative Biology, University of Wisconsin - Madison, Madison, WI

Background: Uterine cancer is the 4th most common cancer in women. Its incidence is increasing and its mortality rate also is rising. Uterine serous carcinoma (USC) is an aggressive uterine cancer subtype that is responsible for 40% of uterine cancer deaths. Although 50% of USC patients present with cancer localized to the uterine body (FIGO stage I) and should be cured by staging hysterectomy, 30% of these patients later recur in the absence of adjuvant combination paclitaxel-carboplatin chemotherapy. There is no reliable method to identify which USC patients are at risk of USC recurrence, so most patients receive risk-reducing adjuvant chemotherapy associated with significant morbidity. A priori knowledge of recurrence risk would enable a risk-stratified approach to adjuvant therapy to reduce morbidity and optimize survival. GATA Binding Protein 2 (GATA2) is a transcription factor that supports progesterone receptor signaling in the uterus. We recently generated anti-GATA2 monoclonal antibodies that can routinely detect GATA2 by standard immunohistochemistry (IHC).

Methods: We assembled a retrospective multi-institutional cohort of 81 patients with primary FIGO stage I USCs. Associations between GATA2 levels and clinicopathologic metrics were evaluated using Student's t-test, Fisher's exact test, Kaplan-Meier method, and Cox proportional hazards ratio. Gene targets including GATA2 were depleted from Ark1 and Ark2 patient-derived USC cell lines using siRNA or shRNA, and cell invasion evaluated using Matrigel-coated membranes and organoid-based natural hydrogel. RNA-seq, anti-GATA2 ChIP-seq, and western blotting enabled identification of GATA2 gene targets.

Results: GATA2 expression in USC tumors ranged from 0-100% GATA2+ tumor nuclei. USCs with >15% GATA2+ nuclei were defined as GATA2-high based on an initial inflection point in the data that optimally delineated patients by outcome. The 39% of patients with GATA2-high USCs had 100% recurrence-free, 100% disease-specific, and 87% overall survival. These outcomes were significantly better than patients with GATA2-low USCs. Depletion of GATA2 in USC cell lines increased invasion *in vitro*. In patients who received no adjuvant chemotherapy (n=18), those with GATA2-high USCs had 100% recurrence-free survival compared to 50% recurrence-free survival in GATA2-low USC patients. A multi-omic approach identified SIN3 Transcription Regulator Family Member B as a GATA2 target gene that suppressed USC invasion *in vitro*.

Conclusions: GATA2 IHC identifies FIGO stage I USC patients with a greatly reduced risk of USC recurrence. A GATA2 guided personalized medicine approach using standard IHC methods could be rapidly implemented in most hospital settings, would reduce treatment-related morbidity, and may optimize survival for USC patients.

#3350 Prognostic importance of physical activity in the chemotherapy of esophagogastric cancer; associations with skeletal muscle, systemic inflammation, and lifestyle.

Koichi Hayano, Natsiko Arimatsu, Yasunori Matsumoto, Yoshihiro Kurata, Ryota Otsuka, Akira Nakano, Tadashi Shiraishi, Nobufumi Sekino, Takeshi Toyozumi, Masaya Uesato, Gaku Ohira, Hisahiro Matsubara

Department of Frontier Surgery, Chiba Univ. School of Medicine, Chiba, Japan

Background: Physical activity (PA) must be an important intervention in the treatment of cancer. However, it is unknown what kinds of PAs can improve patients' outcome in the chemotherapy of esophagogastric cancer (EGC).
Methods: Unresectable or recurrent EGC patients treated with chemotherapy were prospectively investigated. PA was measured using an accelerometer for 1 week before and after the chemotherapy administration. PA was classified as sedentary behavior (< 1.5METs, SB), light-intensity PA (1.6-2.9 METs, LPA), and moderate-to-vigorous PA (≥ 6.0 METs, MVPA). PA parameters were compared with disease specific survival (DSS), inflammatory and nutritional markers, subsequent skeletal muscle (SM) volume change, and lifestyle.
Results: Thirty-nine patients were evaluated. In Cox regression analyses, better DSS was significantly correlated with longer times of LPA (P=0.02), but not with MVPA (P=0.2). LPA showed significant negative correlations with WBC, CRP, and modified GPS score (P=0.03, 0.03, 0.004, respectively), and positive correlations with serum total protein (TP) and albumin (Alb) levels and SM change (P=0.01, 0.003, 0.01, respectively). The longer times of LPA was significantly associated with better socialization with neighbors (P=0.001).
Conclusions: LPA would be recommended during the chemotherapy of advanced EGC patients, keeping their better inflammatory and nutritional status and preventing SM loss. Socialization might play a key role in increasing LPA.

#3351 From bench to bedside: generalizable AI model for ADC biomarker evaluation in NSCLC.

Philipp Anders[1], Philipp Erwin Seegerer[2], Katja Lingelbach[2], Suhas Pandhe[2], Sandip Ghosh[2], Cornelius Bohm[2], Stephan Tietz[2], Rosemarie Krupar[2], Lars Tharun[1], Marie-Lisa Eich[1], Julika Ribbat-Idel[2], Verena Aumiller[2], Sabine Merkelbach-Bruse[3], Alexander Quaas[3], Nikolaj Frost[4], Georg Schlachtenberger[5], Matthias Heldwein[5], Ulrich Keilholz[6], Khosro Hekmat[5], Jens-Carsten Ruckert[7], Reinhard Buttner[3], David Horst[1], Maximilian Alber[2], Lukas Ruff[2], Frederick Klauschen[8], Gabriel Dernbach[2], Simon Schallenberg[1]

[1]Institute of Pathology, Charite - Universitatsmedizin Berlin, corporate member of Freie Universitat Berlin, Humboldt-Universitat zu Berlin and Berlin Institute of Health, Berlin, Germany,[2]Aignostics GmbH, Berlin, Germany,[3]Institute of Pathology, University Hospital Cologne, Cologne, Germany,[4]Department of Infectious Diseases and Respiratory Medicine, Charite - Universitatsmedizin Berlin, corporate member of Freie Universitat Berlin, Humboldt-Universitat zu Berlin and Berlin Institute of Health, Berlin, Germany,[5]Department of General, Visceral, Oncological and Thoracic Surgery, University Hospital Cologne, Cologne, Germany,[6]Charite Comprehensive Cancer Center, Charite - Universitatsmedizin Berlin, corporate member of Freie Universitat Berlin, Humboldt-Universitat zu Berlin and Berlin Institute of Health, Berlin, Germany,[7]Department of General, Visceral, Vascular and Thoracic Surgery, Charite - Universitatsmedizin Berlin, corporate member of Freie Universitat Berlin, Humboldt-Universitat zu Berlin and Berlin Institute of Health, Berlin, Germany,[8]Institute of Pathology, Ludwig-Maximilians-University Munich, Munich, Germany

Background:Antibody-drug conjugates (ADCs) targeting trophoblast cell-surface antigen 2 (TROP-2) and hepatocyte growth factor receptor (cMET) are promising therapies for non-small cell lung cancer (NSCLC). However, their clinical application requires robust and rapid biomarker evaluation that addresses expression heterogeneity and avoid interobserver variability. Current approaches based on pathologist assessments are limited by subjectivity and scalability. This study aimed to develop a generalizable AI model for ADC biomarker evaluation, trained on TROP-2 and inferred on cMET, to validate its adaptability across markers. Additionally, the model's performance was compared with expert pathologists to assess its clinical utility. Finally, biomarker prevalence in the two main NSCLC subtypes, namely adenocarcinoma (LUAD) and squamous cell carcinoma (LUSC), was evaluated.
Methods: We collected a bicentric real-world sample group of 1142 patients with resected NSCLC from the Charité, Berlin and the University Hospital Cologne. For tissue microarray construction, two 1.5-mm tissue cores were punched from formalin-fixed and paraffin-embedded tumor blocks. Immunohistochemical staining for TROP-2 and cMET was performed and sections were scanned for AI-based analysis. The AI pipeline comprised three models: a cell detection model for the identification of cells, a cell classification model for the differentiation of tumor and other cells, and an expression scoring model for membranous biomarker quantification. The model was trained on TROP-2, and subsequently inferred on cMET, thus enabling an evaluation of cross-marker generalization. Five pathologists with varying levels of expertise manually evaluated a representative subset, using H-scoring. Finally, the results were compared with those yielded by the AI model.
Results: The expression scoring model achieved a macro-averaged F1 score of 94% for TROP-2 and 91% for cMET. Moreover, the model demonstrated excellent concordance with expert pathologists (TROP-2: 93%; cMET: 95% average pair-wise Pearson correlation). TROP-2 overexpression was significantly higher in LUSC (mean H-score: 154.67) than LUAD (mean H-score: 86.57), while cMET showed the opposite trend (mean H-score LUAD: 59.52; LUSC: 25.68).
Conclusion:This study highlights the potential of AI models to address key challenges in ADC biomarker evaluation, including expression heterogeneity, interobserver variability, and reduction in time expenditure. By successfully generalizing between TROP-2 and cMET, the model demonstrates adaptability and scalability for broader clinical applications. These findings pave the way for integrating AI into clinical workflows, improving patient stratification, and optimizing ADC therapy selection. Future efforts will focus on expanding this approach to additional biomarkers and validating its utility in prospective clinical trials.

#3352 Profiling impact of genomic alterations on the BCL2-family protein interactions in acute myeloid leukemia using the SPID platform.

Saem Hong[1], Yunseo Lee[1], Byungsan Choi[1], Hee-Je Kim[2], Byung-Sik Cho[2], **Hongwon Lee**[1]

[1]Proteina Co., Seoul, Korea, Republic of,[2]Department of Hematology, Catholic Hematology Hospital, Seoul, Korea, Republic of

Introduction: Acute myeloid leukemia (AML) is a genetically heterogeneous malignancy, leading to varied therapeutic outcomes with targeted therapies. Venetoclax, a BCL2 inhibitor, has shown efficacy in treating AML patients by disrupting BCL2 functions. Genomic mutations like TP53, IDH1/2, PTPN11, and NRAS are associated with response rates to venetoclax. However, profiling the association between these mutations and BCL2-family protein interactions remains limited in clinical specimens. This study utilized the single-molecule protein interaction detection (SPID) platform to map BCL2-family interactions and examine their links to TP53, IDH1/2, PTPN11, FLT3, and NRAS mutations.

Methods: Bone marrow mononuclear cells (BMMCs) from AML patients were retrospectively analyzed using the SPID platform to measure BCL2-family protein expression and complex levels. 10 assays evaluated Active BAX, Active BAK, BCL2, BIM levels, and complexes like BCL2-BAX and BCLxl-BAK. A BIM-BH3 mimicking probe quantified unoccupied anti-apoptotic protein levels. Mutational status was determined using next-generation sequencing, and Mann-Whitney U tests compared protein profiles between wildtype and mutant groups.

Results: Among 80 patients (median age: 65 years), 43 (48.75%) had TP53, IDH1/2, PTPN11, FLT3, or NRAS mutations. IDH1/2 mutations were linked to higher BCL2-BAX complexes and unoccupied BCL2 levels ($p<0.05$). TP53 mutations were associated with reduced Active BAX and BCL2-BAX complex levels ($p=0.015$ and $p=0.003$). NRAS mutations led to reduce BCLxl-BAK ($p=0.0019$) and MCL1-BAK ($p=0.0504$) complexes, while PTPN11 mutations lowered BIM-el and MCL1-BAK levels ($p<0.05$). No significant biomarkers were linked to FLT3 mutations.

Conclusion: This study reveals how genomic alterations in AML impact BCL2-family signaling, influencing venetoclax response. IDH1/2 mutations enhance BCL2-BAX complexes, potentially associating with favorable venetoclax sensitivity. Conversely, TP53 mutations reduce pro-apoptotic signaling, conferring resistance to venetoclax. NRAS and PTPN11 mutations affect anti-apoptotic complexes, further influencing therapeutic outcomes. Taken together, these discoveries provide how genomic alterations can impact on the BCL2-family signaling.

#3353 Predicting the prognosis of ductal carcinoma in situ through chemical analysis of breast microcalcifications and soft tissue using infrared and Raman spectroscopy.

Jayakrupakar Nallala[1], Doriana Calabrese[1], Sarah Gosling[2], Esther Lips[3], Ihssane Bouybayoune[4], Rachel Factor[5], Sarah Pinder[4], Lorraine King[5], Jeffrey Marks[5], Thomas Lynch[5], Donna Pinto[6], Alastair Thompson[7], Elinor Sawyer[4], Jelle Wesseling[3], Shelley Hwang[5], Keith Rogers[2], Nick Stone[1], Grand Challenge PRECISION consortium

[1]Physics and Astronomy, University of Exeter, Exeter, United Kingdom,[2]Cranfield Forensic Institute, Cranfield University, Cranfield, United Kingdom,[3]Department of Pathology & Division of Molecular Pathology, The Netherlands Cancer Institute, Netherlands, Netherlands,[4]Comprehensive Cancer Centre at Guy's Hospital, School of Cancer & Pharmaceutical Sciences, Kings College London, London, United Kingdom,[5]Department of Surgery, Duke University School of Medicine, Durham, NC,[6]www.DCIS411.com, San Diego, CA,[7]Division of Surgical Oncology, Baylor College of Medicine, Houston, TX

Introduction: Ductal carcinoma in situ (DCIS) is a potential precursor to invasive breast cancer (IBC). The trajectory of an individual's DCIS, if it will progress to IBC or remain as DCIS is difficult to predict. Currently >80% of DCIS is detected through mammographic screening of breast calcifications. Despite the close association of calcifications with DCIS, their role in the development of DCIS and/or its progression to IBC remains largely unexplored. In this study, we present a spectroscopy based analytical approach to probe chemical compositional changes of both DCIS associated breast calcifications and surrounding soft tissue aiming to identify a cohort at increased risk for invasive progression.

Experimental Procedures: Tissue samples from 316 DCIS patients without invasive cancer were obtained from multiple centres as part of the PRECISION consortium (The Netherlands, UK and USA). Three consecutive tissue sections were obtained each of the tissue biopsies. Mid-infrared (mid-IR) and Raman hyperspectral imaging was performed independently on two sections that were left unstained. The third H&E-stained section was used to annotate calcifications and histopathological features. All DCIS samples had known outcome (i) 'pure DCIS as controls' (DCIS without progression to invasion) (n=193), (ii) 'DCIS with progression to invasion as cases' (DCIS from patients who subsequently developed invasive disease after initial treatment) (n=123). Spectral features of DCIS calcifications and surrounding soft tissue were used as inputs for analysis. Data was divided into a discovery and a validation set. Cluster analysis followed by Principal component analysis fed linear discriminant analysis was carried out on the discovery set to develop DCIS prediction models.

Results: For the Raman data, a mean area under the receiver operating characteristic curve (AUROC) value of 0.85 was obtained using calcification spectral features, and 0.75 using soft tissue spectral features in distinguishing controls from cases (N=118 vs 52). Similar analysis on the IR data showed a mean AUROC value of 0.68 for calcification, 0.78 for epithelial and 0.80 for stromal components (N=97 vs 61). Preliminary analysis shows changes in phosphate to carbonate ratio and variations in magnesium whitlockite content in calcifications, and protein secondary structural changes in soft tissue, between the two groups. The models will be tested independently on the validation set and the outcomes will be presented at the AACR conference.

Conclusion: Spectroscopic chemical analysis of breast calcifications and soft tissue show promise in predicting the likely progression of DCIS to IBC. Pending further independent validation, these techniques appear to be novel image-based risk assessment tools that can potentially be utilised to inform DCIS prognosis and treatment options.

#3354 Hsp70 is an independent predictor of recurrence-free survival in differentiated thyroid cancer.

Sandeep K. Parvathareddy, Zeeshan Qadri, Abdul K. Siraj, Padmanaban Annaiyappanaidu, Nabil Siraj, Khawla S. Al-Kuraya

King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia

Background: Differentiated Thyroid Cancer (DTC) has an indolent nature and generally has favorable prognosis. However, tumor recurrence is a major concern and can be noted several years after initial treatment. Identifying markers that can predict recurrence could lead to better management of DTC. Heat shock protein 70 (Hsp70), a molecular chaperone, has been shown to be associated with tumor recurrence and poor prognosis in other tumors. However, its role in predicting outcome in DTC is not well explored.
Methods: A total of 1710 DTC cases were included in the study. Hsp70 expression was evaluated by immunohistochemistry using tissue microarray to analyze the clinico-pathological associations. Kaplan-Meier curve analysis was used to compare recurrence-free survival (RFS). Cox proportional hazards model was used for multivariable analysis.
Results: Hsp70 over-expression was noted in 71.6% (1224/1710) of DTC cases and was significantly associated with adverse clinico-pathological characteristics such as extrathyroidal extension ($p = 0.0039$), T4 tumors ($p = 0.0002$), lymph node metastasis ($p = 0.0118$), distant metastasis ($p = 0.0130$), advanced tumor stage ($p = 0.0312$) and tumor recurrence ($p < 0.0001$). Interestingly, HSP70 over-expression was found to be associated with shorter RFS ($p < 0.0001$). On multivariable analysis, HSP70 was an independent predictor of RFS (Hazard ratio = 1.82; 95% confidence interval = 1.33 - 2.55; $p = 0.0001$).
Conclusion: Our data suggests that Hsp70 is associated with poor prognosis in DTC and is a useful biomarker for predicting tumor recurrence. DTC patients whose tumor shows over-expression of Hsp70 should be subjected to more intense follow-up to identify potential tumor recurrence.

#3355 FTO in smoking-associated lung cancer and lung cancer tumor progression.

Rachel Campoli, Rong Qiu, Robert Hillwig, Neelu Puri

University of Illinois at Chicago, Chicago, IL

In 2024, an estimated 234,580 patients will be diagnosed with lung cancer and 125,070 are expected to die, making lung cancer the leading cause of cancer-related deaths. Early detection of lung cancer is critical for improving prognosis, hence the need for early detection biomarkers. Fat mass and obesity-associated gene (FTO) had earlier been linked with obesity, however current studies indicate it may have a role in tumor development and could be a potential biomarker. In this study, we aimed to identify a possible link between FTO and non-small cell lung cancer (NSCLC), which accounts for 85% of lung cancer diagnosis. We hypothesize FTO is involved in increasing tumorigenicity and mortality among lung cancer patients. The role of FTO was studied in tumor progression, patient survival analysis, and smoking induced lung cancer, which is not established. Using immunohistochemistry, 115 tumor sections of NSCLC patients were studied; of these patients, 64 were early-stage NSCLC and 51 were late-stage. Patient tissues were obtained from local hospital pathology archives. Staining was completed using FTO primary antibody and a biotinylated secondary antibody. FTO brightness scores were generated using the BZX-800 analyzer software. FTO expression was also calculated using an H-score with the help of a pathologist. Both imaging studies and pathology grading indicated that late-stage lung cancer tissues had significantly ($p<0.05$) higher FTO expression compared to early-stage cases. When subdivided into low and high expression levels, 69% of early-stage tissue samples exhibited low expression levels and 55% of late-stage tumor tissues had high FTO expression. To assess the role of FTO expression in lung cancer survival, a Kaplan-Meier analysis was done with 47 patients. Results showed that NSCLC patients with higher expression had a shorter median survival time (14 months) compared to NSCLC patients with low expression (27 months) ($p=0.03$). These results suggest that patients with higher FTO expression may have poorer prognosis. Since 80-90% of lung cancer patients had a history of smoking, we studied the connection between FTO expression and smoking associated lung cancer. 50 NSCLC tumor sections were stained, 28 being smokers and 22 being non-smokers. The average FTO expression level was 24% higher in smokers compared to non-smokers ($p<0.02$). Using H-scores, smokers were divided into low and high expression levels. 93% of smokers had a high FTO expression compared to 7% in non-smokers indicating that smokers had higher expression of FTO compared to non-smokers ($P=0.001$) In conclusion, FTO may have a role in tumor progression as it is highly expressed in late-stage lung tumor tissues. High expression of FTO is also a potential indicator of patient survival, as patients who had an upregulation of FTO had shorter survival time. Finally, we found a possible link between high FTO expression and smoking-induced lung cancer.

#3356 Construction of a 23-gene risk scoring system to predict disease recurrence and chemotherapy response in mucinous colorectal cancer.

J.-W. Seo[1], J.-Y. Kim[1], Y.-J. Ha[2], S.-W. Baek[1], J.-L. Park[1], S.-W. Lee[1], J.-L. Lee[2], S.-Y. Kim[1], S.-K. Kim[1];

[1]Korea Research Institute of Bioscience & Biotechnology (KRIBB), Daejeon, Korea, Republic of, [2]Asan Medical Center, Seoul, Korea, Republic of

Backgrounds: Mucinous adenocarcinoma (MuC), a unique subtype of colorectal cancer (CRC), exhibits distinct molecular features and is associated with poorer outcomes compared to non-mucinous adenocarcinoma (NMuC). Standard CRC treatments often overlook the molecular diversity within CRC, especially in stage II, where the benefit of adjuvant chemotherapy remains debated. Biomarkers are needed to improve risk assessment and guide tailored treatments.

Methods: We conducted molecular profiling of 259 CRC samples, including MuC and NMuC subtypes, to identify MuC-specific gene signatures. A 23-gene risk score (MuC-RS) was developed and validated in four independent cohorts (n = 1,157). Prognostic significance of MuC-RS was assessed using various statistical methods, including Kaplan-Meier survival analysis, log-rank tests, and Cox regression.

Results: In the discovery cohort of fresh-frozen tissues, unsupervised clustering revealed distinct gene expression patterns differentiating MuC from NMuC. MuC showed notable enrichment in fibroblast-associated genes, EMT pathways, and mucin glycosylation processes. The MuC-RS effectively stratified patients into high-risk (MuC-H) and low-risk (MuC-L) categories. Multivariate analysis confirmed MuC-RS as an independent prognostic factor. Importantly, stage II MuC-L patients showed limited response to standard chemotherapy but increased responsiveness to immune checkpoint inhibitors (ICIs), associated with higher tumor mutation burden and immune activation. MuC-RS's prognostic utility was further validated through comparisons with consensus molecular subtypes.

Conclusion: MuC-RS offers a promising tool for predicting recurrence and informing personalized treatment strategies in CRC, potentially enhancing risk stratification and supporting novel therapies, such as ICI, particularly for stage II MuC patients.

Keywords: Mucinous colorectal cancer, biomarker, risk score, chemotherapy, immunotherapy

Grant Support: This research was supported by the Bio & Medical Technology Development Program of the National Research Foundation (NRF) funded by the Korean government (MSIT) (2022R1A2C2008480 to S.K. Kim, 2018R1C1B6008571 and 2022R1F1A1074317 to J.L. Lee). This study was also supported by grants from the Korea Research Institute of Bioscience and Biotechnology (KRIBB) Research Initiative Program (KGM5192423).

#3357 Identification of outcome-associated tumor perivascular features in renal cell carcinoma.

Alfonso Martin-Bernabe[1], Victor Sanchez-Minarro[1], Philipp Schmucker[1], Magnus Lindskog[1], Ulrika Harmenberg[1], Martin Johansson[2], Lars Egevad[1], Arne Ostman[1]

[1]Karolinska Institutet, Stockholm, Sweden,[2]Goteborgs Universitet, Gothenburg, Sweden

Background: One third of patients with clear cell renal cell carcinoma (CCRCC) eventually develop metastasis. The introduction of anti-angiogenic therapy and immunotherapy in metastatic CCRCC (mCCRCC) has significantly improved outcomes for many patients. Among vascular endothelial growth factor tyrosine kinase inhibitors (TKIs), sunitinib is the most commonly used first-line drug. However, treatment is administered without specific patient selection criteria and relapse occurs in approximately 40% of cases. Given the lack of clinical stratification of these patients, predictive and prognostic biomarkers are needed to improve their clinical outcome.
Methods: This work explored the clinical impact of perivascular (PV) characteristics in RCC by performing multiplex-based tissue profiling in a population-based cohort (N = 70) and a sunitinib-treated mCCRCC cohort (N = 61). Vessel features and tumor PV cell subsets were characterized based on multimarker (CD34, PDGFRα, PDGFRβ, αSMA and pSMAD2) expression combinations. In both cohorts, patients were categorized using a tertile-based dichotomization of the variables, with the upper tertile compared against the combined lower and middle tertiles to explore associations.
Results: Two PV cell subsets, PER4 (PDGFRB+/ASMA+/PDGFRA-/pSMASD2-) and PER5 (PDGFRB+/ASMA-/PDGFRA-/pSMASD2-), showed statistically significant survival associations using multiple endpoints in both cohorts. In the sunitinib-treated cohort (OS from treatment), PER4 (log-rank $p < 0.001$) and PER5 (log-rank $p = 0.002$) were associated with poor survival. Similarly, in the population-based cohort (OS), PER4 (log-rank $p = 0.043$) and PER5 (log-rank $p = 0.001$) were also linked to worse survival. Univariate and multivariate analyses confirmed robust survival associations for the identified PV cell subsets PER4 and PER5.
Conclusions: Collectively, this study identified candidate prognostic or TKI predictive response markers in RCC. These data provided in-depth characterization of PV cell subsets associated with clinical outcome in RCC. These data could be further explored to find clinically useful patient selection to improve the accuracy of anti-angiogenic therapy administration in RCC.

#3358 Tertiary lymphoid structures (TLS) estimated by AI tools from digital H&E slides significantly enhance survival prediction in high-risk AJCC stages III/IV melanoma.

Ahmad A. Tarhini[1], Tingyi Li[1], Ranran Tao[1], Sandra J. Lee[2], Islam Eljilany[1], F. Stephen Hodi[3], Howard Streicher[4], Arivarasan Karunamurthy[5], John M. Kirkwood[5], Xuefeng Wang[1]

[1]H. Lee Moffitt Cancer Center & Research Institute, Tampa, FL,[2]Dana Farber Cancer Institute, Harvard Medical School, Boston, MA,[3]Dana-Farber Cancer Institute, Boston, MA,[4]National Cancer Institute, Investigational Drug Branch, Cancer Therapy Evaluation Program, Bethesda, MD,[5]UPMC Hillman Cancer Center, Pittsburgh, PA

Tertiary lymphoid structures (TLS) in tumors have emerged as novel disease prognostic and predictive biomarkers with immunotherapy. Recent advances in whole-slide image (WSI) digitization of pathology slides and AI tools are making in situ prediction of TLS more feasible.

Methods: We applied HookNet-TLS, a deep learning-based automated TLS quantification tool, to identify and quantify TLS and germinal centers (GC) in digitized H&E slides from 376 patients (pts) with resected cutaneous melanoma enrolled in the E1609 phase 3 trial that tested adjuvant ipilimumab (IPI) vs interferon-α (IFN). We tested the prognostic value of TLS by correlating the presence of TLS and the normalized number of TLS (number of TLS divided by total area of segmented tissue) in E1609 pts with AJCC7 stages IIIB (n=180), IIIC (n=151), M1a (n=30), M1b (n=15), by stage group, sex, age, treatment and tumor ulceration, utilizing Kaplan-Meier analysis and log-rank tests.

Results: TLS were present in the tumors of 207 pts (55%) and predicted better overall survival (OS) ($P = 0.09$), especially in those with >1 TLS ($P = 0.0096$). TLS density (TLS per unit area) was even more prognostic ($P = 0.0036$ for median cutoff; $P = 0.0012$ for optimal cutoff). Presence of both TLS and GC within TLS (n = 114) demonstrated significantly better OS compared to those without GC ($P = 0.022$). Higher TLS scores were associated with significantly better OS in IIIB ($P = 0.021$) and IIIC ($P = 0.019$) with a similar trend towards improved recurrence free survival (RFS). Associations in M1a and M1b were limited by sample size, although improvement in RFS was seen in M1a with higher TLS ($P = 0.07$) and presence of GC ($P = 0.007$). By treatment, higher TLS predicted better OS ($P = 0.033$) and RFS ($P = 0.018$) among IPI treated patients (n=246). A similar trend in OS was seen among IFN treated patients (n=130) that did not reach significance. By sex, higher TLS & presence of GC were associated with better OS ($P = 0.0062$ & $P = 0.072$) and RFS ($P = 0.01$ & $P = 0.04$), respectively in males (n=226). By age, higher TLS was associated with better OS among pts <65 (n = 310) ($P = 0.0002$). Similar trends in females ($n = 150$) and age ≥65 (n = 66) that were not significant, likely limited by sample size. Higher TLS predicted better OS and RFS in pts with non-ulcerated melanoma (n=138) ($P = 0.001$ & $P = 0.022$) but not those with ulceration (n=165).

Conclusions: Automated TLS quantification using a deep learning tool (HookNet) effectively identified and characterized TLS in H&E slides where the application of TLS significantly enhanced survival prediction by AJCC stage group, sex, age, treatment and tumor ulceration. These findings highlight the potential of AI-driven approaches to standardize TLS assessment using low-cost H&E staining, with the potential to improve prognostic stratification within AJCC, that warrants further investigation and validation.

#3359 Prevalence of heterozygous and homozygous 9p21 deletions in human cancer: a tissue microarray study on 4999 tumors from 125 different tumor types.

Natalia Gorbokon, Katharina Teljuk, Katharina Moller, Seyma Buyucek, Maximilian Lennartz, Sebastian Dwertmann Rico, Simon Kind, Viktor Reiswich, Florian Viehweger, Elena Bady, Lisa Hornsteiner, Guido Sauter, Ronald Simon, Stefan Steurer, David Dum, Sarah Minner, Frank Jacobsen, Till S Clauditz, Martina Kluth

University Medical Center Hamburg-Eppendorf, Hamburg, Germany

9p21 deletions including CDKN2A belong to the most common chromosomal aberrations in cancer. Most of the topical interest in 9p21 comes S-methyl-5′-thioadenosine phosphorylase (MTAP) which is also included in most 9p21 deletions. Homozygous 9p21 deletions are the major cause for MTAP deficiency which results in a critical vulnerability of cancer cells towards drugs targeting several different pathways. Fluorescence in situ hybridization (FISH) is the gold standard method for deletion detection because single cells are always analyzed independent of any admixture of non-neoplastic cells. To assess the prevalence of heterozygous and homozygous deletions in cancer, a tissue microarray containing 7,172 samples from 125 different tumor entities was analyzed by FISH. Consecutive sections were immunostained for MTAP and p16. Among 4,999 evaluable cases, 10.7% had a heterozygous and 7.4% a homozygous deletion. Heterozygous and homozygous did not predominate in the same tumor categories. Homozygous deletions were most frequent in mesotheliomas (up to 47.8%), pancreatic ductal adenocarcinoma (44,7%), and in urothelial carcinoma (up to 36.4%) while the heterozygous deletions were most common in squamous cell carcinomas (up to 34.3%), leiomyosarcoma (31.4%), adenocarcinomas of the esophagus (30.1%), malignant melanoma (29.4%), and cholangiocarcinoma (21.2%). Accordingly, the proportion of homozygous deletions within the 9p21 deleted cases varied markedly. It was high in mesothelioma (up to 91.7%), urothelial carcinoma (up to 80%), pancreatic ductal adenocarcinoma (76.4%), and mucinous carcinoma of the ovary (66.7%). It was intermediate in squamous cell carcinomas of different organs (10-50%) and adenocarcinoma of the lung (46.3%), and it was particularly low in endometrioid (9.1%) and in high-grade serous (4%) carcinoma of the ovary. Both MTAP and p16 were not detectable in cancers with 9p21 deletion, but otherwise the results differed markedly between these proteins. The expression of MTAP was markedly lower in heterozygously deleted cancers as in wild type cancers ($p<0.0001$) while p16 expression did not change significantly from normal to heterozygously deleted cases. In summary, these data provide a unique FISH based catalogue of 9p21 deletions in cancer and demonstrate that the proportions of heterozygous and homozygous MTAP deletions vary markedly between tumor entities. The near perfect concordance between homozygous MTAP deletions and absence of MTAP immunostaining further supports the use of IHC for detecting MTAP deficiency.

#3360 Pre- and post-operative analysis of circulating tumor DNA in patients with breast cancer treated with neoadjuvant therapy using a tissue-free, methylation-based approach.

Arielle J. Medford[1], Justine Knape[2], Derek Dustin[3], Haiyang Zhang[3], Caroline Weipert[3], Shivahamy Maheswaran[4], Irene Kuter[1], Jeffrey Peppercorn[1], Seth Wander[1], Steven J. Isakoff[1], Beverly Moy[1], Dejan Juric[1], Laura M. Spring[1], Aditya Bardia[5]

[1]Hematology/Oncology, Mass General Cancer Center/Harvard Medical School, Boston, MA,[2]Hematology/Oncology, Mass General Cancer Center, Boston, MA,[3]Guardant Health, Redwood City, CA,[4]UMass Chan Medical School, Boston, MA,[5]Hematology/Oncology, UCLA Health Jonsson Comprehensive Cancer Center, Los Angeles, CA

Background: Detection of circulating tumor DNA (ctDNA) in early breast cancer (BC) is a prognostic biomarker for disease recurrence. This pilot study evaluates the performance of a tissue-free epigenomic ctDNA assay in pre-neoadjuvant therapy (NAT), on-NAT and post-op plasma samples from patients (pts) with BC.

Methods: Pre-NAT, on-NAT and post-op plasma samples from 13 pts that received NAT for BC were retrospectively analyzed for ctDNA using Guardant Reveal powered by Infinity, a tissue-free assay that analyzes differentially methylated regions of DNA using an applied bioinformatics filter optimized to detect BC. It results in binary ctDNA detection calls and a quantitative estimate of tumor fraction (TF) in ctDNA+ samples.

Results: A total of 27 samples from 14 pts were evaluated, with 96% (26/27) samples passing quality control and included in the analysis (10 pre-NAT, 3 on-NAT, and 13 post-op). ctDNA was detected in 42% (11/26) of samples: 70% (7/10) pre-NAT, 33% (1/3) on-NAT and 23% (3/13) post-op (Table). For post-op samples collected within one year of recurrence, sensitivity was 100% (3/3). 2/5 pts who experienced recurrence, whose post-op samples were collected during adjuvant therapy and were ctDNA-, had a recurrence >15 months after the sample collection. No pts (0%, 0/8) without recurrence were ctDNA+ post-op. A pt with a brain-only recurrence had the lowest TF fraction amongst ctDNA+ post-op samples at 0.9%, with a median post-op TF of 2.5% (range, 0.9-23%) among the 3 ctDNA+ samples.

Conclusion: ctDNA was detectable in 70% of pts pre-NAT, 33% on-NAT and 23% post-op, with persistent ctDNA associated with recurrence. In the subsequent full study, ~ 600 samples will be evaluated at these timepoints. The dataset will provide a rich clinical landscape to understand sensitivity and specificity of methylation-based ctDNA testing, optimal timing and key areas to study therapeutic interception.

#3365 Preview of early adverse event landscape and association with clinical outcomes in advanced non-small cell lung cancer.

Dung-Tsa Chen, Jhanelle Gray, Andreas Saltos, Timothy Shaw

Moffitt Cancer Center, Tampa, FL

Background: AE incidence and the association with clinical outcomes are still not well defined in advanced NSCLC. Most trial studies published AE results limited in treatment-related (Tr) AE using worst grade approach in descriptive manner. As a result, it fails to delineate AE landscape and explore AE potential role as a prognostic factor.
Methods: All AEs were coded using the Medical Dictionary for Regulatory Activities (MedDRA) and classified by MedDRA system organ class and preferred term. The severity of AEs was assessed according to National Cancer Institute Common Terminology Criteria for Adverse Events (NCI CTCAE). AE data were collected from 7 advanced NSCLC trial cohorts, including 3 immunotherapy cohorts, 2 chemotherapy cohorts, and 2 targeted therapy cohorts. Early AE was defined as AE occurrence since first treatment until day 30, equivalent to period time of dose limiting toxicity. AE incidence was calculated by percentage of patients with AE experiences. Cox proportional hazards model and log-rank test were used for survival analysis.
Results: Analysis of early AE landscape showed (a) low-grade AEs were more common than high-grade AEs regardless of treatment types. It makes sense otherwise the trials would be closed in early stage due to safety concern, (b) non-Tr AEs were not always more common than Tr AEs. It depends on degree of toxicity of treatments. There were one immunotherapy cohort, two chemotherapy cohorts, and one targeted therapy cohort had a higher incidence of Tr AEs over non-Tr AEs. Likely more toxic drugs were used in these cohorts, and (c) patients without non-Tr AEs may not tend to experience more low-grade Tr AEs than patients with non-Tr AEs. Two immunotherapy cohorts and one chemotherapy cohort had a higher incidence of low-grade Tr AEs in patients without versus with non-Tr AEs. In contrast, one immunotherapy cohort, one chemotherapy cohort (all patients experienced Tr AEs), and two targeted therapy cohorts had an opposite trend with higher or comparable incidence level of low-grade Tr AEs in patients with non-Tr AEs. Regarding survival association in early AEs, we found some early AE biomarkers were associated with survival outcomes in 5 cohorts. Specifically, one immunotherapy cohort and one chemotherapy cohort showed patients experienced treatment related grade 1 (Tr-G1) early overall AE had improved PFS or OS. Other significant associations were non-Tr AEs either low or high-grade level associated with poorer PFS or OS in three immunotherapy cohorts and one targeted therapy cohort. Another common pattern observed was hazard ratio (HR)>1 in high-grade AEs and HR<1 in some low-grade AEs.
Conclusion: This is the first study to portray early AE outlook in advanced NSCLC. Further analysis of survival association in early AEs identified low-grade treatment related early AEs correlated with better PFS or OS.

#3366 Determinants of survival in hemophagocytic lymphohistiocytosis: A real-world database analysis.

P. A. Haddad, S. Chennapragada, D. Kantamani, S. Gaddam;
LSUHSC-S Feist-Weiller Cancer Ctr./Overton Brooks VAMC, Shreveport, LA

Background: Hemophagocytic lymphohistiocytosis (HLH) is a severe, life-threatening syndrome characterized by the uncontrolled activation of lymphocytes and macrophages, resulting in hyperinflammation and tissue damage. HLH manifests in two forms: primary (familial), driven by genetic mutations affecting cytotoxic function, and secondary (acquired), triggered by infections, malignancies, autoimmune disorders, or other conditions. This study aims to identify key prognostic factors, clinicopathologic characteristics, and therapeutic strategies that impact survival outcomes in HLH patients through a pooled database analysis.
Methods: We analyzed a real-world database of confirmed HLH cases, evaluating demographic features, molecular and immunohistochemical profiles, potential prognostic indicators, treatment interventions, and survival outcomes. Kaplan-Meier survival curves were generated, and Cox proportional hazards models and Log-rank tests were applied to assess the effect of various clinicopathologic factors on overall survival (OS).
Results: The study included 255 confirmed HLH patients, with a median age of 32 and a male-to-female ratio of 1.5. Primary HLH comprised 8% of cases, with PRF1 mutations present in 33%. Triggering etiologies included infections (49%), malignancies (19%), autoimmune conditions (8%), and unknown causes (24%). Tissue hemophagocytosis was observed in 56% of cases, while liver (58%), pulmonary (25%), renal (23%), neurological (15%), and cardiac (9%) dysfunction were also noted. Median OS for the entire cohort was 24 months. Factors significantly associated with worse OS included age $\geq$50 (p=0.003), splenomegaly (p=0.02), malignancy (p=0.0004), LDH $\geq$1000 U/L (p=0.003), sIL2R $\geq$5000 U/ml (p=0.03). Patients with pulmonary or renal dysfunction also had worse OS. Etoposide-based regimens and non-chemotherapy immunosuppression improved median OS compared to supportive care (24 vs. NR vs. 3 months, p=0.038). Of note, etoposide-based regimens arm had a greater percentage of high-risk patients. Complete responders had superior OS compared to those with partial and no response, respectively (NR vs. 18 vs. 0.75; p<0.0001). Moreover, patients with relapse <2months had worse survival (6 vs. NR months, p=0.01).
Conclusion: This analysis, from the largest real-world HLH cohort, highlights key prognostic factors such as age, splenomegaly, malignant etiology, LDH, sIL2R, organ dysfunction, treatment approach, and quality of response as critical determinants of overall survival in HLH patients.

#3367 Determinants of survival in acute megakaryocytic leukemia: A real-world database analysis.

P. A. Haddad[1], S. Vutukuri[2], A. Gupta[2];

[1]LSUHSC-S Feist-Weiller Cancer Ctr./Overton Brooks VAMC, Shreveport, LA, [2]Overton Brooks VAMC, Shreveport, LA

Background: Acute megakaryocytic leukemia (AMKL) is a rare and aggressive subtype of acute myeloid leukemia (AML), characterized by the malignant proliferation of megakaryoblasts. It accounts for less than 1% of AML cases in adults but is more prevalent in pediatric patients, particularly those with Down syndrome. AMKL poses unique diagnostic and therapeutic challenges due to its distinct clinical and biological features, and overall prognosis remains poor. The prognostic factors influencing survival in AMKL are not well-defined, prompting this pooled real-world database analysis to identify clinicopathological characteristics and treatment strategies associated with survival outcomes.

Methods: A pooled database of confirmed AMKL cases was analyzed to assess demographic characteristics, molecular and immunohistochemical profiles, therapeutic interventions, and survival outcomes. Kaplan-Meier survival curves were used to estimate overall survival (OS), while Cox proportional hazards models and Log-rank tests assessed the impact of clinicopathologic factors on OS.

Results: A total of 220 patients with confirmed AMKL were included, with a median age of 3 years. The M:F was 1.3 overall, differing between pediatric (M:F of 1) and adult (M:F of 2) subgroups. The median duration of symptoms before diagnosis was 1 month. Constitutional symptoms, lymphadenopathy, splenomegaly, hepatomegaly, and bone involvement were present in 40%, 19%, 34%, 26%, and 13% of cases, respectively. The cohort median OS was 13 months, with pediatric patients showing significantly better OS compared to adults (44 vs. 5.9 months, $p<0.0001$). Patients with constitutional symptoms ($p=0.05$), lymphadenopathy ($p=0.06$), or elevated LDH (>500 U/L, $p=0.07$) had worse OS, with borderline statistical significance. However, patients with Down syndrome had significantly improved OS (NR vs. 12 months, $p=0.01$). Positive staining for CD4 (<0.0001), CD7 ($p=0.04$), or CD13 ($p=0.03$) was associated with better OS. Sex, WBC count, hemoglobin levels, platelet count, t(1;22), inv(16), and splenomegaly did not significantly impact OS. AMKL arising in the context of malignancy or myeloproliferative disorders was associated with worse OS ($p<0.0001$). Chemotherapy and stem cell transplantation provided superior OS compared to no treatment (10 vs. 23 vs. 1.5 months, $p<0.0001$). Low-intensity regimens offered no significant benefit over no treatment. Patients who achieved complete remission (CR) had significantly improved OS compared to those who did not (44 vs. 4 months, $p<0.0001$).

Conclusion: The analysis of this large pooled cohort of AMKL patients identified key factors influencing survival, including age, Down syndrome status, association with malignancy or myeloid disorders, treatment intensity, and quality of response. These findings provide valuable insights for improving prognostication and guiding treatment strategies in AMKL.

#3368 Hemophagocytic lymphohistiocytosis provisional prognostic score.

P. A. Haddad, S. Chennapragada, D. Kantamani, S. Gaddam;
LSUHSC-S Feist-Weiller Cancer Ctr./Overton Brooks VAMC, Shreveport, LA

Background: Hemophagocytic Lymphohistiocytosis (HLH) is a life-threatening syndrome characterized by the uncontrolled activation of lymphocytes and macrophages, leading to excessive cytokine production, hyperinflammation, and tissue damage. HLH presents in two forms: primary (familial) HLH, associated with autosomal recessive genetic mutations affecting cytotoxic function, and secondary (acquired) HLH, triggered by infections, malignancies, autoimmune diseases, or other underlying conditions. Given the variability in HLH outcomes, this study aimed to develop a provisional prognostic score (HLHPS) to stratify patient risk.
Methods: We analyzed data from a real-world HLH database, comprising 255 cases. Data included demographic information (sex, age, race), blood counts, comorbidities, immunohistochemical and molecular disease phenotypes, treatment types, and survival outcomes. Of these, 219 cases with complete survival data were selected for analysis. A Cox proportional-hazards model and Log-rank tests were applied to identify clinicopathologic factors significantly affecting overall survival (OS), which were then incorporated into a provisional prognostic score based on the impact of hazard ratios.
Results: The median OS for the cohort was 24 months. The key prognostic factors identified were: age $\geq$50 (9 vs. 60 months; p=0.003), underlying malignancy (2 vs. 60 months; p=0.0004), splenomegaly (22 vs. NR months; p=0.02), LDH $\geq$1000 U/L (24 vs. NR months; p=0.003), and sIL2R $\geq$5000 U/ml (6 vs. NR months; p=0.03). A prognostic model was created using these variables, with each variable assigned 1 point when present, for a total score ranging from 0 to 5. Risk categories were defined as low (0-1 points), intermediate (2 points), and high (3-5 points). This prognostic score system led to our cohort's most optimal risk discriminatory model, with low, intermediate, and high risk groups having a median OS of NR, 22, and 1.8 months, respectively (p<0.0001).
Conclusion: The HLHPS is a promising tool for risk stratification in HLH patients, offering a new approach to predict outcomes. However, further prospective validation is necessary to confirm its utility.

#3369 Identifying biomarkers of resistance for immunotherapy-treated patients with non-small-cell lung cancer using real-world evidence and machine learning.

Chao Fang[1], **Natasha Markuzon**[1], Sajan Khosla[2]

[1]AstraZeneca Oncology, Waltham, MA,[2]AstraZeneca Oncology, Cambridge, United Kingdom

Immunotherapy (IO) has revolutionized the management of non-small-cell lung cancer (NSCLC), leading to groundbreaking improvements in patient survival. However, resistance to IO in some patients remains a challenge. Existing IO resistance biomarkers are based on either clinical or genomic factors. Combining genomic factors with patient health characteristics is pivotal in developing new resistance markers and improving the accuracy of predictions of treatment resistance.

The objective of this study is to develop a data-driven model with no a priori assumptions using real-world evidence (RWE) data to identify predictors of treatment resistance in NSCLC patients treated with first-line IO. By integrating clinical and genomic features, we aim to assess the differences in the importance of genomic mutations under various clinical conditions and identify new biomarkers associated with IO resistance.

Using clinical and genomic features from real-world evidence (RWE) Flatiron dataset for an NSCLC cohort treated with first-line IO, we developed a machine learning (ML) model to identify predictors of treatment resistance. Using progression-free survival (PFS) as an endpoint, the model identified key contributing factors, a combination of clinical and genomic features, where the importance of genomic mutations varies under different clinical conditions. Specifically, in patients with ECOG scores of 0 or 1 and no metastasis, the CDKN2A mutation was associated with reduced PFS; for those with ECOG scores of 0 or 1 and with metastasis, CDKN2A was associated with decreased PFS and KRAS with improved PFS; and for patients with ECOG scores of 2-4, KRAS was associated with improved PFS.

Our results underscore the value of RWE in identifying resistance biomarkers, demonstrate the efficacy of a data-driven methodology able to extract combinations of important features without prior assumptions, and highlighted the importance of integrating clinical and molecular data to understand patient-level risk factors of treatment resistance. Using our methodology, we pinpointed statistically significant biomarkers linked to an increased risk of treatment resistance in NSCLC patients undergoing first-line IO treatment.

#3370 MCC-MELD: A diverse lung cancer registry with detailed molecular and environmental annotation.

Luchang Cui[1], Juhong Lee[2], Sajjad Abedian[2], Minmeng Tang[3], James Solomon[4], Robert Crupi[5], Juliet Miller[6], H. Oliver Gao[3], Evan Sholle[2], Christine Garcia[6], Eunji Choi[1], Yiwey Shieh[1]

[1]Department of Population Health Sciences, Weill Cornell Medicine, New York, NY,[2]Information Technologies & Services Department, Weill Cornell Medicine, New York, NY,[3]School of Civil and Environmental Engineering, Cornell University, Ithaca, NY,[4]Department of Pathology and Laboratory Medicine, Weill Cornell Medicine, New York, NY,[5]Ambulatory Care and Population Health, NewYork-Presbyterian Queens, New York, NY,[6]Department of Medicine, Weill Cornell Medicine and New York Presbyterian Hospital, New York, NY

Background: Research on EGFR-mutated lung cancers has been constrained by the scarcity of large, diverse datasets integrating molecular, clinical, and environmental data. To address this gap, we built the Meyer Cancer Center Molecularly Enhanced Lung Cancer Database (MCC-MELD), which combines molecular testing results, detailed clinical information, and fine-resolution environmental data while leveraging the diversity of our catchment area.

Methods: MCC serves as the cancer center for Weill Cornell Medicine, comprising three clinical sites in New York City: Manhattan, Queens, and Brooklyn. We extracted electronic health record (EHR) data for patients diagnosed with lung cancer from all sites using Epic, and from Queens (AllScripts) and Brooklyn (Cerner Millennium) sites prior to Epic implementation in 2020. We obtained tumor characteristics and treatment history from the ONCOLog internal tumor registry (2010-2020) and a manually curated lung cancer database maintained by our thoracic oncology clinic (2010-2024). We retrieved molecular testing results from an in-house pathology database (cBioPortal) and from the EHR. We used natural language processing (NLP) powered by generative artificial intelligence (AI) using Gemini-1.0-pro to abstract additional factors, including quantitative smoking data. Area-level factors - including air pollution, neighborhood socioeconomic status, and built environment - were linked to geocoded patient addresses at diagnosis. To address the challenges of measuring air pollution in densely populated urban areas, we will use a hyperlocal AI model that estimates longitudinal air pollutant levels on a 1000-by-1000-meter grid scale.

Results: We identified a maximally inclusive cohort of 12,285 patients, with 8,754 comprising the analytic cohort (2010-2024) of confirmed lung cancer patients. The cohort included 53% female patients (compared to 44% nationally), with racial and ethnic representation of 20% Asian, 13% Black, 8% Hispanic, and 46% White patients. Lung cancer cases among nonsmokers increased from 9.9% to 20.0% over the study period. Of the cases that received in-house comprehensive genomic profiling, EGFR alterations were found in 28.7% (766 of 2,671). Our preliminary NLP achieved high accuracy in extracting smoking status (87.1%) and smoking intensity (94.4%, measured as packs smoked per day).

Discussion: MCC-MELD shows the feasibility of integrating AI-powered annotation and prediction into clinical research, providing a robust platform to study risk factors, prognostic indicators, and care patterns for EGFR-mutated lung cancers. Our planned analysis using our hyperlocal air pollution model will allow us to assess the relationship between air pollutants and EGFR-mutated lung cancer at a uniquely fine scale. We expect MCC-MELD will be a valuable resource for advancing research on lung cancer risk and outcomes in a diverse urban population.

#3371 Gene deletions in estrogen receptor positive HER2-negative breast cancer are associated with worse outcome than predicted by diagnostic-grade gene expression assays.
