Background: Duchenne muscular dystrophy (DMD) is a severe X-linked neuromuscular disease caused by mutations in the *DMD* gene, resulting in progressive muscle degeneration and premature mortality. Current therapies, including antisense oligonucleotides such as Casimersen (targeting exon 45) and Eteplirsen (targeting exon 51), achieve dystrophin restoration to < 2% of normal levels after 1-year with the burden of weekly administration. Similarly, AAV-micro-dystrophin gene therapies require high doses, often leading to adverse events such as liver toxicity, immune-related myositis, and myocarditis. To address these limitations, we developed HG302, a one-time, CRISPR-high-fidelity(hf)Cas12Max-based single-cut genome editing therapy designed to induce exon skipping and restore dystrophin expression with minimal off-target effects. Preclinical studies demonstrated robust safety and efficacy, and HG302 is now being evaluated in the MUSCLE clinical trial to assess its therapeutic potential in DMD patients.

Methods: A novel humanized DMD mouse model carrying human exon 51 was generated to evaluate single-cut genome editing using human sgRNAs and Cas variants in vivo. HG302, a single adeno-associated virus (AAV) vector delivering hfCas12Max and a guide RNA targeting the splice donor (SD) site of human exon 51, was evaluated for in vitro and in vivo editing efficiency, dystrophin restoration, and muscle function. Preclinical studies were conducted in both *DMD* mice (**Fig.1A**) and wild-type non-human primates (NHPs) (**Fig.1G**) to assess safety and efficacy. The ongoing **MUSCLE** trial (an open-label, **M**ultidose, dose-escalation study to **U**nderstand the **S**afety of **C**RISPR gene-editing therapy and its long-**L**asting **E**ffects in DMD patients; NCT06594094) is enrolling ambulant DMD boys aged ≥4 years with impaired muscle function to evaluate the safety, tolerability, and clinical efficacy of HG302 (**Fig. 2**).

Results: The humanized *DMD* mouse model exhibited severe DMD disease phenotypes, making it suitable for in vivo evaluation of CRISPR-based therapies. HG302 achieved efficient exon skipping in vitro, targeting the SD site of human DMD exons 51. Systemic AAV delivery of HG302 in DMD mice restored dystrophin protein levels to up to 70% of wild-type levels (**Figs.1C** and **1D**) and significantly improved motor functions, as evidenced by enhanced rotarod performance and grip strength (**Figs.1E** and **1F**). In NHPs, low-dose systemic HG302 administration confirmed efficient genome editing across muscle tissues (**Figs.1H** and **1I**). Safety evaluations revealed no abnormalities in liver enzymes (ALT, AST) or kidney function in either DMD mice or NHPs. In the **MUSCLE** trial (**Fig.2**), the first DMD boy dosed with HG302 demonstrated favorable safety and tolerability, with no observed elevations in ALT, AST, total bilirubin, or thrombotic microangiopathy. Early clinical data at a low AAV dose (E13

vg/kg) demonstrated improved motor function post-injection, outperforming reported outcomes for AAV micro-dystrophin gene therapies.

Conclusions: CRISPR/hfCas12Max-mediated single-cut genome editing therapy offers a transformative, "one-and-done" therapeutic approach for DMD. It provides significant advantages over existing treatments in safety, efficacy, and durability. The U.S. FDA has recognized HG302 with Orphan Drug Designation and Rare Pediatric Disease Designation, underscoring its potential to revolutionize DMD therapy and improve patient outcomes.

Prion disease is a progressive and fatal neurodegenerative disorder arising from misfolding of the normal cellular prion protein (PrP^{C}) into a pathogenic "Scrapie" form (PrP^{Sc}). There are at least 1300 new cases each year in the US and Europe. While there is currently no approved treatment for prion disease, the histopathological, biochemical, and genetic evidence all converge on PrP^{C} as the primary drug target for treating prion disease. We are developing a one-time, intravenously (IV) administered AAV-based therapy using a zinc finger repressor (ZFR) epigenetic regulator to achieve sustained lowering of prion protein (PrP^{C}) in neurons throughout the brain as a potential therapeutic for prion disease. We conducted pharmacology and efficacy studies to investigate the dose-response relationship between prion repression and survival across a 10-fold AAV dose range (1E+13 to 1E+14 vg/kg) and used a combination of bulk and single-cell measurements to assess the relationship between pharmacology and efficacy. In C57BL/6 mice, brain-wide neuron-selective ZFR expression mediated up to 50% bulk level mRNA repression of mouse prion gene, *Prnp*, and 45% PrP protein reduction in a dose-dependent manner. Moreover, ZFRs were stably expressed and lowered neuronal *Prnp* expression throughout the central nervous system for at least 17 months with no diminution of effect. At the single-cell level, near complete repression was observed in multiple brain regions in ZFR+ cells at all AAV doses tested, indicating that the dose-dependent repression observed at the bulk level is primarily driven by the fraction of neurons transduced. In a parallel efficacy study, C57BL/6 mice were

inoculated with Rocky Mountain Laboratory (RML) prions and dosed with an AAV-ZFR at these same doses and at different timepoints during the disease course. A significant and dose-dependent increase in median survival was observed for all AAV-ZFR treatment groups, even in mice exhibiting clinical signs of prion disease at the dosing time, with many mice surviving until the planned endpoint of the study (500 days post RML inoculation).

We next used a single IV dose of a novel BBB-penetrant AAV capsid (STAC-BBB) to deliver a single construct expressing green fluorescent protein (GFP) and a human *PRNP*-targeted ZFR to nonhuman primates (NHPs). Neuronal transduction efficiency ranged from ~26-65% across a range of cortical and subcortical regions. We detected ZFR expression and *PRNP* mRNA reduction in all 35 brain regions analyzed. At the single-cell level, STAC-BBB mediated brain-wide ZFR expression and significant *PRNP* repression in transduced neurons across prion disease relevant brain regions, including the postcentral gyrus (82.5%), precentral gyrus (90%), supramarginal gyrus (80%), hippocampus (90.5%), midbrain (72%), putamen (95%), caudate (95%), and thalamus (82%). Critically, AAV transduction and *PRNP* repression levels observed in the NHP study were similar to those associated with profound survival benefits in RML disease mice, supporting the translational potential of STAC-BBB delivered ZFRs for the potential treatment of prion disease.

3 Comet LV: a lentiviral vector-based mRNA co-packaging technology for enhanced *ex vivo* and *in vivo* gene therapy

Chiara Bresesti[1], Eleonora Carito[1], Attya OMER[2], Gabriele Pedrazzani[3], Marco Notaro[4], Giovanna Giacca, Maristella Borghetti[5], Sara Breggion[5], Luigi Naldini, Mario Leonardo Squadrito[6]*

**Corresponding Author*

Background

Lentiviral vectors (LVs) are versatile tools for genetic engineering, capable of stably transducing both dividing and non-dividing cells. LVs have been traditionally used to integrate foreign genetic material into the host's genome, enabling its stable expression. However, persistent transgene expression may be undesirable in some applications, such as those involving toxic payloads or selectors of transduced cells. To address this limitation, we developed Comet LV, a novel LV-based platform which enables the simultaneous delivery of transiently and stably expressed genetic payloads to targeted cell populations.

Materials and Methods

Comet LVs incorporate RNA-binding proteins localized to the viral envelope via a membrane-targeting domain. In turn, these proteins bind mRNAs of interest thanks to specific aptamer-protein interactions, promoting their packaging into the viral particle. Thus, Comet LVs can be employed to co-deliver mRNAs of interest in vitro to cell lines and primary cells, or in vivo to mice by intravenous injection. The expressions of the transgenes encoded by either the integrated viral vector or the co-packaged mRNA was evaluated by flow cytometry or ELISA.

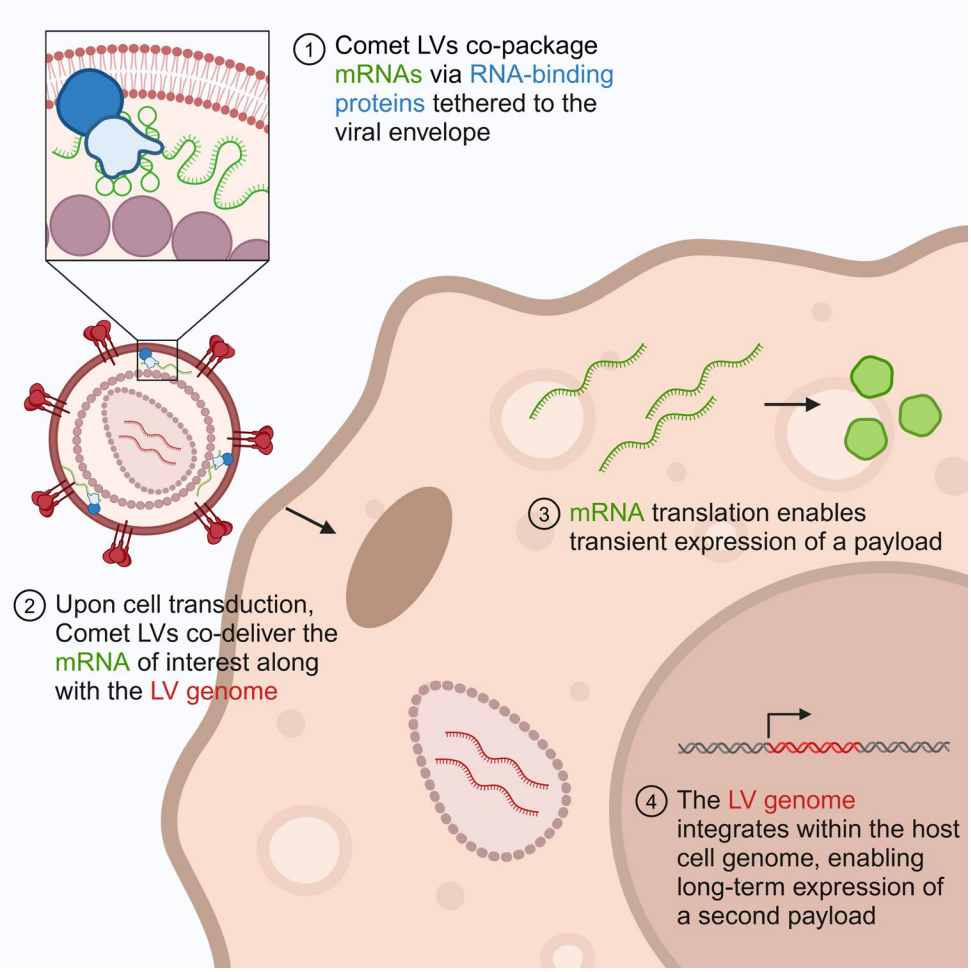
Results

We employed Comet LVs for in vivo antitumor vaccination, delivering a tumor antigen (TA) mRNA alongside an integrating cassette encoding IFNa, an immune-stimulating cytokine. Mice injected with these vectors presented elevated circulating IFNa levels comparable with standard vectors and developed TA-specific T cells.

Additionally, we employed Comet LVs to deliver CXCR4 mRNA to hematopoietic stem and progenitor cells (HSPCs) while transducing them with a corrective integrating payload. Of note, transient CXCR4 expression enhances HSPC engraftment, enabling a chemotherapy-free, mobilization-based conditioning regiment. HSPCs transduced with Comet LVs displayed transient CXCR4 overexpression compared to untreated cells.

Conclusions

Our system couples the benefits of mRNA transient expression with LV potential for stable transduction and favorable safety profile. This approach offers a modular, customizable tool for cell engineering that can be especially useful in applications requiring joint short and long-term transgene expression. For instance, Comet LV could prove useful for antitumor vaccination and enhanced engraftment of edited HSPCs. Furthermore, this platform could improve genome editing strategies by enabling temporary expression of gene editors delivered alongside corrective IDLV templates. For these reasons, Comet LVs represent an innovative tool that could significantly advance both therapeutic and research applications in genetic engineering.



Clinical Trial Spotlight Symposium

4 Treatment effect of atidarsagene autotemcel (arsa-cel) in age-matched treated vs. untreated sibling pairs with early-onset metachromatic leukodystrophy (MLD)

Valeria Calbi[1], Jean Brooks[2], Margite Borth[3], Charlotte Chanson[3], Andrew Shenker[4], Nicholas Gollop[2], Maria Ester Bernardo[5], Alessandro Aiuti[6], Francesca Fumagalli[7], Karen Bean[3]

INTRODUCTION

Metachromatic leukodystrophy (MLD) is a rare neurodegenerative lysosomal storage disease caused by a deficiency of arylsulfatase A (ARSA) enzyme that leads to rapid motor and cognitive decline and premature death in untreated patients. Atidarsagene autotemcel (arsa-cel) is a hematopoietic stem cell gene therapy consisting of autologous CD34+ cells transduced *ex vivo* with a lentiviral vector encoding the human *ARSA* gene. Primary efficacy and safety data have previously been presented for 39 early-onset MLD patients (consisting of late infantile [LI] and early juvenile [EJ] subtypes) treated with arsa-cel, compared to 49 patients from a natural history (NHx) cohort; however, no specific analysis of paired treated and untreated siblings has been presented. Sibling pair analyses undertaken to estimate treatment effect in patients with any genetic disease remove some of the inherent uncertainty related to variability in disease progression due to different genotypes or environmental influences. This analysis compares clinical outcomes for age-matched arsa-cel treated vs. untreated NHx sibling pairs.

METHODS

Twenty-five patients treated pre-symptomatically in the arsa-cel clinical development program (CDP) had a sibling in the NHx cohort (16 LI pairs; 9 EJ pairs); all were identified because of their older untreated symptomatic sibling's diagnosis. Pairs of siblings were included in the analysis if a gross motor function assessment (GMFC-MLD or GMFM-88) for the NHx siblings was performed at an age of assessment within +/- 3 months of the treated sibling, and the treated sibling had been followed up for at least 2 years post gene therapy. The latest matched assessments were used to achieve the longest follow-up (range: age at assessment 30.6-106.7 months).

RESULTS

Of the age-matched sibling pairs (N=22), 86.4% (n=19) had a difference of at least 4 levels in the GMFC-MLD scale in favor of arsa-cel (Wilcoxon signed rank test for difference in GMFC-MLD levels $p<0.001$) at the last age-matched assessment. Specifically, 86.4% (n=19) of the treated siblings retained the ability to walk independently (GMFC-MLD level 0 or 1), while 81.8% (n=18) of NHx LI and EJ siblings had lost all gross motor function (GMFC-MLD level 6).The mean (95% CI) absolute difference in total GMFM-88 score for all sibling pairs (N=11) was 76.3 (58.4, 94.3) in favor of arsa-cel ($p<0.001$). This difference was more pronounced in the LI subtype where the mean absolute difference was 84.9. Table 1 presents gross motor function outcomes for the sibling pairs by MLD subtype.

CONCLUSION

The results for the subset of sibling pairs align with the previously presented data from the presymptomatic LI and EJ CDP population vs. the NHx cohort. Given the stark difference in motor outcomes between the treated and untreated sibling pairs, this analysis reinforces the importance of early diagnosis through newborn screening to enable all early-onset patients to have the opportunity for pre-symptomatic treatment, not just the younger siblings of symptomatic patients.

Clinical trial registration: NCT01560182, NCT03392987, EudraCT 2009-017349-77, EudraCT 2017-001730-26

Table 1: Gross motor function outcomes for LI and EJ MLD sibling pairs by MLD subtype

Subtype	Proportion with difference in GMFC-MLD level of ≥ 4			Absolute difference in total GMFM-88 score		
	N	n (%)	P value [a]	N	Score (95% CI)	P value [b]
Late infantile	15	14 (93.3%)	p<0.001	8	84.9 (77.3, 92.5)	p<0.001
Early juvenile	7	5 (71.4%)	p=0.016	3	53.6 (-62.9, 100)	p=NS

Background:
Current therapies for idiopathic inflammatory myopathy (IIM) aim to control inflammation and disease activity and decrease long-term morbidity and mortality but many do not provide durable clinical responses without requiring chronic immunosuppressive drugs. CD19-targeting chimeric antigen receptor (CAR) T cells have achieved durable, drug-free responses in IIM patients in an academic program. Rese-cel (formerly referred to as CABA-201) is a fully human, autologous 4-1BB anti-CD19-CAR T cell therapy, designed to deeply and transiently deplete CD19 positive B cells following a one-time weight-based infusion of $1x10^6$ CAR T cells/kg. This approach may enable durable responses in patients without the need for chronic immunosuppression. RESET-Myositis™ (NCT06154252) is an ongoing Phase 1/2 trial evaluating rese-cel in three independent cohorts of adults with IIM (immune mediated necrotizing myopathy (IMNM), dermatomyositis (DM), and antisynthetase syndrome (ASyS)), as well as a fourth cohort of patients with juvenile IIM (JIIM).

Results:
Here we report on the first three patients with IIM treated with rese-cel that have completed at least 1 month of follow-up in the RESET-Myositis™ trial (IMNM-1, IMNM-2 and DM-1). Rese-cel has been well-tolerated with no dose-limiting toxicity, cytokine release syndrome (CRS) or immune effector cell-associated neurotoxicity syndrome (ICANS) in these patients with at least 1 month of follow-up.

Infusion products consisted of predominantly CD4+ CAR T cells and exhibited in vitro cytolytic activity towards a NALM6 target cell line. Leukocyte and lymphocyte counts dropped quickly and transiently after a standard preconditioning regimen of fludarabine ($25mg/m^2$/day x 3) and cyclophosphamide ($1000mg/m^2$) which inversely corresponded with a transient elevations in serum IL-15 levels in all patients. Following infusion of rese-cel, CAR T cells peaked in circulation between days 8 and 15 (C_{max}). CAR T cells were undetectable peripherally by day 29 for

IMNM-1 and IMNM-2 and remained detectable at low levels for up to 12 weeks for DM-1. Serum IFN-γ levels increased prior to or in parallel with rese-cel C_{max} and CAR T cells exhibited a predominantly CD8+ phenotype at C_{max}. B cells were rapidly depleted by 15 days post rese-cel infusion and remained undetectable through the first month in all 3 patients. Repopulation with transitional naïve B cells ($CD19^{+}CD20^{+}CD38^{++}CD24^{++}$) occurred at 8 weeks post-infusion in IMNM-1 and DM-1. B cells were detected at low levels in IMNM-2 at 12 weeks following rese-cel infusion. Antibodies associated with infectious diseases and vaccinations remained generally stable in patients, whereas serum levels of myositis-specific autoantibodies, including SRP-54, SAE1/2, and HMGCR decreased over the follow-up period in IMNM-1, DM-1, and IMNM-2, respectively. To date, all patients have had increases in their total improvement scores despite discontinuation of all immunosuppressants at the time of infusion, a clinically validated scoring system used to assess improvements in IIM patients.

Conclusions:
These emerging data detail the pharmacokinetics and pharmacodynamics of rese-cel in adult patients with IIM, supporting the potential for rese-cel to induce durable, drug-free remissions. Evaluation of the safety and efficacy of rese-cel continues in the ongoing Phase 1/2 RESET-Myositis™ trial.

6 Extensive detoxification and favorable effects on systemic clinical outcomes after Hematopoietic Stem Cell Gene Therapy for Mucopolysaccharidosis Type I-Hurler (OTL-203)

Francesca Tucci[1], Giulia Consiglieri[2], Francesca Fumagalli[2], Maurizio De Pellegrin[2], Maria Luz Uria Oficialdegui[3], Matilde Cossutta[1], Chiara Filisetti[1], Maria Pia Manitto[4], Carla Butera[5], Giulia Danè[5], Chiara Camesasca[6], Francesca Ciotti[2], Marina Sarzana[7], Serena Gasperini[8], Mireia Del Toro[3], Cristina Diaz de Hereida[3], Rossella Parini[9], Bernhard Gentner[10], Alessandro Aiuti[11], **Maria Ester Bernardo[12]**
[1]San Raffaele Telethon Institute for Gene Therapy, Milano, Milano, Italy, [2]San Raffaele Telethon Institute for Gene Therapy, Milano, Italy, [3]Vall d'Hebron Hospital, Barcelona, Spain, [4]San Raffaele Hospital, Milan, Italy, [5]San Raffaele Hospital, Milano, Italy, [6]San Raffaele Hospital, Milano, Milano, Italy, [7]San Raffaele Telethon Institute for Gene Therapy, Milano, Lodi, Italy, [8]IRCCS San Gerardo Hospital, Monza, Monza e Brianza, Italy, [9]San Raffaele Hospital, Milano, Italy, Italy, [10]SR-TIGET, Lausanne, Switzerland, [11]San Raffaele Telethon Institute for Gene Therapy, ITALY, [12]San Raffaele Telethon Institute, Milan, Milano, Italy

Preliminary results of a phase I/II study of OTL-203, an autologous hematopoietic stem cell gene therapy (HSC-GT, NCT03488394), in 8 patients (6M, 2F; mean ±SD age at treatment: 1.9±0.5 years) with mucopolysaccharidosis type I-Hurler (MPS-IH) suggest superior metabolic correction compared to an external cohort treated with allogeneic hematopoietic stem cell transplantation (allo-HSCT) and initial clinical response in several organs (Gentner *et al. N Engl J Med* 2021; *Consiglieri et al. Sci Transl Med 2024*). Here we report interim multi-system clinical outcomes at a median follow-up of 5 years post-HSC-GT (range 4-5 years).

IDUA activity was measured in blood and cerebrospinal fluid (CSF) and glycosaminoglycans (GAGs) in urine and CSF at baseline and regular timepoints up to 5-years post-treatment. Skeletal, neurological, corneal clouding (CC), carpal tunnel syndrome (CTS) and cardiac score were assessed at baseline and up to 5-years post-treatment. For specific outcomes OTL-203 patients were compared with retrospectively collected data from two external cohorts of MPS-IH patients who underwent allo-HSCT in two experienced transplant centres (N=9 and 14, respectively).

All OTL-203 treated patients are alive after a median follow-up of 5 years, without any evidence of anti-IDUA IgG antibody response or vector integration site-driven clonal dominance. At last evaluation, all patients continued to show sustained engraftment of gene-corrected cells and supraphysiologic IDUA activity in blood, resulting in extensive urinary GAG substrate clearance (dermatan sulfate (DS) to normal/near normal levels). In CSF, IDUA activity became detectable as early as 3 months post-OTL-203 and persisted over time, accompanied by extensive reduction of GAGs in CSF. All patients exhibited longitudinal growth within expected reference ranges according to age and gender, and experienced a complete and earlier normalization of joint mobility compared with allo-HSCT patients. Both hip X-ray and MRI parameters improved after OTL-203 treatment, indicating amelioration of hip dysplasia up to last follow-up. A specific spine MRI score showed stabilization of the typical spine MRI features at last follow-up. After OTL-203 treatment, 7/8 patients continued to gain motor and cognitive skills in line with

typically developing children and experienced an improvement/stabilization of typical brain MRI abnormalities. At baseline, all patients showed mild to moderate CC. Of the OTL-203 treated patients, 4/8 achieved CC resolution and 4/8 had mild CC at last follow-up. In the allo-HSCT cohort, no patient experienced CC resolution with all patients showing moderate CC at 5-years post-treatment. One OTL-203 patient underwent carpal tunnel surgery pre-treatment and another 6 months after OTL-203 due to pre-existing severe damage pre-treatment. The remaining patients did not develop CTS. In the allo-HSCT cohort 7/9 patients developed CTS, requiring surgery at a median of 3.7 years post-allo-HSCT. A specific echocardiac score showed worsening of cardiac involvement in allo-HSCT patients compared to OTL-203 patients who stabilized or improved their score.

Our results indicate sustained engraftment of gene-corrected cells, extensive detoxification of GAGs and favorable effects of OTL-203 on MPS-IH multi-systemic clinical manifestations up to 5-years after treatment. Long-term comparative studies are warranted for definitive conclusions.

7 Phase I Clinical Trial of Safety and Efficacy of the dAd5GNE Anti-Cocaine Vaccine

Stephen Kaminsky[1], Bishnu De[2], Sandra Hyde[1], Niamh Savage[1], Madeline Galbraith[3], Sara Cram[1], Anisette Ruda[1], Anthony Caragiulo[1], Che Martin[1], Cheyenne McKnight[1], Victor Wakim[1], Dolan Sondhi[1], Mirella Salvatore[1], Ann Beeder[1], Ronald Crystal[4]
[1]Weill Cornell Medical College, New York, NY, [2]Weill Cornell Medical College, New York, New York, [3]Weill Cornell Medical College, New York, NY, [4]Weill Cornell Medical College, New York

Cocaine addiction is a major health issue for which there is no effective therapy. We have developed a vaccine (dAd5GNE) to treat cocaine addiction, based on the cocaine analog GNE linked to the capsid proteins of a disrupted serotype 5 adenovirus. The vaccine is designed to evoke anti-cocaine antibodies that sequester cocaine in the blood, preventing access to the CNS and blocking access to the cocaine cognate receptors, abrogating the reward mechanism. The dAd5GNE vaccine is a disrupted $E1^{-}E3^{-}$ serotype 5 Ad with GNE, a stable cocaine analog covalently linked to the Ad capsid proteins. In rodents and nonhuman primates, dAd5GNE evoked persistent, specific, high titer and high affinity anti-cocaine antibodies that prevent cocaine from reaching the brain, blocking cocaine-induced hyperactivity and limiting cocaine self-administration behavior with an acceptable safety profile for a clinical trial. Based on this data, we initiated a phase I, blinded, placebo controlled clinical trial where chronic cocaine addicts (average use of cocaine 3.9 gm/week) were immunized with dAd5GNE together with the Adjuplex® adjuvant. This interim report summarizes the assessment of dose 1 (100 μg intramuscular (IM) monthly x 6 months dAd5GNE n=7, placebo n=3) and dose 2 (316 μg IM monthly x 6 months dAd5GNE n=3, placebo n=3). Drug-related adverse events included minor arm soreness, transient fever and headache. Both doses evoked highly stable levels of anti-cocaine specific antibodies (100 μg dose, titer $2.4x10^5 \pm 1.2x10^5$, 316 μg dose, titer $3.6x10^5 \pm 2.1x10^5$). Assessment of the 2 dose cohorts demonstrated that for dAd5GNE vaccination *vs* placebo: (1) higher levels of anti-cocaine titers were associated with less craving ($p<0.02$); (2) cohort 1 had less craving and fewer days of cocaine use ($p<0.05$); (3) cohort 2 used less cocaine ($p<0.02$); and (4) cohort 2 was associated with more days in a row of no cocaine use ($p<0.02$). In summary, dAd5GNE has an excellent safety profile, high titer antibody response and initial measures of efficacy, suggesting it may be a useful vaccine for treatment of cocaine addiction.

8 Phase I/II Trial of Adipose Tissue Derived Mesenchymal Stem Cell Delivery of a Measles Virus Strain Engineered to Express the Sodium Iodine Symporter (MV-NIS) in Ovarian Cancer Patients

Evanthia Galanis[1], Pamela Atherton[2], Erik Asmus[2], John Weroha[2], Amanika Kumar[2], Gretchen Glaser[2], Carrie Langstraat[2], Katharine Dooley[2], Carolyn Klampe[2], Kim Viker[1], Aminah Jatoi[2], Mark Federspiel[2], Autumn Schulze[2], Kah-Whye Peng[2], Megan Grudem[2], Courtney Erskine[2], Siddhartha Yadav[3], Keith Knutson[4], Allan Dietz[2], Wen Lu[2], Maryam Shahi[2], Andrea Wahner-Hendrickson[2], Matthew Block[2]
[1]Mayo Clinic, Rochester, Minnesota, [2]Mayo Clinic, Rochester, MN, [3]Rochester, MN, [4]Mayo Clinic, Jacksonville, FL

Ovarian cancer is the most lethal gynecologic malignancy with an urgent need for development of novel therapeutics. Overexpression of the measles virus (MV) receptor CD46 and nectin-4 in ovarian cancer makes the latter an ideal target for MV based therapeutics. We conducted first in human trials of intraperitoneal administration

of the MV-NIS strain, and we demonstrated excellent safety and evidence of biologic activity as indicated by decreases in tumor marker CA125, dose dependent disease stabilization and promising median overall survival of 26.6 mo or higher in a heavily pretreated patient (pt) population (Galanis et al, Cancer Res). We hypothesized that MV delivery using adipose tissue derived mesenchymal stem cells (MSC) as carriers can further improve efficacy by facilitating viral homing in tumor sites and protecting the virus from antibody neutralization. Following proof-of-principle studies supporting efficacy in orthotopic ovarian cancer models and FDA guided toxicology and biodistribution studies demonstrating safety, we activated a phase I/II trial. Primary endpoints were to determine the maximum tolerated dose of MV infected MSC/characterize safety (Ph I) and evaluate efficacy (Ph II). Eligible ovarian cancer pts had platinum resistant or refractory disease, were immune to MV and had acceptable, hematologic liver and kidney function. A total of 11 pts were enrolled in the phase I trial, 4 at dose level 0 (10^7 MSC infected with 10^9 TCID50 MV-NIS) and 7 pts at dose level 1 (10^8 MSC infected with 10^9 TCID50 MV-NIS). Abdominal fat was harvested at the time of intraperitoneal catheter implantation and MSC were produced by the Mayo Clinic's Center for Regenerative Biotherapeutics. Pts received 10^9 TCID50 of MV-NIS in cycle 1; MSC at the corresponding dose level were thawed and infected with MV prior to intraperitoneal administration in cycles 2-6. There was no dose-limiting toxicity in Phase I and no patient experienced ≥ grade 3 toxicity. A total of 25 patients were evaluable for efficacy in phase II: the study met its primary efficacy endpoint: 18/25 pts (72%) were alive at 1 year post treatment initiation, despite heavy pretreatment (median of 3 chemotherapy regimens for recurrent disease). Median overall survival was 37.4 months (95%CI 16.6-50.5). Treatment was well tolerated: most common toxicities were grade 1, including fever (20 %,), chills (20%) and thrombocytopenia (16%). To further investigate the ability of this approach to elicit an antitumor immune response, we tested for the development of humoral and cellular immunity (using IFN-g, IL-4 and IL-17 ELISPOTs) against the ovarian cancer antigens folate receptor alpha, HER2/neu and IGFBP2: 81.0% (17/21) of patients developed a T cell response to at least one of the tested antigens, while 70.8% (17/24) of patients developed an antibody response to at least one of the tested antigens. **Conclusions:** Adipose tissue derived mesenchymal stem cells can safely deliver measles virus strains engineered to express sodium iodine symporter gene without dose limiting toxicity being encountered. This form of cell-based virus delivery led to efficacy that was significantly better than virus alone or contemporary data on standard of care treatments in pretreated recurrent ovarian cancer and to the development of antitumor cellular and humoral immune responses. Further clinical development is warranted. Supported by R01 CA200507, P50 CA136393.

9 Safety and Efficacy of DYNE-101 in Adults with DM1 in the Phase 1/2 ACHIEVE Trial

Doug Kerr[1], Guillaume Bassez[2], Jordi Diaz-Manera[2], Joost Kools[3], James Lilleker[4], Marika Pane[5], Richard Roxburgh[6], Benedikt Schoser[7], Christopher Turner[8], Chris Mix[1], Soma Ray[9], Huaihou Chen[1], Daniel Wolf[9], Shauna Andersson[10], Ashish Dugar[1], Valeria Sansone[11]
[1]Dyne Therapeutics, Waltham, MA, [2]Institut de Myologie, Paris, France, [3]Radboud University Medical Center, Nijmegen, Netherlands, [4]Muscle Disease Unit, Northern Care Alliance NHS Foundation Trust, Manchester Academic Health Science Centre, Manchester, United Kingdom, [5]Fondazione Policlinico Universitario A. Gemelli, Rome, Italy, [6]Neurogenetics Clinic Centre for Brain Research, University of Auckland, Auckland, New Zealand, [7]Friedrich-Baur Institute, Munich, Germany, [8]University College London Hospitals, London, United Kingdom, [9]Dyne Therapeutics, Waltham, [10]Dyne Therapeutics, Lexington, MA, [11]Centro Clinico NEMO, University of Milan, Milan, Italy

Myotonic dystrophy type 1 (DM1) is rare, progressive, genetic disease caused by the expansion of an unstable CTG trinucleotide repeat in the 3' noncoding region of the gene encoding *DMPK*. RNA transcribed from the mutated *DMPK* gene forms stable hairpin-loop structures that are retained in the nucleus where they form toxic foci and sequester RNA-binding proteins including splicing factors. This results in dysregulated alternative splicing, called spliceopathy, in hundreds of genes and leads to multisystem clinical manifestations. Individuals with DM1 experience a wide range of symptoms related to skeletal and non-skeletal muscle involvement such as myotonia and muscle weakness, cardiac and pulmonary dysfunction, gastrointestinal issues, and CNS-related symptoms such as fatigue and cognitive impairment. There are no approved therapies for the treatment of DM1.

DYNE-101, an investigational therapeutic for the treatment of DM1, consists of a transferrin receptor 1-binding Fab conjugated to an antisense oligonucleotide designed to target mutant nuclear *DMPK* RNA to correct splicing. The

safety and efficacy of DYNE-101 in adults with DM1 are being investigated in the Phase 1/2 ACHIEVE trial (NCT05481879). In the 24-week placebo-controlled multiple ascending dose (MAD) portion of ACHIEVE, 56 participants received one of 5 dose/dose regimens of DYNE-101. All 56 participants have completed the MAD.

At the dose selected for the registrational expansion cohort of ACHIEVE (6.8 mg/kg Q8W), DYNE-101 demonstrated robust total *DMPK* knockdown (33% mean change from baseline) and splicing correction (25% mean change from baseline in the composite alternative splicing index [CASI]) at 3 months. Correction in splicing was associated with early and robust functional benefit across multiple measures of muscle strength and function at 6 months, including video hand opening time (vHOT, -38% mean change from baseline vs. +5% for placebo), Quantitative Muscle Testing total score (+10.1% mean change from baseline vs. -3.9% for placebo), 10-meter walk/run test (-7.2% mean change from baseline vs. +4.3% for placebo), and 5 times sit-to-stand (-12.4% mean change from baseline vs. +5.2% for placebo). Importantly, regression analyses show that CASI improvement at 3 months was well correlated with functional improvements at 6 months, suggesting that CASI is a reliable biomarker predictive of functional outcomes. Trends in improvement with 6.8 mg/kg Q8W DYNE-101 were also noted in the myotonic dystrophy health index (MDHI) total score, a patient reported outcome, including in the CNS-related subscales of fatigue, cognitive impairment, sleep, communication, emotional issues, and pain. DYNE-101 had a favorable safety profile as of the data cut date, with mostly mild/moderate TEAEs, and no serious related TEAEs.

Data from the ACHIEVE trial suggest that DYNE-101 has a favorable safety profile and results in improvement in molecular biomarkers, such as CASI, that may have the ability to predict clinical outcomes in DM1.

10 Hemophagocytic Lymphohistiocytosis (HLH)/hyperinflammatory syndrome following high dose AAV9 therapy

Aimee Donald[1], Simon Jones[2], Barry Byrne[3], Randy Cron[4], Cynthia Feng[5], Effie Albanis[6], Francesco Bibbiani[7], Stuart Cobb[8], Julie Jordan[7]
[1]University of Manchester, Manchester, United Kingdom, [2]Manchester University NHS Foundation Trust, UNITED KINGDOM, [3]University of Florida, GAINESVILLE, FL, [4]University of Alabama at Birmingham, Birmingham, AL, [5]Neurogene Inc., New York, New York, [6]Neurogene, New York, NY, [7]Neurogene Inc., New York, NY, [8]The University of Edinburgh, UNITED KINGDOM

Background:
Hemophagocytic Lymphohistiocytosis (HLH) is a rare, severe hyperinflammatory syndrome characterized by excessive activation of the immune system, widespread inflammation, and tissue damage. Most cases are triggered by strongly immunogenic stimuli such as infection, malignancy, or CAR-T therapy. Key features of HLH include fever, elevated ferritin, cytopenia, and evidence of hepatic injury. Cases of HLH reported after high dose adeno-associated virus (AAV) gene therapy, have been reversible with prompt recognition and treatment. Galletta et al described a case of HLH symptoms at 36-hours with elevated ferritin of 2959 ng/mL (normal <150 ng/mL) at 48-hours post treatment with Zolgensma (1.1 E14 vg/kg dose), resolving with high-dose corticosteroids. Byrne et al noted HLH cases, with a systemically administered AAV9 product at a similar dose, resolving with anakinra, an IL-1 receptor antagonist. The FDA Adverse Event Reporting system database for Zolgensma reveals serious adverse events with symptoms consistent with HLH, including elevated ferritin and fever. Early recognition and aggressive treatment of HLH with immunosuppression and immunomodulation are critical for favorable outcomes.

Methods:
Rett syndrome is a severe X-linked neurodevelopmental disorder caused by mutations in the MECP2 gene leading to deficiency of MeCP2 protein. NGN-401 is an AAV9 gene therapy containing full-length human MECP2 gene given via a one-time intracerebroventricular (ICV) administration. In an ongoing clinical trial of NGN-401, as of January 21, 2025 five subjects were dosed with 1E15 vg (estimated peripheral exposure: 3.6-7E13 vg/kg) and 3 subjects were dosed with 3E15 vg (1.4-1.5E14 vg/kg). The 1E15 vg dose was well-tolerated with no treatment-related serious adverse events and only Grade 1 treatment-related AEs. The first two subjects treated with 3E15 vg experienced no treatment-related SAEs. Most TEAEs have resolved or are resolving. The case report below focuses on the 3rd subject dosed with 3E15 vg.

Case summary:
A 7-year-old female with classic RTT was treated with 3E15 vg (1.5E14 vg/kg) of NGN-401 via ICV administration with no procedure-related complications. Prophylactic immunosuppression included rituximab, sirolimus, and corticosteroids. On Day 5 post dosing, she developed fever, vomiting, and lethargy and was admitted for dehydration. On Day 6, she rapidly declined, and ferritin was markedly elevated at 18,850 ng/mL, along with elevated liver enzymes, coagulopathy, and thrombocytopenia. She developed respiratory failure, acute kidney injury, and hypotension and was intubated, admitted to intensive care, and received Continuous Veno-Venous Hemofiltration and inotropic support. Due to suspected HLH, she was given high dose corticosteroids and anakinra. A single dose of eculizumab was given as a precaution, without signs of thrombotic microangiopathy based on negative blood smear. Ferritin improved to 6439 ng/mL; however, multi-system failure was too far advanced on presentation and despite intensive supportive care, her condition declined, resulting in death 2 weeks post dosing.

Conclusions:
High dose AAV has been linked to rare cases of HLH. Monitoring ferritin, complete blood count, and liver function frequently in the early post-dose period is warranted. Prompt treatment for suspected HLH should include high-dose corticosteroids, immunomodulation, and management by a multidisiplinary team.

AAV Biology and Mechanisms

11 Epigenetic Blueprint: Understanding how the AAV Capsid influences the Vector Epigenome

Eirini Vamva[1], Yuqian Jiang[2], Katja Pekrun[3], Adriana Gonzalez-Sandoval[4], Mark Kay[5]
[1]Stanford University Laboratory for Cell & Gene Medicine, Sunnyvale, CA, [2]Stanford University, Stanford, CA, [3]Adverum Biotechnologies, Redwood City, CA, [4]Stanford University, [5]Stanford University School of Medicine, Stanford, CA

We recently showed that the AAV capsid is directly involved in setting up the AAV-vector epigenome (Gonzalez-Sandoval 2023) and that the primate selective tropism of AAV-LK03, which does not transduce rodents well (Lisowski et al., 2014) is not related to differences in cell or nuclear vector DNA entry. We found that the species specific vector-mediated transgene expression was correlated with the prevalence of transcriptionally permissive histone H3 epigenetic modifications (H3K4me3 and H3K27ac) on the vector genome. Interestingly, insertion of a single glycine into position 266 of the LK03 capsid, (266iG) named AAV-AM, enhanced the concentration of permissive histone marks on delivered genomes in mice allowing for efficient and similar transduction in both mice and human cells. Structural simulations suggest that this additional glycine in position 266 establishes a more flexible local structure that could have an influence on interactions between the capsid and/or AAV genome with key host factor(s). To evaluate the structural effect of the 266iG on the capsid, we are currently performing cryo-EM on both LK03 and AM capsids.

Our data taken together had suggested that post nuclear entry events are responsible for setting up the vector epigenome. Therefore, we set out to understand how the two capsids interact with host proteins in the nucleus to achieve different epigenetic structures. To do so, we performed anti-A20 immunoprecipitation and mass spectrometry, followed by siRNA silencing evaluation of candidate hits on AAV-LK03 and AAV-AM transduction. Our siRNA screen identified the replication protein (RPA) complex as a novel host restriction factor required for robust transgene expression. Consistently, further analysis demonstrated that the improvement of transduction efficiency facilitated by RPA inhibition was unrelated to cell and nuclear genome entry but rather due to an increase in the vector genome transcriptional activity. Further supporting the importance of the RPA complex, we performed dCas9-Apex labelling to identify host factors that directly interact with the delivered vector genomes. Several of the identified candidates are proteins that have been shown to directly interact with RPA and are involved in chromatin remodeling.

Furthermore, to investigate the direct effect of RPA on epigenetic regulation, we performed Cut&Tag to determine the relative abundance of 4 modified histone proteins associated with vector genomes delivered by either the LK03 and AM capsids in cells after siRNA-mediated RPA knockdown. RPA knockdown increased transgene expression by 60x and significantly increased the abundance of H3K4me3/H3K27ac active histone modifications while the restrictive epigenetic marks H3K9me3/H3K27me3 remained unchanged on the genomes delivered both with AAV-LK03 and AAV-AM. Because RPA is not only involved in chromatin remodeling but also DNA processing, we are employing Nanopore sequencing to investigate whether differences in AAV vector genome structures may be affected and influenced based on which capsid is used for transduction.

Our study establishes the interplay between the AAV capsid, RPA (a member of the DNA damage repair pathway) and epigenetic regulation. These studies will improve our ability to correlate outcomes in humans based on preclinical testing in animals and offer new approaches to enhance efficacy and improve safety in humans.

12 Vector assembly factories in recombinant adeno-associated virus type 2 producing cells

Srinethe Saravanakumar[1], Thekla Bung[2], Margarita Zayas, R. Jude Samulski[3], Mansuo Shannon[4], Allison Dane[4], Kathleen Boerner[5]*, Vojtech Zila[2]*

**Corresponding Author*

The assembly process of recombinant adeno-associated virus type 2 (rAAV2) is associated with an intranuclear condensate called the nucleolus, where capsid formation and genome encapsidation have been shown to depend on the functions of the viral assembly-activating protein (AAP) and Rep proteins. Better understanding the role of the nucleolus in rAAV2 assembly is crucial for optimizing the production of AAV2-based vectors and further improving their gene therapy applications. The ultrastructural aspects of the AAV assembly process and the mechanism of virion morphogenesis are currently unknown, however. Here, we combined 3D correlative-light-and-electron-microscopy (CLEM) with a trans-complementation assay to capture production of complete rAAV2 capsids in suspension HEK293 cells. Using high-precision on-section CLEM we were able to correlate the signal of fluorescently tagged AAP to positions in the nucleus at early stages of the vector production, and to acquire electron tomograms from these regions. Tomograms revealed that rAAV2 assembly sites did not completely overlap with AAP localization and capsid reminiscent structures were found only inside the nucleolus fibrillar centers (FC) or in perinucleolar chromatin. Accumulations of rAAV2 particles in these two functionally interconnected regions facilitating transcription and processing of rRNA precursors were thus reminiscent of 'virus factories' utilized by rAAV2 as a platform for assembly in association to the nucleolus. In early assembly deposits, only a low number of capsid-like structures contained a dense material suggested to correspond to the viral genome. No significant difference in empty:full ratio was observed between assembly in FC and perinucleolar chromatin, indicating that encapsidation of the viral genome inside the FC is not restricted. Interestingly, structures resembling individual circularizing capsid lattices were also found in sites of assembled particles, suggesting presence of forming capsid intermediates. Later (48 h) post-transfection, accumulation of intact full particles was observed around the nucleolus by CLEM and confocal microscopy. Our data provides high-resolution analysis of the AAV assembly process, indicating that AAP driven formation of AAV2 capsid is initiated in specific sites of the nucleolus or in adjacent nucleoplasm, where formation of empty capsid shell precedes the encapsidation of the viral genome. Further, immunocytochemistry analyses to confirm involvement of the factors in assembly factories, as well as testing the effect of re-targeting rAAV2 assembly into different subcellular locations on vector production by using heterologous AAP, are currently ongoing.

13 Capsid-mediated differences in epigenetic transgene modifications between AAV2 and AAV9

Conradin Baumgartl[1], Dirk Grimm[2]*, Jonas Becker[3]

Vectors based on Adeno-Associated Viruses (AAV) are widely used in clinical trials and are the basis for multiple approved therapies, yet knowledge on epigenetic modifications on the delivered transgenes over time remains sparse. Typically, AAV capsids are selected for their cell binding and transgene expression capabilities, however, the capsid can demonstrably affect transduction beyond mere transgene delivery. This complex influence on the trajectory of the transgene after nuclear entry has recently been demonstrated by others investigating changing histone modification levels that depend on the used capsid serotype and/or VP1 N-Terminus. Here, we specifically investigated AAV9 and AAV2 because both of them are widely studied and because AAV9 is the basis for the majority of variants that are currently in clinical testing. Interestingly, by combining nanopore sequencing with Cut-and-Tag experiments, we find a notable difference in epigenetic modifications between AAV2- and AAV9-delivered transgenes in adult mice. Congruent with the literature, we find that in the liver, AAV9 initially yields higher levels of transgene transcription compared to AAV2. However, over a 12-week time span, AAV9-delivered transgenes continually declined in their transcriptional activity, while AAV2 transgenes remained more stable. While direct nanopore sequencing of transgene episomes only showed a biologically insignificant increase over time in DNA methylation frequency, we found a distinct difference in histone modification levels. In Cut-and-Tag experiments targeting H3K27me3 and H3K27ac, we found the inactivating modification H3K27me3 to accumulate more on AAV9-delivered transgenes compared to AAV2-delivered ones. This occurs predominantly at later time points, corresponding with the decline in transcription from AAV9-delivered transgenes. Histones with H3K27me3 are primarily associated with the gene body of the AAV9 transgenes and less so with the promoter region. Our results show that differences between the AAV2 and AAV9 capsid do not end after successful transduction but reverberate long-term in the form of differential epigenetic transgene modifications. These findings underscore the notion that AAV capsids and vectors derived thereof should be assessed and optimized for their capability to yield episomes that are epigenetically primed to mediate long-term expression.

14 Inverted Terminal Repeat (ITR) Degeneracy Promotes AAV Genomic Integration

Fred Bunz, Johns Hopkins University School of Medicine, Baltimore, MD

Infectious adeno-associated viruses (AAVs) can be rescued from plasmids that harbor a transgene flanked by two ITRs, the only genomic element for viral packaging in *cis*. ITR instability was first observed in the original AAV2 plasmid isolates, which are ancestral to virtually all recombinant AAV (rAAV) vectors currently in use. Propagation of these plasmids commonly results in the expansion of molecular subpopulations that contain a variety of ITR mutations, including deletions.

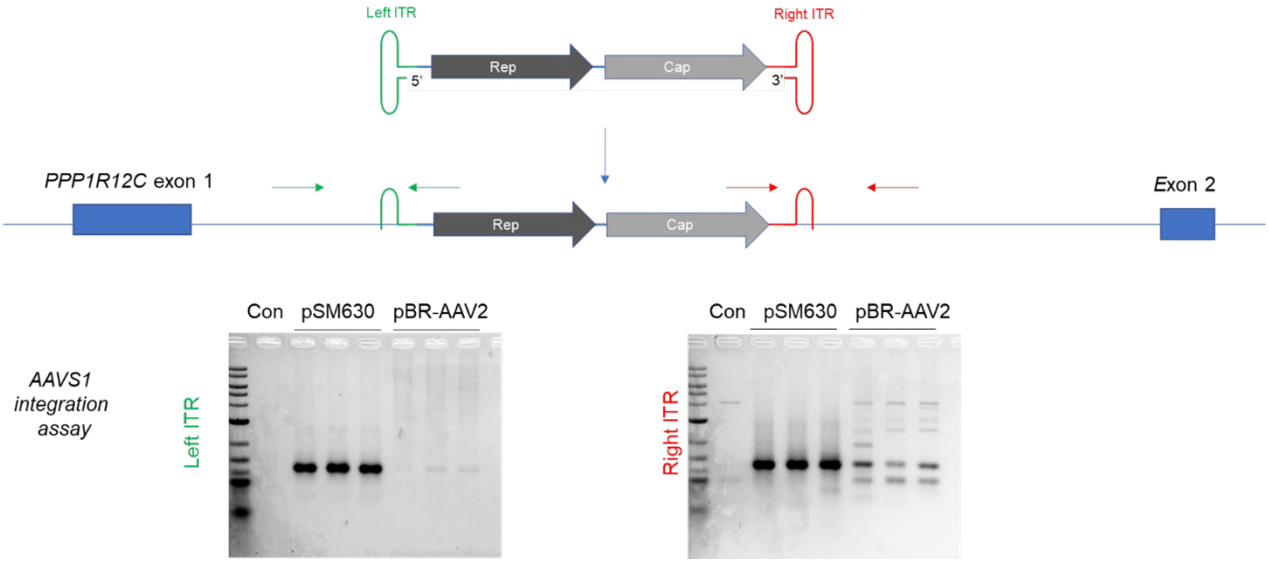
We previously employed long-read DNA sequencing methodology to investigate the basis for ITR instability, and observed that the pattern of instability in the founding AAV2 plasmids was asymmetric. While deletions could arise in either ITR, intermolecular heterogeneity was most prominent in the ITR that was positioned in closest proximity to the origin of replication (*ori*). By repositioning the ITR-transgene-ITR cassette so that both ITRs were equally distant from the *ori* element, we were able to mitigate ITR instability and thereby produce homogenous *cis* plasmid preparations.

Having comparable stocks of ITR-heterogenous and ITR-homogenous plasmids provided us with a unique opportunity to investigate the functional consequences of ITR instability/heterogeneity. A focus of this work has been on genomic integration. It is currently believed that integration into a “safe-harbor” site known as AAVS1 on chromosome 19 is a distinct stage of the natural AAV life cycle that facilitates durable latency. AAV would be the only known DNA-based virus that uses such an integration strategy. We investigated whether ITR instability could influence integration at AAVS1.

AAV2 stocks, containing the endogenous viral genome, were derived from the ITR-unstable and the ITR-stable plasmid vectors. Both viruses were used to infect A549 cells, a human cell line derived from a non-small cell lung adenocarcinoma. Following expansion of infected cells, genomic DNAs were harvested and assessed for genomic

integration. This analysis revealed striking differences between the two stocks. The heterogenous virus stock derived from the unstable vector integrated at a frequency that was >10-fold higher than that observed with the homogenous preparation. We are currently using Oxford Nanopore sequencing technology to quantitatively assess integration at AAVS1 and at other sites around the human genome.

Genomic integration by rAAV vectors used for human therapy has long been considered a potential safety hazard. Our studies suggest that the risk of integration can be mitigated by implementing simple changes in the design of *cis* plasmids. While our studies are still ongoing, our results thus far suggests that it is possible to engineer rAAV vectors with minimal potential for insertional mutagenesis.



15 Genome Wide rAAV Integration Analysis in a Tyrosinemia Mouse Model Revealed Preference for R-loops in Actively Transcribed Genes and in the Absence of Homology Arms.

Andrea Llanos-Ardaiz[1], Martin Bilbao-Arribas[1], Marina Ruiz de Galarreta[2], Aquilino Lantero[3], Leire Neri[1], Itsaso Mauleón[2], Veronica Ferrer[4], Jean-Philippe Combal[5], Rafael Aldabe[6], Gloria Gonzalez-Aseguinolaza[7]*

Recombinant adeno associated virus (rAAV) integration has been a topic of special interest and discussion in the field of gene therapy in the last few years. Although rAAV vectors are mainly maintained as episomes and concatemers in transduced cells, several reports have demonstrated that rAAVs can also integrate into the host cell's genome. rAAV integration has been described to be random, however, a preference for integration happening in transcriptionally active sites, more prone to DNA strand breaks, has been reported. Interestingly, a recent study by Puzzo et al addressed the association between integration sites of an rAAV, containing homology arms targeting the 3' locus of the murine Albumin gene, and regions containing R-loops both in vitro and in vivo by performing DNA-RNA immunoprecipitation sequencing (DRIP-Seq). R-loops are described as three-stranded nucleic acid structures, consisting of a DNA-RNA hybrid and a displaced DNA strand, that are formed during transcription and are linked to transcriptionally active sites and to increased genome instability.
In our work, we describe the integration profile of a hFAH expressing AAV8 vector (AAV-FAH) in the livers of Fah1RTyrc/RJ mice (#018129, Jackson), a model of hereditary tyrosinemia type I (HT1). These mice recapitulate the liver damage caused by accumulation of toxic metabolites, that are also linked to DNA damage and

hepatocellular carcinoma (HCC) promotion, due to mutations affecting the fumarylacetoacetate hydrolase (FAH) gene. Standard of care consists on a diet restrictive in tyrosine and phenylalanine and nitisinone (or NTBC) treatment, which results in the cease of toxic metabolite accumulation. Interestingly, a positive selection for hepatocytes that express the proper FAH gene for liver repopulation has been described. Thus, to assess the therapeutic potential of our therapeutic rAAV, 7-week-old female mice received an intravenous injection of an AAV-FAH vector at a dose of 1E11 vg/kg. Mice were maintained on NTBC for two weeks to allow for rAAV genome stabilization before NTBC removal. 10-weeks-post injection (8-weeks after NTBC removal), mice were sacrificed, livers were extracted and genome wide integration analyses were performed using two different techniques: shearing extension primer tag selection mediated PCR (S-EPTS/LM-PCR) and target enrichment sequencing (TES). Results obtained from both techniques were equivalent and showed preferential integration of rAAVs in actively transcribed genes. Furthermore, a comparison between the integration sites observed in our samples and the previously described DRIP-Seq results identifying R-loops, showed statistically significant association between rAAV integration and R-loops present in transcriptionally active genes. Moreover, our construct carries only one sequence, the promoter, with homology to the mouse genome and we did not find preferential integration in this locus. These results suggest that rAAV integration happens mainly through non-homologous end joining (NHEJ). It is important to note that the observed levels of rAAV integration are favoured by the disease model, in which FAH expressing hepatocytes are selected for liver repopulation and in which considerable levels of DNA damage are observed.

16 An alternate receptor for adeno-associated viruses

Bijay Dhungel[1], Hua Xu[2], Rajini Nagarajah[3], Joseph Vitale[4], Alex Wong[3], Divya Gokal[3], Yue Feng[3], Mehdi Tabar[3], Cynthia Metierre[3], Xiaohui Song[2], Guopeng Wang[5], Xiaodong Su[5], Charles Bailey[3], John Rasko[6]
[1]University of Sydney, Sydney, NSW, Australia, [2]Peking University, Peking, China, [3]Centenary Institute, Sydney, Australia, [4]BEAUMONT HILLS, NSW, Australia, [5]Peking University, Peking, Australia, [6]The University of Sydney, AUSTRALIA

We report the identification and characterization of an alternate receptor for adeno-associated viruses (AAV), distinct from the universal AAV receptor KIAA0319L or AAVR. This receptor, referred to as AAVR2 hereafter, enables the transduction of Clade E AAVs, including AAV8. AAVR2 is also essential for a previously undescribed AAVR-independent transduction pathway for AAV11 and AAV12. We characterised a direct binding between the AAV8 capsid and AAVR2 and identified contact residues using single-particle cryo-electron microscopy. We then observed that AAV8 directly binds to the carboxypeptidase-like domain 1 of AAVR2 via its variable region-VIII and demonstrated that AAV capsids lacking AAVR2 binding can be bioengineered to engage with AAVR2. Finally, we overexpressed AAVR2 to enhance AAV transduction allowing for efficient gene transfer in vivo.

17 Identification of KIAA0319L-interacting host factors during intracellular trafficking of AAV

Xiujuan Zhang[1], Shane McFarlin[2], Donovan Richart[3], Ariful Habib[1], Fang Cheng[4], Jianming Qiu[5]*
[1]KUMC, Kansas City, KS, [2]University of Kansas Medical Center, Kansas City, KS, [3]University of Kansas Medical Center, Kansas City, MO, [4]The University of Kansas Medical Center, [5]University of Kansas Medical Center, Kansas City, Kansas
**Corresponding Author*

In 2016, KIAA0319L was identified as a proteinaceous receptor for multiple serotypes of adeno-associated viruses (AAVs). It is a type I transmembrane protein containing a N-terminal MANSC domain, five extracellular polycystic kidney disease (PKD) domains, and a C6 motif in the transmembrane region at the C tail. KIAA0319L is transiently expressed on the cell surface but primarily locates to the perinuclear trans-Golgi network (TGN), and recycles from cell surface to the TGN. While the PKD domains interact with AAV capsids, what host factors KIAA0319L interact with and how it mediates AAV entry from cell surface and intracellular traffic to the TGN are largely unknown. In this study, using Ascorbate peroxidase (APEX)-based proximity labeling and quantitative mass spectrometry, we identified carboxypeptidase D (CPD) and TBC1D10A (TBC1 Domain Family Member 10A) were closely associated with KIAA0319L. Both in vivo and in vitro interaction assays, as well as confocal microscopy, confirmed

their interactions, highlighting their relevance to AAV intracellular transport. As TBC1D10A is a homolog of TBC1D23, we further explored the involvement of the TBC1D23 in promoting AAV endosome-to-TGN trafficking. CRISPR/Cas9-mediated depletions of CPD, TBC1D10A, or TBC1D23 revealed reduced AAV transduction by over 80% in HEK293 cells and polarized human airway epithelium. Mutagenesis studies identify the critical motif of threonine-leucine-tyrosine (TYL) KIAA0319L in its interaction with TBC1D proteins, underscoring an essential role of KIAA0319L in mediating the endosome-to-TGN trafficking of recombinant AAV vectors. Thus, our work offers valuable insights into promising targets to enhance the efficacy of recombinant AAV-based gene therapies.

AAV Vector Manufacturing: Process Development

18 Engineering Protein Carrier AAV to Rescue Intracellular Trafficking | Selective Purification of AAV Based on Capsid Composition

Mareike Hoffmann[1], **Ryan Sorensen[1]**, Amy Wang[1], Ajay Extross[1], Yungui He[2], Daniel Schmidt[3]
[1]University of Minnesota, Minneapolis, MN, [2]University of Minnesota Twin Cities, [3]Minneapolis, MN

Adeno-associated virus (AAV) is widely used for the efficient delivery of DNA payloads to target cells in both therapy and research. In prior work, we engineered the ability to package protein payloads into AAV capsids through the insertion of a domain in the interior of the capsid that facilitates packaging of a target protein during the capsid assembly process, a technology we termed Protein Carrier AAV (pcAAV). Protein packaging efficiency depended on the location of the domain insertion, the VP isoform into which the domain was inserted, and the intracellular localization of the target protein during pcAAV production. We demonstrated that pcAAV mediates intracellular delivery of target proteins using flow cytometry and further investigated the subcellular localization of the delivered protein by confocal live cell imaging which revealed that a portion of the delivered protein payload localizes to lysosomes with no nuclear delivery being observed. We hypothesize the lack of nuclear delivery is the result of an inability to either internalize or expose VP1u, required for endosomal escape and nuclear import. We are pursuing several strategies to rescue pcAAV trafficking on which we will present initial results characterizing key AAV capsid properties (e.g., capsid morphology and engineered VP subunit incorporation) focused on validating individual system components.

The AAV capsid assembles stochastically from 60 copies of three structural proteins named VP1, VP2, and VP3 in an average ratio of 1:1:10. Insertion of domains or peptides into individual VP isoforms can affect the rate of incorporation and potentially influence both particle yield and infectivity. To explore how VP1 incorporation into assembled capsids affects infectivity and develop a strategy to purify capsids containing domain insertions, we developed a system capable of separating capsids based on their composition. This system works through the insertion of the small, rationally designed ALFA tag into a target VP subunit. By incubating crude AAV productions with magnetic beads conjugated to the ALFA nanobody, which recognizes the ALFA tag with high affinity and specificity, AAV capsids incorporating the target VP subunit can be selectively purified. We demonstrate that our purification strategy can purify AAV capsids containing a retargeting domain insertion and that purified capsids retain their infectivity towards target cells. Further, we explore if our purification strategy can be used to separate capsids based on the extent of VP1 incorporation by modulating the elution temperature. Our preliminary results suggest that capsid populations eluted at distinct temperatures exhibit differing infectivity, which we hypothesize may be due to differences in VP1 incorporation between these populations.

19 Post-Processing Conjugation System for Manufacturing of Retargeted AAV-SpyT-SpyC-Ab Molecules

Garima Thakur, Sheldon Mink, Zhe Zhang, Yahui Lan, Kyle Plasterer, Sven Moller-Tank, Hanne Bak, Andrew D. Tustian
Regeneron Pharmaceuticals Inc., USA

Adeno-associated viral vectors (AAV) have emerged as a leading platform for gene therapy due to their safety

profile and ability to deliver therapeutic genetic payloads *in vivo*. However, a challenge facing the field is delivery of AAV genetic payloads to specific tissues or organ targets, as even AAV serotypes with tissue-specific tropism are mostly directed to the liver for clearance. Thus, higher patient doses are required to achieve therapeutic activity in tissues outside the liver. An approach for delivering AAV vectors at a lower dose to specific tissue types includes (i) detargeting AAV from the liver using capsid point mutations and (ii) covalently linking antibodies (Abs) to AAV to retarget it to specific tissue types. The AAV-Ab conjugates are manufactured using a SpyTag-SpyCatcher ("SpyT-SpyC") Post Processing Conjugation System, where a SpyT peptide inserted into AAV capsid proteins spontaneously forms a covalent bond with a SpyC domain expressed on the antibody light or heavy chain.

The post-processing conjugation system enables development of a scalable and robust manufacturing process as both the AAV-SpyT and SpyC-Ab molecules can be produced separately, meeting efficacy, yield and purity targets for the individual components. Once manufactured, the two components are combined in an *in-vitro* conjugation reaction that is well-characterized, resulting in a consistent number of conjugated antibodies for each conjugation reaction before removal of unconjugated species and final formulation. In this presentation, we present the AAV9-SpyT manufacturing process, development of optimized conditions for the *in-vitro* post-processing conjugation reaction, approaches for at-line monitoring of reaction kinetics, and techniques for removal of unconjugated species. We also showcase successful application of the platform for a 500 L scale production of an AAV9-SpyT-SpyC-Ab molecule carrying a therapeutic transgene.

20 DMSO Enhances Recombinant AAV Production via Downregulation of the Expression of the KAT5/TIP60 Acetyltransferase

Yingchao Nie[1]*, **Huimin Na[2]**, Leo Dworkin[3], Karen Karottki[4], Hao Pan[2], Rebecca Jeppson[5], Eunil Im[3], Sarat Gopalakrishnan[3], Amit Mathur[5], Madhuresh Sumit[5], Karen Vincent[2], Nathan Lewis[3], Bruno Figueroa[6]

Vectors based on adeno-associated virus (AAV) are a promising delivery platform for gene therapies. To manufacture AAV vectors, producer cell lines (PCL) can be employed, in which the AAV *rep/cap* genes and the recombinant AAV vector genome are integrated into the genome and vector is produced following Adenovirus (wtAd5) infection. However, a primary challenge remains in producing sufficient AAV vector to permit accessible and affordable treatments. Here we report that supplementing the culture media with DMSO can improve AAV vector production in a PCL by two to three-fold. DMSO enhanced AAV production without impacting wtAd5 infection efficiency or adenoviral titer; however, an increase in Adenovirus E1A gene expression was observed. To identify the mechanism of enhanced AAV production, we conducted RNA-Seq analysis and found numerous biological processes significantly impacted by DMSO, including reduction in histone acetyltransferase KAT5 expression and differential regulation of genes regulated by KAT5. Knockdown of KAT5 via siRNA simulated the DMSO effect on AAV productivity and on the expression of the viral Rep, Cap, and E1A proteins. Thus, DMSO seems to act at least in part through KAT5 to increase viral gene expression and AAV vector production. Though the DMSO effect on AAV vector production was also observed in the context of transient transfection of HEK293 cells, evaluation of DMSO supplementation in additional producer cell lines revealed heterogeneity in the response to KAT5 knockdown, suggesting that there may be multiple factors contributing to the DMSO mechanism of action. Nevertheless, KAT5 mRNA downregulation by DMSO was observed in all producer cell lines tested and KAT5 knockdown may provide an additional low-cost approach to increase AAV vector production.

21 Development of a Commercial Manufacturing Process for RGX-202, a Systemically Delivered AAV for the Treatment of Duchenne Muscular Dystrophy

Don Startt[1], Michael Winkler[1], Michael Gillmeister[2], Jeanne Branson[1], Sajini Randeniya[1], Ya-Chen Chang[1], Mark Bundy[1], Sara St. Ledger[1], Ayda Mayer[2], Bonnie Wu[2], Win Cheung, Bella Bidzhieva[2], Ye Liu, Ting Chen, Craig Malzahn[1], Tristan Marshall[2]
[1]REGENXBIO Inc., Rockville, MD, [2]Regenxbio, Rockville, MD

RGX-202 is REGENXBIO's investigational gene therapy for the treatment of Duchenne Muscular Dystrophy (DMD). It uses an AAV8 vector, packaging a novel, next-generation microdystrophin expression cassette encoding functional elements of the C-terminal domain found in full-length dystrophin.

Gene therapies for the treatment of DMD typically require large doses of systemically delivered AAV. This creates several critical manufacturing-related challenges:

1. Product quality profile – To minimize patient safety risk, reducing impurities is key, specifically empty and partially filled capsids. This is reflected in informal regulatory guidance suggesting at least a "majority" of full capsids for systemic administration. The currently approved DMD gene therapy reportedly contains ~50-60% full capsids (Memo from FDA Division of Pharmacology/Toxicology dated June 2023).
2. Batch yield – The amount of vector required for clinical development and commercialization can be significant and early-stage processes may be low yielding and costly. It is important that batch yields are sufficiently high to supply the patient population.
3. Robustness – The manufacturing process should be robust to ensure a high level of consistency.

The initial proof-of-concept (POC) batches utilized a first-generation process with transient transfection of suspension HEK293 cells, designed for programs with lower doses. It had low batch yields meaning that supply would be constrained during clinical development and was nonviable for eventual commercial manufacturing. The capsid population from this preclinical POC manufacturing process was ~35% full with high levels of empty and partial capsids and did not meet the regulatory expectation.

REGENXBIO undertook a project to develop a new, enhanced manufacturing platform that would improve the product quality profile to enable high systemic doses and improve batch yields to allow efficient clinical development and eventual commercial supply. This was a cross-functional effort by the entire development team to further characterize, optimize, and improve upon the process used for the POC batches. A comprehensive effort examined the entire manufacturing process including expression system, cell culture conditions, plasmid design, transfection, and chromatography resins and conditions. In addition, an extensive set of analytical tools was used to characterize the product and capsid population to provide a deeper understanding of the product profile and how it may be improved.

These efforts were successful. The scale independent batch yield was improved 56-fold from the POC process to the commercial-ready process driven by a 28-fold improvement in the cell culture productivity and 2-fold improvement to the processing yields. The capsid population was improved from ~35% full to >80% full. The relative *in vitro* potency of the product was unchanged. Other product attributes such as mispackaged host cell DNA were significantly improved. The resultant NAVXpress® manufacturing process is an industry leading platform in terms of productivity and purity. With these improvements, the commercial manufacturing process for RGX-202 is more robust, more scalable and operationally simpler. The cost per dose has been greatly reduced and the overall supply chain has been simplified and is much more efficient. The RGX-202 commercial manufacturing process has been successfully executed at the REGENXBIO Manufacturing Innovation Center.

22 Nutritional Counselling at the Cellular Level – Combining Ambr® 15 and Orbitrap Mass Spectrometry to Analyze the Metabolome of HEK293 During AAV Production

Niklas Kraemer[1]*, Almuth Maehrlein[1], Maren Lehmkuhl[2], Tim Steffens[2], Kathrin Teschner[3], Pia Brinkert[4], Alyssa Buve[5], Dennis Karthaus[1], Vera Ortseifen[1]
[1]Sartorius Xell GmbH, Bielefeld, Nordrhein-Westfalen, Germany, [2]Sartorius Xell GmbH, Schloss Holte-Stukenbrock, Nordrhein-Westfalen, Germany, [3]Sartorius Xell GmbH, Bielefeld, Germany, [4]Schloß Holte-Stukenbrock, Germany, [5]Sartorius Xell GmbH, Bielefeld-Sennestad, Germany
**Corresponding Author*

Despite significant advancements in the field, the production of adeno-associated viruses (AAVs) for in vivo gene therapy remains insufficient for widespread use, necessitating further research to optimize HEK293 suspension

processes and address the current supply-demand gap. Omics provides a powerful tool for analyzing viral vector production at different cellular levels, including DNA, RNA, and metabolism. The analysis of metabolites, both secreted and retained, can facilitate the identification of cellular changes that impact AAV production, thereby offering insights into both favorable and detrimental processes, particularly in comparisons between HEK293 processes exhibiting different yields.

In light of the aforementioned premise, a comparative analysis of the metabolome and secretome alterations in HEK293 cells during the production of AAV2 and AAV8 was undertaken. Furthermore, the production of AAV2 was evaluated after subjecting the cells to a commercially available enhancer, which has previously resulted in titer increases of 50 to 100%. To achieve this, a commercially available HEK293 cell line was cultivated and transfected using a proprietary three-plasmid system and FectoVIR (Polyplus), with the Ambr® 15 (Sartorius) serving as the cultivation platform. Samples of biological duplicates were taken at 6, 24, and 48 hours after transfection for analysis of the metabolome and secretome. Following the preparation of the samples and the extraction of the metabolites, an analysis was conducted using an Orbitrap mass spectrometer (Thermo Fisher Scientific). All samples were compared to a mock-transfection process, which only received the ITR-containing plasmid and FectoVIR, in order to control for any effects related to GFP expression and impact of the transfection reagent.

Following a thorough data curation process, 1,500 compounds present within the intra- and extracellular space were considered and analyzed using SIMCA® (Umetrics), a sophisticated multivariate data analysis (MVDA) tool. Principal component and orthogonal partial least squares analysis revealed a pronounced separation between sample groups, which reflected the tested conditions, including AAV2 and AAV8 production, enhancer addition, and temporal changes.

The analysis yielded the identification of several metabolic pathways and mechanisms that were deemed to be of interest for the purposes of AAV production, including nucleotide metabolism. In accordance with these findings, the process was sought to be enhanced by activating or inhibiting each of the identified mechanisms. This was achieved by subjecting the cells to active compounds, where feasible, or by supplementing biological precursors.

This approach utilizes untargeted analytical techniques, such as high-resolution mass spectrometry in conjunction with MVDA, to investigate alterations in the metabolic profile of HEK293 cells during viral vector production. It is further demonstrated how the generated data can be utilized to further optimize AAV production processes, thereby contributing to a broader objective of enhancing the accessibility of in vivo gene therapy applications.

23 Small-Scale Manufacturing of Innovative rAAV Capsid Variants for Enhanced Retinal Gene Therapy

Kimchi Strasser[1]*, **Igor Alves Mancilla[2]**, Irene Ferreira[3], Janina Haar[4], Michelle Fraser[5]
[1]Revvity Gene Delivery, Graefelfing, Bayern, Germany, [2]Revvity Gene Delivery, Graefelfing, Bavaria, Germany, [3]Revvity, Germany, [4]Revvity Gene Delivery, Heidelberg, Baden-Wuerttemberg, Germany, [5]Revvity, Waltham, MA
**Corresponding Author*

Recombinant adeno-associated viral vectors (rAAV) have emerged as promising tools for gene therapy, offering potential "one-and-done" treatments that surpass conventional therapies. Recent advancements in AAV capsid engineering have focused on enhancing vector tropism and transduction efficiency, including for retinal applications. To accelerate AAV capsid development, we established a robust small-scale production and purification strategy for manufacturing a diverse array of rAAV capsid variants with process compatibility for rapid scale up of promising candidates.

In this example, we aimed to generate a rAAV pool to identify novel capsids with improved retinal transduction capabilities in non-human primates (NHP). We packaged a comprehensive collection of 105 recombinant rAAV capsid variants – each individually barcoded – using a HEK293 suspension cell line. The variants were engineered using two primary methods: peptide display and DNA shuffling. The collection also includes parental controls for comparison. The engineered capsids were pre-selected based on their performance in previous NHP biodistribution

studies. To prevent selection bias from affinity chromatography, purification was conducted exclusively via iodixanol gradient ultracentrifugation.

Our goal was to purify $1.3x10^{10}$ vector genomes (VG) of each variant. We found that the GFP transgene, fused with KASH tag and barcodes, showed poor packaging efficiency, so we produced the particles at a 30 mL scale. The cells were either centrifuged and lysed with detergent while the supernatant was PEG-precipitated and resuspended with the lysate, or detergent lysis was performed directly in the culture medium. Both lysis methods proved equally effective, however, because the maximum sample volume for Quick-Seal ultracentrifugation tubes is 19 mL, we opted to use the former method to ensure the entire sample could be processed in bulk. By leveraging this method, we successfully purified up to 36 vectors concurrently. Each purified vector was quantified by qPCR using ITR-specific primers. The final yields ranged from $6.48x10^{9}$ to $1.4x10^{12}$ VG, with only three vectors being below the $1.3x10^{10}$ VG target yield. The vectors were analyzed on an SDS-PAGE gel to examine the VP1, VP2, and VP3 capsid proteins, confirming the integrity and purity of the viral particles. All 105 vectors were generated by a single individual over a period of four weeks, including a few repeat productions.

The rAAVs were then pooled in equal amounts to create a comprehensive collection of vectors for ocular research purposes. Three vectors were underrepresented in the pool due to their lower than target yield. The pool was administered via subretinal injection to two NHPs, ultimately leading to the identification of novel capsids with enhanced tropism for specific retinal cell types.

Iodixanol gradient ultracentrifugation, a method used for over 20 years in rAAV manufacturing, remains a cornerstone technique, even as the field shifts towards more scalable methods like chromatography. Our approach combines this classical method with higher-throughput capabilities for the rapid production and purification of >100 rAAVs, as used in generating rAAV libraries. By processing multiple samples in parallel and applying economies of scale, we streamline small-scale rAAV manufacturing in suspension, saving time and reducing costs associated with the discovery of next-generation gene therapy vectors.

24 Harnessing protein trans-splicing by combining inteins and SpyTag systems

Serena Giannelli[1], Margherita Rossi[2], Carmelo Gentile[3], Mirko Luoni[4], Sharon Muggeo[2], Vania Broccoli[1]
[1]Ospedale San Raffaele, Milan, Milano, Italy, [2]Ospedale San Raffaele, Milano, Italy, [3]Ospedale San Raffaele, Milano, Milano, Italy, [4]San Raffaele Scientific Institute, Busto Arsizio, Varese, Italy

Approximately 15% of the gene coding regions are longer than 4 Kb, making difficult or impossible to package them into AAVs for gene therapy applications. A transformative system to overcome this limitation is based on inteins, which promote their own excision from a precursor protein and the subsequent ligation of the flanking peptides chains to reconstitute the complete protein. Intein-based trans-splicing (ITS) can occur when the two separate parts are cloned in independent AAVs and the complete protein is fully reconstituted in co-infected cells. ITS-mediated protein reconstitution has been successfully applied to express long genes by dual AAV delivery for gene therapy applications. However, in some cases, particularly for very long genes, its efficiency may not be high enough and additional improvements are needed. We have combined the SpyTag/SpyCatcher module together with the inteins and have shown that the two systems work synergically to enhance protein trans-splicing. Initially, using the GFP protein reconstitution assay, we showed that the SpyTag/SpyCatcher module does not interfere with the intein self-processing, but significantly increases the reconstitution rate of the functional full protein. We named this approach STRING, for SpyTag-assisted tRans-splicING. We then selected ATM, a very long protein of 3056 amino acids, and compared ITS with STRING for efficient protein reconstitution. In HEK293 cells, fibroblasts and human fibroblasts STRING outperformed ITS for full reconstitution of ATM. To assess the functionality of the complete protein, ATM was reconstituted in mutant fibroblasts and the active forms of key ATM downstream targets were evaluated. Interestingly, pKAP1, pCHK2 and p53 were more upregulated after ATM protein reconstitution by STRING compared to ITS. ATM loss-of-function mutations cause ataxia telangiectasia (A-T), a neurological disease associated with immunodeficiency and high cancer predisposition. Due to its excessive length, ATM gene replacement therapy using viral vectors has not been feasible. We therefore generated a dual lentiviral system expressing the two halves of the gene associated with the STRING modules. After dual lentiviral infection fibroblasts from A-T patients reconstituted high levels of the full ATM protein and the phosphorylated forms of its

direct protein targets. Altogether, the STRING methodology ensures high efficiency of protein trans-splicing and may represent a suitable methodology for ATM gene replacement therapy, a long-sought translational opportunity for A-T.

Advances in Gene Therapy of Neurological Diseases in Small Animal Models

25 Gene Therapy for Megalencephalic Leukoencephalopathy with Subcortical Cysts: Restoring Brain Homeostasis in Preclinical Models

Alejandro Brao[1], Irina RodrÃguez[2], Angela Sanchez[3], Javier Del Rey[4], Silvia Lope-Piedrafita[2], Esther Prat[5], Virginia Nunes[5], MIguel Chillon[6], RaÃºl EstÃ©vez[7], Assumpcio Bosch[8]*

**Corresponding Author*

Megalencephalic leukoencephalopathy with subcortical cysts (MLC, or Van der Knaap disease) is an ultrarare, infantile onset, and orphan leukodystrophy characterized by white matter swelling and vacuolation, macrocephaly, cerebellar ataxia, spasticity and muscle stiffness, epileptic seizures, and mild cognitive decline. Most patients carry biallelic loss-of-function mutations in the astrocyte-specific gene *MLC1* (~75%), or *GLIALCAM* (~7%). MLC1 and GlialCAM oligomerize to form a functional unit at glial cell junctions, where they regulate the activity and membrane localization of key players involved in brain water and ion homeostasis, including aquaporins (AQP4), ion channels and transporters (Kir4.1, ClC-2, Na^+/K^+-ATPase), and G protein-coupled receptors (GPRC5B), among others. Disease-associated mutations in *MLC1* or *GLIALCAM* disrupt this essential interaction network, leading to pathological brain edema and neurological dysfunction.

To address the underlying molecular basis of MLC, we developed two preclinical gene therapy strategies using adeno-associated viral vectors (AAVs) in *Mlc1*$^{-/-}$ and *Glialcam*$^{-/-}$ mice, two knockout models of the disease. First, we intravenously injected 3.2 x 10^{13} vg/kg of an AAV9P31 vector encoding the human *MLC1* cDNA under the control of the full-length human glial fibrillary protein (GFAP) promoter, gfa2, to 10-month-old *Mlc1*$^{-/-}$ mice, seven months after the onset of white matter vacuolation. This noninvasive treatment provided long-term, astrocyte-driven expression of MLC1 for over one year, and reversed interstitial and intramyelinic oedema, as demonstrated by histological analyses and magnetic resonance imaging (MRI; T_2 relaxometry, and diffusion tensor imaging). Most importantly, motor tests used to assess cerebellar ataxia-like behaviors in mice (hanging wire and hindlimb clasping tests), revealed that treated *Mlc1*$^{-/-}$ mice exhibited a complete normalization of motor performance.

GLIALCAM is expressed in astrocytes and oligodendrocytes, so we implemented a dual therapy based on the administration of AAV9P31 vectors encoding the human *GLIALCAM* cDNA under the gfa2 (astrocyte-specific) or the human myelin basic protein (MBP, oligodendrocyte-specific) promoters. To achieve simultaneous expression from both cell types, we delivered 5 x 10^{10} vg via intra-cisterna magna injection (2.5 x 10^{10} vg/vector) to 15-month-old *Glialcam*$^{-/-}$ mice. Preliminary data suggest that this alternative administration route resulted in molecular and neuroimaging correction comparable to our previous approach for *Mlc1*$^{-/-}$ mice, despite the later and lower-dose intervention, six months after viral vector administration. Taken together, our results not only demonstrate the longevity of astrocyte-driven therapeutic gene expression at safe AAV dosages, but also the reversibility of two key hallmarks of MLC, white matter edema and motor impairment, establishing a foundation for potential clinical translation.

26 In Vivo Systemic Genome Editing to Correct Mecp2 Mutations Improves Symptoms and Extends Lifespan in a Severe Model of Rett Syndrome

Swati Bijlani[1], Ka Ming Pang[2], Amin Kudsi[2], Lakshmi Bugga[2], Vinodh Narayanan[3], Saswati Chatterjee[4]*
[1]City of Hope, Duarte, California, [2]City of Hope, Duarte, CA, [3]Translational Genomics Research Institute, Phoenix, AZ, [4]Beckman Research Institute of City of Hope, Duarte, California
**Corresponding Author*

Rett Syndrome is a debilitating neurodevelopmental disorder associated with de novo mutations in the X-linked MECP2 gene. Due to random X chromosome inactivation, females with Rett Syndrome display a spectrum of severities, while affected hemizygous males rarely survive. Mecp2 is a multifunctional methyl CpG binding protein that functions as transcription regulator, chromatin modifier and mRNA processor. Mecp2 is expressed in all tissues with the highest levels observed in the brain. Expression of Mecp2 requires stringent regulation as both under- and over-expression are pathogenic. Two early-stage gene therapy clinical trials for Rett Syndrome utilizing vectors that incorporate some of the regulatory elements are underway. Here we describe a genome editing strategy that corrects pathogenic MECP2 mutations directly in the genome while retaining all native regulatory elements and resulting in physiologic expression. Importantly, this approach avoids both over-expression-related toxicity and under-expression-related pathogenesis. Correction of MECP2 mutations was achieved using the nuclease-free, BRCA2-dependent, homologous recombination-based AAVHSC mediated editing platform. Since AAVHSC vectors cross the blood brain barrier and transduce both peripheral tissues and the central nervous system (CNS), we hypothesized that systemic administration of the AAVHSC Mecp2 editing vector would result in the permanent systemic correction of Rett-mutations. Recent studies suggest that MECP2 mutations in the periphery contribute significantly to disease progression in addition to the primary sequelae of Rett in the CNS, emphasizing the importance of systemic editing. Here, we evaluated the in vivo efficacy of AAVHSC mediated systemic genome editing in the Bird Mecp2 knockout mouse model, which exhibits a severe disease phenotype. Mecp2-deficient hemizygous male mice have a shortened lifespan of approximately 8 weeks and display severe Rett symptoms including hindlimb clasping, abnormal gait, uneven breathing, tremors and mobility problems. We designed an AAVHSC genome editing vector to insert the missing portion of the murine Mecp2 gene in the genome, restoring Exons 3, 4 and the 3' untranslated (UTR) region. The murine Mecp2 editing vector was packaged in AAVHSC15 and injected intravenously in hemizygous Bird mice at 5E+13 to 6E+13 vg/kg. Mice were scored weekly for Rett symptoms and compared with untreated Bird mice and wild-type controls. The AAVHSC-treated mice exhibited significant symptomatic improvement including mobility, breathing and exploratory behavior in open field tests. Immunofluorescence analysis revealed that symptomatic improvement correlated with restoration of Mecp2 expression in CNS neurons. Notably, we observed a significant extension in lifespan as compared with untreated Bird mice. We conclude that systemic in vivo genome editing to permanently correct Mecp2 mutations offers an attractive platform for the treatment of Rett syndrome while maintaining durable and physiologic levels of expression. Thus, supporting the therapeutic potential of AAVHSC to mediate efficient, safe, nontoxic, durable in vivo genome editing of the Mecp2 gene to treat Rett syndrome.

27 Preclinical Study for the Treatment of Hereditary Spastic Paraplegia Type 52 (SPG52)

Hereditary spastic paraplegia type 52 (SPG52) is an ultra-rare inherited neurological disorder characterized by weakness and spasticity in the lower limbs, global developmental delay, intellectual disability, and seizures. SPG52 is caused by loss-of-function mutations in the *AP4s1* gene, which encodes the sigma subunit of the adaptor protein complex 4 (AP-4). Disruptions in any subunit of the AP-4 complex lead to its destabilization and degradation, resulting in a shared pathophysiology and symptomatology. While the exact function of AP-4 remains unclear, it is believed to have a role in the biogenesis of the autophagosome. Currently, there is no cure or treatment available. Therefore, a gene therapy approach to restore *AP4s1* expression represents a rational therapeutic approach for SPG52.

To develop a suitable human model to test the efficacy of our viral vector gene therapy strategy, we have generated and characterized induced pluripotent stem cells (iPSCs) from skin biopsies of an SPG52 patient and two controls. The patient's iPSC-derived cortical neurons showed an accumulation of the main cargo of the AP-4 complex at the trans-Golgi level, reduced neuronal arborization, impaired autophagy flux, as well as decreased neuronal activation when compared to both controls. Upon overexpression of the *AP4s1* gene, we are able to completely rescue distinct cellular disease phenotypes.

In parallel, we have developed and characterized the first murine model for SPG52 carrying a complete knock-out (KO) of the *AP4s1* gene. This animal model recapitulates one of the main hallmarks described in patients of the disease, a thinning of the corpus callosum. In addition, KO mice display a decrease in body weight, muscle strength, motor coordination, and lifespan when compared to wild-type (WT) mice. Neuromuscular deficits in the hindlimb muscle of KO mice were corroborated by neuromuscular functionality assays showing a decreased compound muscle action potential (CMAP). The compromised sensory function of these animals was also confirmed by nerve conduction tests. KO mice also display behavioral differences when compared to WT mice such as increased exploratory behavior without signs of anxiety, and short and long-term memory deficiencies. To test the efficacy of our gene therapy approach we have treated two cohorts of animals. One cohort of animals has been treated at the neonatal stage and the other one at the young-adult stage. Both cohorts of animals were administered with a neurotropic adeno-associated viral vector carrying a correct copy of the *AP4s1* gene. Phenotype rescue was assessed in both cohorts showing a complete rescue of the CMAP and sensory nerve, partial rescue of the thinning of the corpus callosum, motor coordination, and force, but no effect on the animals' body weight.

Collectively, these promising results pave the way for the final safety trials, bringing us closer to a clinical study that could offer a treatment option for children with SPG52, who currently have no other treatment available.

28 Targeting MSH3 for Huntington's Disease: Preclinical Validation of AAV-DB-3-miRNA to Prevent Somatic CAG Repeat Expansion

Bryan Simpson[1], Icnelia Huerta-Ocampo[2], Ryan Giovenco[3], David Leib[1], Paul Ranum[4], Noah Smith[1], Amiel Hundley[1], Elizabeth Kropf[1], Luis Tecedor[3], Yonghong Chen[3], Jenna Soper[5], John Connelly[5], Leslie Thompson[6], George Yohrling[7], Beverly Davidson[3], Jang-Ho Cha[5]
[1]Latus Bio, Philadelphia, PA, [2]Children's Hospital of Philadelphia, Philadelphia, [3]Children's Hospital of Philadelphia, Philadelphia, PA, [5]Latus Bio, Boston, MA, [6]University of California, Irvine, Irvine, [7]Latus Bio, Princeton, NJ

The identification of genetic modifiers of Huntington's disease (HD) onset and progression were landmark findings; the data provided insight into key pathogenic pathways and revealed novel, potentially more druggable, and genetically validated therapeutic targets (e.g. MSH3) to treat HD (GeM-HD Consortium, 2015, 2019; Hensman-Moss et al., 2017). Preclinical studies in HD models have shown that reducing MSH3 protein expression through genetic (Dragileva et al., 2009, Ferguson et al., 2023, Mouro-Pinto et al., 2024) or pharmacological manipulation (O'Reilly et al., 2023, Driscoll et al., 2024) effectively prevents somatic instability of the CAG trinucleotide repeat expansions in the *HTT* gene.

Latus Bio is developing a gene therapy to reduce MSH3 as a potential treatment for HD. The LTS-201 candidate is an engineered AAV capsid (AAV-DB-3) designed to deliver an artificial microRNA to reduce human MSH3

(miMSH3) and halt somatic CAG repeat expansion in medium spiny neurons of the caudate nucleus and putamen and in striatal projection neurons in layer 5 of the motor cortex. miMSH3 also shows potency against murine Msh3.

To establish preclinical proof-of-concept for AAV-DB-3.miMSH3, LTS-201 was evaluated in Q111 knock-in mice, a HD model that undergoes progressive disease phenotypes including somatic repeat expansion in striatal neurons. Following bilateral intrastriatal injections of AAV-DB-3.miMSH3 to 8 week old Q111 mice, AAV biodistribution (vector genome copy number) measured by ddPCR was high in the striatum and cortex, and undetectable in peripheral and off-target tissues. *Msh3* mRNA levels were reduced by 20% in bulk striatal tissue resulting in a 51% reduction in Msh3 protein levels. Somatic instability in the striatum was reduced by 57% at 24 weeks old, demonstrating proof-of-concept for the potential clinical efficacy of LTS-201 and warranting its advancement for further translational development.

In conclusion, human genetics and preclinical proof-of concept data in HD mouse models support the therapeutic hypothesis that depletion of MSH3 protein using a miRNA expressed by Latus' novel AAV-DB-3 delivery vector, may significantly delay symptom onset in HD through prevention of somatic CAG repeat expansions in the *HTT* gene.

29 Achieving 'Just Right': Preclinical Development of A Gene Therapy for *SURF1* Leigh Syndrome Using Two Disease Models

Qinglan Ling[1]*, Matthew Rioux[2], Yuhui Hu[3], Scarlett Dwyer[4], Harrison Higgs[3], Steven Gray[5]*
[1]UMass Chan Medical School, Worcester, MA, [2]University of Texas Southwestern Medical Center, Dallas, TX, [3]UT Southwestern, Dallas, [4]UT Southwestern Medical Center, Dallas, TX, [5]University of Texas Southwestern Medical Center, Dallas, Texas
**Corresponding Author*

SURF1 (surfeit locus protein 1) Leigh syndrome is an early onset neurodegenerative disorder, characterized by a reduction in complex IV activity that disrupts mitochondrial function. Currently, there are over 150 patients identified worldwide, and no disease-modifying treatments available. Previously, we reported that a gene replacement therapy for *SURF1* Leigh syndrome showed improved complex IV activity, restored exercise-induced lactate acidosis in a *Surf1* KO mouse model, and displayed a high safety profile in wildtype (WT) mice. However, further investigations of this original SURF1 vector design uncovered cytotoxicity in multiple tissues of WT rats despite having minimal immune responses. We hypothesized that this cytotoxicity was elicited by SURF1 protein overexpression driven by the strong ubiquitous promoter, CBh. Thus, we designed 4 new vectors by modifying the promoter and poly(A) sequence, along with revising the transgene codon optimization. Of the 4 candidate vector constructs, one vector showed both short-term and long-term therapeutic efficacy in the *Surf1* KO mouse model, including improved complex IV activity, improved endurance capacity, and reduced exercise-induced lactate acidosis after the treatment, to an extent that is comparable to the original CBh version. Additionally, we performed studies to compare the short-term efficacy using three different doses and two treatment ages. Our data indicates that earlier treatment with a higher dose of vector is necessary to achieve maximum treatment benefits. To further support the efficacy of the gene therapy treatment, we also developed a *Surf1* KO rat disease model using CRISPR/Cas9 technology. In this model, female *Surf1* KO rats showed reduced locomotor activity and grip strength at 4 months old, as well as reduced body weight starting from 6 months old, compared with WT and HET littermates. Our treatment was able to partially restore their grip strength and body weight. More importantly, this vector did not show toxicity when tested in normal rats at two ages (young and adult). Taken together, our revised vector design was able to achieve similar preclinical efficacy for *SURF1* Leigh syndrome as our original strong expression design, but with minimal toxicity. This therapeutic candidate warrants further translational evaluations to benefit *SURF1* Leigh syndrome patients.

30 Therapeutic and Safe *GFAP* Silencing in Astrocytes Rescues Alexander Disease in a Rat Model

Alexander disease (AxD) is a rare, devastating neurodegenerative disease known as leukodystrophies. AxD is caused by dominant gain-of-function mutations in the glial fibrillary acidic protein (GFAP) gene and occurs in approximately one in one million births. The disease is progressive and fatal, ranging from infancy to adulthood. GFAP is mainly present in astrocytes of the central nervous system (CNS) and plays an essential role in controlling myelination. Mutations in *GFAP* result in the overproduction and accumulation of the mutant form of GFAP, which causes the formation of Rosenthal fibers, the histopathological hallmark of AxD throughout the CNS. Currently, there is no therapy available to treat AxD. Thus, silencing of *GFAP* expression could be an attractive therapeutic strategy in AxD.

We developed a scAAV9 vector (scAAV9-GfaABC1D-amiR-*GFAP*) expressing an artificial microRNA (amiR) to target the conserved *GFAP* sequences among mice, rats, NHPs, and humans. The amiR-*GFAP* is driven by the endogenous promoter of *the GFAP gene,* which restricts the amiR-*GFAP* expression within the GFAP-expressing cells. We delivered the scAAV9-GfaABC1D-amiR-*GFAP* into three-week-old AxD rats by intracerebroventricular (i.c.v.) administration at a dose of 2.0 x e13 vector genome/kg. We found that the treated AxD rats started gaining body weight 3 weeks after the vector treatment as compared to the untreated AxD rats. Four weeks later, the treated AxD rats showed significant motor function improvements, including the rotarod test, grip strength, and horizontal ladder test, when compared to the untreated animals. In addition, histopathologic analysis showed a significant reduction of Rosenthal fibers in the brain of treated AxD rat. Reduced hyperintense signals (i.e. signs of brain edema) on T2 MRI imaging were observed in the treated AxD rat brains as well. Recently, dorsal root ganglion (DRG) toxicity was observed in non-human primates and mice after AAV intra-CSF delivery of RNAi expression constructs, evidenced by increased neurofilament-light in plasma. We analyzed the neurofilament-light in the plasma from AxD rats dosing with vector after one month and observed no elevation compared to the untreated disease rats, indicating no treatment-associated DRG toxicity. Furthermore, the treated AxD rats continue to show improved performances in motor function tests at 13 weeks post-injection. Taking together, our data suggests that astrocyte-restricted gene silencing is a promising strategy for efficient and safe treatment of AxD and potentially other gain-of-function diseases that affect astrocytes. GG and JX are co-corresponding authors.

31 Assessing the Cognitive Benefit of a Vectorized Tau Reduction Therapy

Tauopathies are a broad group of neurodegenerative diseases (ND) defined by the aberrant misfolding, fibrillization, and spread of microtubule associated protein tau (tau). There are no approved therapies targeting misfolded tau. Clinical trials of antisense oligonucleotides (ASOs) targeting tau provide evidence that tau reduction is a promising therapeutic option. However, ASOs require multiple doses which confer financial and temporal burdens on patients and their caregivers. Our lab has developed an artificial miRNA targeting human tau (hTaui), but not mouse tau, which reduces toxic tau for up to three months in the brains of a mouse model of tauopathy (PS19) following a single dose. PS19 mice develop severe neuromuscular impairment and social cognitive deficits due to overexpression of human tau. We hypothesized that AAV9-hTaui provides long-term reduction of tau and prevents cognitive deficits associated with the spread of toxic tau. To test our hypothesis, we packaged our previously reported hTau5i candidate and a newly designed candidate predicted to improve selectivity for tau (hTau13i) into separate recombinant AAV9 capsids for delivery to the brain. AAV9-hTau5i, AAV9-hTau13i, AAV9-Scri (scrambled miRNA control) or vehicle control was administered to 6-month-old male and female PS19 mice via a single bolus injection into the intra-cisterna magna. Wild-type littermates received AAV9-hTau13i or vehicle to

serve as controls. Mice were monitored for activity, body weight, and disease progression for six months. Neuromuscular outcomes were evaluated via hindlimb clasping and social cognition was assessed in the 3-Chamber Social Approach Task at 8.5 months (early-stage ND) and 11 months (late-stage ND) of age. Brains were collected at 12 months of age and evaluated for tau expression via qPCR and ELISA and for tau seeding.

In agreement with our prior studies, PS19 mice that received AAV9-hTau5i exhibited improved survival and reduced disease severity by 40-50%. Mice that received AAV9-hTau13i also had improved survival and reduced disease severity but to a lesser extent (12-15%). Biochemical analysis confirmed tau was significantly reduced in the brains of both AAV9-hTaui treated groups. At early-stage ND, moderate to severe hindlimb clasping was already evident in 10% of PS19 control mice, whereas AAV9/hTaui treated mice had no to up to 5% moderate hindlimb clasping. At late-stage ND, only 19% of PS19 control mice had no or mild hindlimb clasping, which was improved to 40% for AAV9-h13i treated mice and 35% for AAV9-hTau5i treatment. No deficits in social cognition were observed in early-stage ND PS19 mice compared to WT controls while there was significant social cognitive impairment in late-stage ND PS19 control mice. Importantly, tau reduction by either AAV9-hTau5i and AAV9-hTau13i prevented social cognitive impairment at late-stage ND. Together, this data provides evidence that a vectorized tau reduction gene therapy using 2 different tau miRNA targeting sequences can provide lasting neurocognitive benefit.

In summary, both hTaui candidates significantly reduced tau levels in the brain, reduced disease severity and progression, and prevented cognitive deficits when assessed at the late stage timepoint. Our study provides novel evidence that reducing tau can preserve cognitive function. These findings support further development of this therapeutic approach for human use.

Gene and Cell Therapy for Ophthalmic and Auditory Diseases

32 HG004 Gene Therapy Reduces Chorioretinal Atrophy and Demonstrates Superior Retinal Safety Over Luxturna Clinical Settings

Yiqun Yuan[1], Alvin Luk[2], Ping Fei[3], Yuan Yang[4], Jie Peng[5], Yanfei Wang[6], Shuaishuai Zhang[1], Peiquan Zhao[5]
[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China, Shanghai, Shanghai, China, [2]Huidagene Therapeutics Inc, Clinton, NJ, [3]Department of Ophthalmology, Xinhua Hospital Affiliated To Shanghai Jiao Tong University School of Medicine, Shanghai, China, Shanghai, Shanghai, China, [4]Department of Ophthalmology, Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China., Shanghai, China, [5]Department of Ophthalmology, Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China, Shanghai, China, [6]HuidaGene (Shanghai) Therapeutics Co. Ltd., Shanghai, China, Shanghai, China

Background:
Chorioretinal atrophy is a significant complication associated with Luxturna therapy, reported in up to 80% of treated eyes in real-world studies, with progressive atrophy affecting therapeutic outcomes in patients with *RPE65*-mediated inherited retinal dystrophy (IRD). This study compares the retinal safety profiles of HG004 (AAV9-*hRPE65*), developed with an AAV9 vector showing enhanced retinal pigment epithelium (RPE) tropism, lower total vector doses, and reduced injection volumes, against real-world Luxturna data. The **LIGHT** trial evaluates HG004's potential to mitigate chorioretinal atrophy while maintaining efficacy.

Methods:
Nine participants with Leber's congenital amaurosis type 2 (LCA2) received subretinal injection of HG004 (6×10^9 to 2×10^{10} vg/eye) in **LIGHT** trial (NCT06088992). Chorioretinal atrophy was assessed using optical coherence tomography (OCT), fundus autofluorescence, and fundus photography, defined by loss of autofluorescence, pigmentary changes, and thinning or loss of the outer retina on OCT. HG004-treated eyes were compared to real-world Luxturna-associated chorioretinal atrophy, as documented in the literature (Gange 2022; Reichel 2023; Stingl 2023).

Results:
Over a 52-week follow-up, localized retinal atrophy was observed in 33.3% (3/9) of cases in the low- and middle-dose cohorts, confined to the retinotomy sites. OCT revealed stable, non-progressive thinning of the outer nuclear layer and RPE at retinotomies (**Figs. 1a** and **1b**) without structural damage. In the high-dose cohort, no retinal atrophy was observed during the 38-week follow up. One subject (#009, **Fig. 1c**) exhibited pigment displacement around blebs, with no retinal structural damage. Importantly, no progressive chorioretinal atrophy was detected in any dose cohort.
By contrast, real-world data of Luxturna reported chorioretinal atrophy in up to 80% of treated eyes, with progressive perimacular atrophy affecting up to 55.5% cases (published example in **Fig. 2**). The differences are attributed to HG004's AAV9 vector, featuring superior RPE transduction efficiency, lower total vector dose (1/25 to 1/7.5th of Luxturna), reduced injection volume (200 µL vs. 300 µL), and optimized surgical techniques that minimize inflammation and mechanical retinal stretching.
Conclusions:
The **LIGHT** trial demonstrates that HG004 significantly mitigates the risk of progressive chorioretinal atrophy commonly observed with Luxturna. Retinal atrophy with HG004 is confined to retinotomy sites and remains non-progressive, emphasizing the benefits of enhanced RPE tropism, lower dosing, and optimized surgical techniques to provide a safer alternative for LCA2 patients. These findings underscore the critical role of vector design and delivery optimization in improving gene therapy safety profiles for IRDs. HG004 is being evaluated in an ongoing multi-national trial (NCT05906953) and has received Orphan Drug and Rare Pediatric Disease Designations by the U.S. FDA and Orphan Drug Designation by the EMA's COMP (a total of three designations).

Figure 1: Fundus images of the injected eyes before and after HG004 administration

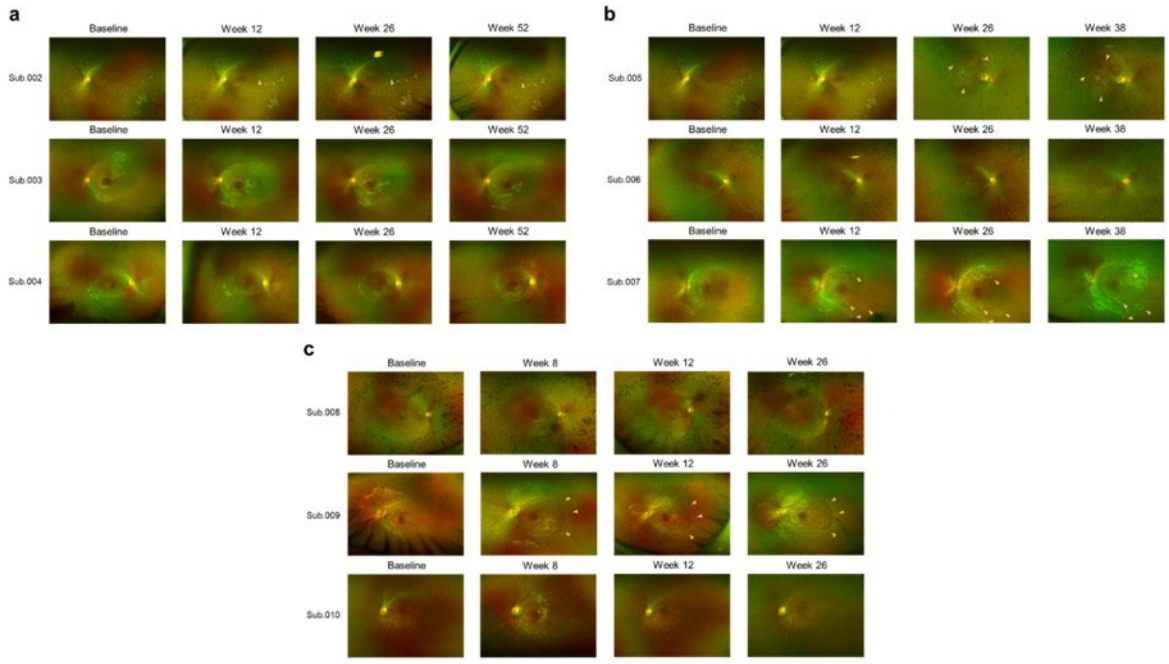

Fig 1a, **1b** and **1c** show fundus images of low-dose, middle-dose and high-dose cohorts. Yellow arrows (Sub#002, #005 and #007) indicate localized retinal atrophy at the injection sites and the pigment displacement (Sub#009).

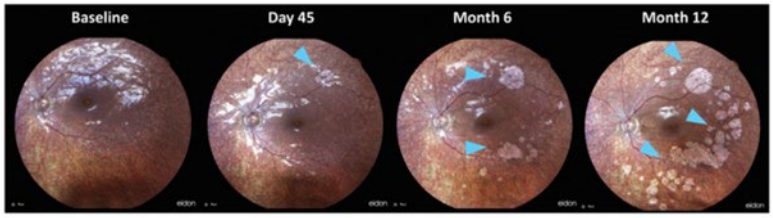
Figure 2: Progressive atrophy developed after Luxturna in real world study



Growth of progressive atrophy (blue arrows) occurred within 1 year post-injection of Luxturna.
Progressive atrophy was observed as early as 45 days after injection of Luxturna*.

33 CRISPR-Cas13 Gene Editing Therapy Targeting VEGFA Demonstrated Early Efficacy in Neovascular Age-Related Macular Degeneration

Dongjun Xing[1], Boshi Liu[1], Weiwei Liu[2], Shuaishuai Zhang[2], Yuhan Jiang[2], Linyu Shi[2], Hui Yang[3], Xin Zhang[4], Alvin Luk[5], Yiqun Yuan[2], Xiaorong Li[1]
[1]Tianjin Branch of National Research Center for Ocular Disease, School of Optometry and Eye Institute, Tianjin Medical University Eye Hospital, Tianjin 300384, China, Tianjin, China, [2]HuidaGene Therapeutics Co., Ltd., Shanghai, China, Shanghai, Shanghai, China, [3]HuidaGene Therapeutics Co., Ltd., Shanghai, China; Shanghai Institute of Meteria Medica, Chinese Academy of Sciences, Shanghai, China, Shanghai, Shanghai, China, [4]HuidaGene Therapeutics Co., Ltd., Shanghai, China; HuidaGene Therapeutics, Clinton, NJ, USA, Shanghai, Shanghai, China, [5]Huidagene Therapeutics Inc, Clinton, NJ

Background:
Neovascular age-related macular degeneration (nAMD) is a leading cause of vision loss worldwide, driven by abnormal choroidal neovascularization primarily mediated by vascular endothelial growth factor (VEGF) overexpression. While anti-VEGF therapies have become the first line of treatment and significantly improved visual outcomes, their dependence on long-term repeated intravitreal injections and frequent clinic monitoring poses substantial burdens on patients and healthcare systems, often resulting in suboptimal treatment adherence and under-treatment. To address these challenges, the SIGHT-I clinical trial (NCT06031727) was initiated to evaluate HG202, a novel CRISPR-Cas13 RNA-targeting therapy designed to partially reduce VEGF-A mRNA expression and mitigate disease progression.

Methods:
The SIGHT-I trial is a multicenter, open-label, dose-escalation study evaluating the safety, tolerability, and preliminary efficacy of HG202, a one-time CRISPR-Cas13 RNA-editing treatment delivered via a single adeno-associated virus (AAV) vector, in patients with nAMD. Nine patients aged 50-80 years with active choroidal neovascularization, a best-corrected visual acuity (BCVA) between 73 and 23 letters, and either hard-to-treat or responsive to prior anti-VEGF therapy were enrolled. Participants were assigned to receive one of three doses of HG202 (1×10^{10}, 6×10^{10}, or 1×10^{11} vg/200 µL/eye) via subretinal injection. The primary endpoints were safety and tolerability, assessed through ocular and systemic adverse events (AEs), serious adverse events (SAEs), and immunogenicity. Secondary endpoints included changes in BCVA, central retinal thickness (CRT) measured via spectral domain optical coherence tomography (SD-OCT), and the annualized frequency of supplemental anti-VEGF injections.

Results:
As of October 2024, 6 subjects have been enrolled across the low- and middle-dose cohorts. Two subjects in the low-dose cohort have completed their 52-week follow-up, while the last subject in the mid-dose cohort has completed the 4-week follow-up. A total of 2 serious adverse events (SAEs) occurred: one case of subretinal hemorrhage secondary to polypoidal choroidal vasculopathy (PCV) and another case of rapid cataract progression post-surgery. Both SAEs resolved following surgical intervention, and no drug-related AEs, including retinal detachment, inflammation, or acute retinal toxicity, were observed.
For the first 5 patients (3 in the low-dose cohort and 2 in the mid-dose cohort), the CRT decrease ranged from 13 to 88 µm. The annualized frequency of supplemental anti-VEGF injections was reduced by 45.8% to 100%. In the low-

dose cohort, two phakic subjects experienced approximately a 10-letter BCVA decline due to cataract progression. In contrast, one subject in the mid-dose cohort exhibited a 7-letter improvement in BCVA following cataract surgery.

Conclusion:
Subretinal injection of HG202, a CRISPR-Cas13 RNA-targeting gene therapy, demonstrates a favorable safety profile with no retinal detachment, drug-related inflammation, or retinal toxicity. Early efficacy data reveal significant reductions in CRT and the frequency of anti-VEGF injections. These results suggest that HG202 has the potential to provide a durable, one-time therapeutic option for nAMD, addressing critical unmet needs in the management of this chronic disease.

34 Development of an AAV-Based Gene Therapy for the Ocular Phenotype of Friedreich's Ataxia

Heyu Tang[1], Emily Xu[1], Siddhant Gupte[2], Kaitlyn Calabro[1], Diego Fajardo[3], James Peterson[3], Hannah Friend[1], Sanford Boye[4], Shannon Boye[5]*
[1]Division of Cellular and Molecular Therapy, Department of Pediatrics, University of Florida, Gainesville, FL, Gainesville, FL, [2]Division of Cellular and Molecular Therapy, Department of Pediatrics, University of Florida, Gainesville, FL, Jersey City, NJ, [3]Division of Cellular and Molecular Therapy, Department of Pediatrics, University of Florida, Gainesville, FL, [4]Powell Gene Therapy Center, University of Florida, Gainesville, FL, Gainesville, Florida, [5]Division of Cellular and Molecular Therapy, Department of Pediatrics, University of Florida, Gainesville, FL, Gainesville, Florida
**Corresponding Author*

Purpose:
Friedreich's ataxia (FA) is an autosomal recessive neurodegenerative disorder caused by mutations in the FXN gene that affects multiple systems. Up to a third of patients exhibit ophthalmic abnormalities by the second decade of life, including nystagmus, saccadic dysmetria, and optic nerve atrophy, along with a reduction in both retinal ganglion cells (RGCs) and retinal nerve fiber layer (RNFL) thickness. The purpose of this study is to generate and characterize a novel mouse model wherein FXN is preferentially ablated in RGCs, and to design an adeno-associated virus (AAV)-mediated gene therapy for subsequent evaluation in this model.

Approach:
Mice expressing Cre recombinase under the *Pou4f2* promoter, a transcription factor predominantly expressed in RGCs (Pou4f2Cre mice), were bred with $Fxn^{+/-}$ mice to generate $Pou4f2^{Cre+/-}$*;flFxn+/Fxn-* (Pou4f2-FXN KO) and $Pou4f2^{Cre-/-}$*;flFxn+/Fxn-* (Pou4f2-FXN control) mice. A natural history study lasting six months was performed to characterize retinal structure and function. Retinal nerve fiber layer (RNFL), ganglion cell layer + inner plexiform layer (RGC+IPL), inner nuclear layer (INL), and outer nuclear layer (ONL) thicknesses were measured via optical coherence tomography (OCT) and full-field (ffERG) and pattern (pERG) electroretinography assessed retinal function. Optokinetic tracking (OKT) was conducted to characterize visual function. Immunohistochemistry (IHC) was performed on retinal sections postmortem to evaluate transgene expression and to quantify RGC abundance. For gene therapy, an engineered AAV capsid, AAV.P2-V1(Y-F+T-V), was used to deliver AAV-hSyn1-FXN-HA (AAV-FXN), while AAV-hSyn1-GFP (AAV-GFP) served as a control. Intravitreal injections were performed in Pou4f2-FXN KO mice (one eye receiving AAV-FXN and the contralateral eye receiving AAV-GFP). Retinal structure and function were assessed by the in-life and post-mortem methods mentioned above.

Results:
Pou4f2-FXN KO mice remained healthy throughout the study, displaying no ataxia or other systemic signs of FXN deficiency. By postnatal day 30 (P30), OCT revealed a progressive thinning of the RNFL and GCL+IPL, with INL thinning becoming evident by P120. pERG showed a significant reduction in P1 amplitudes in KO mice relative to controls at P30; by P90, both P1 and N2 waveforms were significantly reduced. OKT assessments corroborated a reduced visual response in KO mice compared to controls as early as P30. Retina wholemount staining at P180 with RBPMS, an RGC marker, confirmed a loss of RGCs in KO mice. In the gene therapy arm, AAV-FXN treatment conferred significant protection of retinal structure (thickness of the GCL+IPL and INL) at 1 MPI (P60) compared

to AAV-GFP–treated eyes, and retinal function (pERG amplitudes) by 3 MPI (P120). RBPMS staining further showed that RGC loss was partially mitigated in AAV-FXN–treated eyes relative to AAV-GFP–treated controls.

Conclusions:
We successfully generated and characterized an RGC-specific FXN knockout mouse model that exhibits marked and progressive retinal dystrophy and mirrors the ocular phenotype of FA. Preliminary findings indicate that AAV-mediated FXN supplementation preserves retinal structure and function in Pou4f2-FXN KO mice, establishing proof-of-concept for this therapeutic strategy. Ongoing work will explore enhanced vector designs and extended evaluations of AAV-FXN in the Pou4f2-FXN KO model.

35 Safety and efficacy of Multi-characteristic opsin gene therapy in improving vision in NHP model of geographic atrophy

Samarendra Mohanty[1]*, SUBRATA BATABYAL[2], Michael Carlson[3], Lucero Garcia[2], AMIR SINGH[4], Sanghoon Kim[5]
[1]Nanoscope Therapeutics Inc, Bedford, TX, [2]Nanoscope Technologies LLC, Bedford, TX, [3]Nanoscope Therapeutics Inc, Dallas, [4]Nanoscope Therapeutics, Arlington, TX, [5]Nanoscope Instruments, Inc., Bedford, TX
**Corresponding Author*

Intravitreally delivered AAV2 packaged ambient light activatable multi-characteristic opsin (MCO) has demonstrated durable safety and efficacy in clinical trials on patients with severe vision loss due to inherited retinal diseases. Here, we report an evaluation of the safety, expression, and functional efficacy of MCO treatment in a non-human primate (NHP) model of geographic atrophy (GA) created using optical coherence tomography (OCT)-guided laser micro-irradiation.

The GA model was created in African green monkeys using OCT-guided scanning green (532 nm, 120 mW) laser micro-irradiation of the retinal pigment epithelium (RPE) and photoreceptor layers between the temporal vascular arcades leading to progressive RPE and outer retinal atrophy, confirmed by OCT, color fundus photography, and confocal scanning laser ophthalmoscopy (cSLO) imaging. Two weeks after laser injury, unilateral intravitreal AAV-MCO (0.5E11 gc/eye) injection was carried out in the treatment group to match the human experience (~1E11 gc/eye), while the control group was monitored to evaluate the progression of the atrophy. Evaluation of safety included monitoring of body weight, clinical observations, and pathological analysis. Further, measurement of intraocular pressure, and slit lamp examinations was carried out. OCT imaging was conducted to monitor any post-injection changes in retina structure, and multifocal electroretinography (mfERG) was performed at baseline and up to 13 weeks post-treatment to evaluate functional changes. Upon euthanization at the end of the 13-week study period, immunohistochemical (IHC) analysis was conducted to determine gene expression in retina.

The MCO treatment was well-tolerated, with only mild, transient inflammation observed in treated eyes two days post-injection. The treated animals maintained stable body weights and showed no significant treatment-emergent adverse effects throughout the study period. OCT analysis showed attenuation of retinal degeneration in MCO-treated eyes compared to untreated control eyes. At the end of the study, mfERG signal was significantly higher in MCO-treated eyes with photoreceptor degeneration compared to controls ($p<0.05$). IHC analysis confirmed robust expression of MCO in the higher-order neurons across the retina.

This study demonstrated the therapeutic potential of AAV-MCO gene therapy in an NHP model of GA. Intravitreal AAV-MCO was well-tolerated, with only transient mild inflammation observed shortly after administration. The treated eyes showed attenuation of further retinal degeneration and enhanced retinal functioning as compared to untreated controls. The favorable safety profile and observed efficacy in NHP support further development of MCO as a potential therapeutic approach for patients with GA.

36 Gene Therapy vs Cochlear Implantation in Restoring Hearing Function and Speech Perception for Congenital Deafness Individuals: An Observational Cohort Study

Luoying Jiang[1], Xiaoting Cheng[2], Jiake Zhong[3], Chong Cui, Yang-wenyi Liu[4], Wuqing Wang[2], Bing Chen, Zheng-Yi Chen[5], Huawei Li, Yilai Shu[2]*

[1]Fudan University Eye Ear Nose and Throat Hospital, China, [2]ENT Institute and Otorhinolaryngology Department of Eye & ENT Hospital, NHC Key Laboratory of Hearing Medicine, Key Laboratory of Gene Editing and Cell Therapy for Rare Diseases, Fudan University, Shanghai, China, Shanghai, China, [3]Fudan University - Eye and ENT Hospital - Shanghai, Xuhui District, Shanghai, Shanghai, China, [4]ENT Institute and Department of Otorhinolaryngology, Eye & ENT Hospital, Shanghai, China, [5]Massachusetts Eye & Ear Infirmary, Boston, MA

**Corresponding Author*

IMPORTANCE *OTOF* Gene therapy (GT), a novel therapeutic strategy for congenital deafness, has been shown to improve hearing and speech. The efficacy of GT remains to be compared against the performance of cochlear implantation (CI), which have been the gold standard for congenital deafness in the last half-century.

OBJECTIVE To comprehensively evaluate the treatment outcomes in auditory and speech perception between congenitally deaf patients treated with GT, CI, or both.

DESIGN This observational non-blind cohort study was conducted between 28 December 2022 and 30 November 2024. The GT patients received follow-up at 3 (T1), 6 (T2), and 12 (T3) months; CI patients received one-time evaluation at the corresponding time intervals or longer (T1, T2, or T3).

SETTING Single-center, Class A tertiary hospital in China.

PARTICIPANTS Participants with congenital severe-to-complete hearing loss, aged 1-18 years, who received GT or CI were enrolled. They were matched on duration of deafness, hearing thresholds, and speech ability at the pre-surgical baseline. There were 1568 participants screened and 72 participants enrolled.

EXPOSURE Based on the hearing modality: 1) GT-only patients (n=8) vs matched CI patients (n=43); 2) Bimodal patients (unilateral GT + contralateral CI): GT+CI (n=3) vs bilateral CI (n=12), GT (CI-off) (n=3) vs unilateral CI (n=6).

MAIN OUTCOMES AND MEASURES The primary outcomes were the auditory and speech perception evaluated by questionnaires including the Infant-Toddler Meaningful Auditory Integration Scale/Meaningful Auditory Integration Scale (IT-MAIS/MAIS), Categories of Auditory Performance (CAP), Speech Intelligibility Rating (SIR), and Speech, Spatial, and Other Qualities of Hearing Scale for Parents (SSQ-P) and tests including audiometry, speech in quiet and noise, and music tests, etc. The main secondary outcomes was auditory information processing ability assessed by mismatch negativity (MMN).

RESULTS A total of 11 GT patients (6 males, 55%) and 61 CI patients (34 males, 56%) were enrolled. The average auditory brainstem response thresholds were restored from >95.0 (SD, 0.0) dB nHL to 54.8 (SD, 15.9) dB nHL in nine GT patients at 12 months. For GT-only vs CI in auditory and speech perception, GT patients performed better in IT-MAIS/MAIS (median [IQR], 31.0 [30.0-32.0] vs 23.5 [19.0-26.3], P=0.01), SIR (2.0 [2.0-2.0] vs 1.0 [1.0-2.0], P=0.001), SSQP-speech (7.3 [6.4-7.8] vs 6.1 [4.9-6.7], P=0.03), SSQP-other qualities (7.6 [6.6-8.5] vs 5.5 [3.4-6.7], P=0.01), and SSQP noise related (8.3 [7.5-9.2] vs 6.3 [5.0-7.4], P=0.01) at T2; In IT-MAIS/MAIS (32.0 [31.0-32.0] vs 28.0 [24.5-30.5], P=0.007), and CAP (6.5 [6.0-7.0] vs 6.0 [5.0-6.0], P=0.04) at T3. GT patients showed shorter latencies of MMN at T2 (0.20 s [0.05 to 0.21] vs 0.23 s [0.22 to 0.25], P=0.006). For bimodal patients at T3, GT (CI-off) patients performed better than unilateral CI patients in speech in noise (disyllable, -1.0 [-3.0 to 2.4] dB SPL vs 5.3 [3.1 to 12.1] dB SPL, P=0.03); GT+CI patients performed better than bilateral CI patients in singing in-tune rates (66.6% [53.7 to 83.9] vs 37.1% [30.3 to 56.3], P=0.04); GT + CI patients showed shorter latencies of MMN at T3 (0.08 [0.07-0.10] s vs 0.21 [0.15 to 0.23] s, P=0.01).

CONCLUSIONS AND RELEVANCE GT patients show stable hearing recovery and exhibit more rapid improvements in auditory and speech performance than in CI patients, while outperforming CI in speech in noise

37 Prevention of Vision Loss using Subretinal Gene Therapy in a Mouse Model of Bardet-Biedl Syndrome Type 10

Ying Hsu[1], Brianna Lobeck[1], Tyler Rankin[1], Sarah Stanley[2], Emma VandeLune[1], Ethan Brandauer[1], Joseph Laird[1], Salma Hassan[1], Neda Mokhberian[1], Emily Kalmanek[1], Izabela Klaska[3], Sophia Kleine Holthaus[4], Tassos Georgiadis[5], Arlene Drack[1]
[1]University of Iowa, Iowa City, IA, [2]University of Iowa, Iowa City, [3]MeiraGTX, New York, NY, [4]MeiraGTx - London, LONDON, United Kingdom, [5]MeiraGTx, London, United Kingdom

Introduction:
The Bardet-Biedl Syndrome 10 (BBS10) protein is essential for the assembly of the BBSome and ciliary trafficking, particularly in photoreceptor cells in the eye. Biallelic mutations in BBS10 are the second most common cause of BBS, leading to obesity, polydactyly, and vision loss. Human-grade gene therapy vector candidates, *AAV8-RK-hBBS10* and *AAV8-CAG-hBBS10*, were developed for clinical translation, and *AAV8-RK-hBBS10* was designated as the lead candidate. In this study, we will report the safety and efficacy of subretinal gene delivery using *AAV8-RK-hBBS10* in a murine model of BBS10.

Methods:
The human BBS10 gene driven by either the rhodopsin kinase (RK) promoter or the CMV enhancer/chicken β-actin promoter (CAG) was cloned into a shuttle plasmid, packaged into AAV2/8, and titered by quantitative PCR for in vivo gene delivery. For toxicity testing, 2.5×10^{11} vg (high dose) of either vector was subretinally injected into unaffected wild-type (WT) or heterozygous (HET) mice in a 2 µL volume, and optical coherence tomography (OCT) was performed. For efficacy testing, *Bbs10*$^{-/-}$ mice were subretinally injected with 2.5×10^{11} (high dose), 2.5×10^{10} (medium dose), 2.5×10^{9} (low dose) vg/eye of *AAV8-RK-hBBS10*, and outcome measures including electroretinography (ERG) and OCT were conducted at 1-, 2-, 3-, 5-, and 7-months post injection (MPI). ERG tests for cone- and rod-dependent functions were conducted. A visually-guided swim assay for rodent vision was conducted at 5- to 7-MPI. Results are shown as averages ± standard error of the mean, and p values were derived from two-way ANOVA with post-hoc Tukey's test.

Results:
WT or HET unaffected mice injected with *AAV8-RK-hBBS10* did not show signs of toxicity, in contrast to those receiving *AAV8-CAG-hBBS10*. Efficacy testing was conducted using *AAV8-RK-hBBS10* in a knockout mouse model of BBS10 (*Bbs10*$^{-/-}$). First, cone-dependent electrical function was tested using the 5 Hz flicker ERG test. At 5-MPI, eyes of *Bbs10*$^{-/-}$ mice that received the high dose of *AAV8-RK-hBBS10* had greater ERG amplitudes when exposed to a 5 Hz flicker compared to signals from those receiving the medium dose ($p = 0.0856$), the low dose ($p = 0.0006$), or signals from untreated contralateral eyes ($p < 0.0001$) (high dose: 17.79 ± 5.28 µV; medium dose: 9.596 ± 1.11 µV: low dose: 5.61 ± 1.01 µV; untreated *Bbs10*$^{-/-}$: 4.97 ± 0.68 µV). Flicker amplitudes in eyes that received low dose were not different than those that were left untreated ($p = 0.9972$), indicating that dosing significantly impacts rescue of cone-dependent electrical function. Then, rod electrical function was measured by the 0.01 cd·s/m2 dim flash ERG test. At 5-MPI, ERG amplitudes were greater in eyes injected with the high ($p < 0.0001$) and medium doses ($p = 0.0416$), but not in those injected with the low dose ($p = 0.8763$) when compared to amplitudes in untreated contralateral eyes (high dose: 111.83 ± 10.30 µV; medium: 76.91 ± 13.32 µV; low: 31.04 ± 12.17 µV; untreated: 26.61 ± 5.826 µV). *Bbs10*$^{-/-}$ mice receiving the high dose took less time to find the platform in a visually guided swim assay compared to those that did not, indicating rescue of functional vision.

Conclusions:
Efficacy of subretinal gene therapy using *AAV8-RK-hBBS10* depends on dosing, and toxicity was not observed in any of the dose groups. Rescue in both rod-dependent and cone-dependent function was observed. Subretinal gene therapy using *AAV8-RK-hBBS10* has the potential to prevent vision loss.

38 Sustained Drug Delivery of Ciliary Neurotrophic Factor by Encapsulated Cell Technology: NT-501 Implants:

Eugene Gonzalez-Lopez[1], Konrad Kauper[2], Arne Nystuen[2], Alice Lee[3], Lisa Orecchio[3], Thomas Aaberg[3]
[1]Neurotech Pharmaceuticals, Inc, Cumberland, RI, [2]Neurotech, Cumberland, RI, [3]Neurotech Pharmaceuticals, Cumberland, RI

Purpose:
Neurotech's novel encapsulated cell therapy (ECT) drug product NT-501 utilizes a genetically engineered cell line based on retinal pigment epithelial cells to deliver ciliary neurotrophic factor (CNTF) to the retina. CNTF is a potent neuroprotective protein that promotes the survival and maintenance of photoreceptors and has shown a therapeutic benefit in Macular Telangiectasia type II patients. This study is a retrospective analysis of CNTF release over drug product stability and shelf life. Additionally, the long-term durability and function of the NT-501 implant was evaluated by collecting CNTF delivery data from explanted devices that were implanted from 6 months up to 14.5 years.

Methods:
In-house and commercial methods were used to characterize CNTF including direct Western Blot, ELISA and bioassays. These methods were used to characterize the stability of the implant over shelf life, the rate of CNTF production, and the potency of NT-501 secreted CNTF. NT-501 implants from multiple clinical trials were recovered from participants who underwent explantation over a wide duration. All trials were approved by the relevant institutional review board/ethics committee, and all studies adhered to the tenets of the Declaration of Helsinki.

Results:
The CNTF secretion over product release and shelf-life was shown to deliver CNTF with comparable levels and specific potency to reference protein up to 14 weeks. With regards to the explanted devices, the data from the study participants demonstrate that the NT-501 implants continued to produce steady levels of bioactive CNTF (1.75 ng/day), again with extremely close specific activity with a geometric mean potency of 1.27 (Upper 95% CI 1.38 & Lower 95% CI 1.18) of patients implanted for durations of six months to 14.5 years.

Conclusions:
Neurotech's ECT was developed to overcome the challenge of long-term therapeutic delivery to the retina. NT-501 consists of an encapsulated cell line that has been genetically engineered to produce a novel secreted form of human CNTF. Extensive characterization was conducted across product shelf life, stability, and on explanted devices which were implanted for up to 14.5 years. This retrospective analysis suggests that a single intraocular administration of NT-501 provides sustained, bioactive CNTF to the vitreous for a significant period of time.

Gene and Cell Therapy for Metabolic Diseases

39 Systemically delivered mRNA therapy crosses blood brain barrier and shows neurological benefit in mouse model of Argininosuccinic Aciduria

Sonam Gurung[1], Dany Perocheau[2], Plamena Angelova[3], Ilona Tkachyova[4], Yichen Qiu[5], Loukia Touramanidou[6], Saketh Karamchend[3], Tammy Kalber[3], Gabriele Lignani[7], Andreas Schulze[4], Andrey Abramov, Patrick Finn[8], Andrea Frassetto[9], Julien Baruteau[10]
[1]University College London, LONDON, London, United Kingdom, [2]University College London, Worthing, United Kingdom, [3]University College London, London, United Kingdom, [4]The Hospital for Sick Children, Toronto, ON, [5]UCL Queen Square Institute of Nuerology, London, United Kingdom, [6]LONDON, UK, United Kingdom, [7]University College London, London, France, [8]Moderna Inc, Cambridge, MA, [9]Cambridge, MA, [10]Great Ormond Street Institute of Child Health University College London, London, Kent, United Kingdom

Argininosuccinic aciduria (ASA) is an autosomal recessive metabolic disorder caused by deficiency of cytosolic enzyme argininosuccinate lyase (ASL). ASL converts argininosuccinate into arginine and fumarate, key step in the urea cycle for ammonia detoxification and in the nitric oxide (NO) cycle for NO synthesis. ASA is the second most common urea cycle defect. Patients can develop hyperammonemic decompensations and a systemic disease with neurological symptoms, i.e. intellectual difficulties, epilepsy and movement disorder. The neurological pathophysiology is likely multifactorial, caused by ammonia and argininosuccinate toxicity, nitro-oxidative stress, central catecholamine deficiency and blood-brain barrier (BBB) leakage. Standard of care aims to normalise ammonia levels but limited efficacy, especially on the neurological phenotype, asserts the need for novel therapies. We previously showed proof of concept of intravenously (IV) delivered liver-targeting lipid nanoparticles (LNPs) encapsulating human ASL (hASL) mRNA (ASL-LNP) in a hypomorphic ASA mouse ($Asl^{Neo/Neo}$) in correcting the liver disease. Here, we investigate the efficacy of IV ASL-LNP therapy on the neurological phenotype of AslNeo/Neo mice. $Asl^{Neo/Neo}$ mice were IV-treated weekly with ASL-LNP from birth (neonatally-treated) or from juvenile age (adult-treated). They were compared to wild-type (WT), untreated or Luciferase mRNA (Luc-LNP) neonatally IV-treated weekly $Asl^{Neo/Neo}$ littermates, or ASL-LNP IV-treated weekly AslNeo/Neo mice from birth with therapy stopped at 6-weeks of age (withdrawn group). Surviving animals were harvested at 3 months of age. Alongside confirmed correction of ureagenesis and restoration of hASL liver expression, ASL-LNP neonatally- and adult-treated mice showed cerebral hASL protein expression, demonstrating significant LNP-mRNA crossing of BBB. Behavioural tests showed decreased anxiety and increased locomotion in ASL-LNP treated AslNeo/Neo mice versus withdrawn mice, and comparable to WT. Cerebral biochemistry showed normalisation of toxic metabolites (arginosuccinate, guanidinosuccinate), arginine, citrulline, creatine and creatinine levels, compared to untreated controls. Cerebral Magnetic Resonance Imaging (MRI) showed reduced neurite density index in grey matter areas but preserved white matter in AslNeo/Neo withdrawn versus WT mice. This finding was corrected in ASL-LNP neonatally-treated littermates. Cerebral [18]Fluorodeoxyglucose positron emission tomography (FDG-PET) showed significantly reduced glucose consumption in withdrawn versus WT mice, corrected in ASL-LNP neonatally-treated littermates. We assessed epileptogenesis in withdrawn AslNeo/Neo mice compared to WT and ASL-LNP neonatally-treated mice following injection with seizure-inducing GABA-A antagonist pentylenetetrazole. Withdrawn mutants showed higher seizure probability and severity, compared to WT, which were normalised in ASL-LNP treated mice. Assessment of oxidative stress in brain slices showed glutathione deficiency, and increased levels and altered kinetics of cytosolic and mitochondrial reactive oxygen species in untreated mutants versus WT. These findings were normalised in ASL-LNP neonatally-treated mice at 2-weeks of age. This therapy provides in situ cerebral ASL expression correcting neuropathology and supporting clinical translation in ASA. ASA is a unique genetic disease model enabling first proof of concept of BBB crossing by systemically delivered LNP-mRNA

40 Rescue of Glutaric Aciduria Type I by GalNAC conjugated siRNA against Aminoadipate Semialdehyde Synthase

Yunhan Ma[1], Maiya Fujiwara[2], Mercedes Barzi[1], Natasha Murugan[1], Tong Chen[1], Beatrice Bissig-Choisat[1], Karl-Dimiter Bissig[1]*, Leila Noetzli[3]

**Corresponding Author*

Glutaric Aciduria Type 1 is a serious metabolic disorder that occurs with a frequency of 1:100,000 live births. It is caused by a deficiency in Glutaryl-CoA Dehydrogenase (GCDH), a crucial enzyme in the lysine degradation pathway. The deficiency results in accumulation of toxic metabolites such as glutaric acid (GA) and 3-OH-glutaric acid (3-OH-GA), causing encephalopathic crisis and debilitating movement disorders if untreated. Early detection, strict dietary control and emergency interventions reduce the risk of severe cerebral injury. Nevertheless, complex movement disorders are still encountered in one-third of patients.

We previously showed that restoring a normal lysine catabolism in the liver of adult *Gcdh-/-* mice via hepatocyte transplant or AAV gene therapy is sufficient to rescue the lethality and the neurological phenotype. We also identified Aminoadipic Semialdehyde Synthase (AASS), an enzyme upstream of GCDH in the lysine degradation pathway, as a novel therapeutic target by deleting the gene using a liver-specific CRISPR approach (Barzi et al. *Sci Transl Med* 2023).

Here, we explored the efficacy of an N-acetylgalactosamine (GalNAC) conjugated small interfering RNA (siRNA) targeting *Aass* (siRNA-*Aass*) in *Gcdh-/-* mice. In both adult and neonatal mice treated with siRNA-*Aass*, we observed a dose dependent survival and weight gain. The rescued mice showed no obvious clinical phenotypes. Toxic catabolites GA and 3-OH-GA were reduced in the liver, brain, kidney, urine and plasma. Importantly, siRNA treated mice had fewer vacuolations in the hippocampus, indicating a reduction in brain associated pathologies. In summary, a liver-targeted siRNA-*Aass* therapy is an effective treatment for the GA-I mouse model. These findings hold promise for an improved therapeutic management of GA-I patients, with the potential to prevent debilitating movement disorders.

41 Encapsulated cell therapy demonstrated therapeutic efficacy in metachromatic leukodystrophy and sustained ARSA production in NHP

Elena-Gaia Banchi[1], Rafael ALONSO[2], Kévin Fransquin[3], Timothée de Saint Denis[2], Adrien Engel[4], Sylvie JACQUOT[3], Nicolas Mach[5], Julien Grogg[6], Caroline Sevin[1], **Francoise Piguet[7]**
[1]Paris Brain Institute, Paris, Paris, France, [2]Innovation Unit GENOV, Paris Brain Institute, PARIS, France, [3]GENOV Paris Brain Institute, Paris, Paris, France, [4]Release Therapeutics, geneve, Geneva, Switzerland, [5]University of Geneva Medical Centre, SWITZERLAND, [6]Release Tx, Geneva, Geneva, Switzerland, [7]TIDU GENOV, ICM, Paris, Paris, France

Metachromatic leukodystrophy (MLD) is a lysosomal storage disorder caused by an inherited deficiency of arylsulfatase A (ARSA) and characterized by accumulation of sulfatides in both glial cells and neurons resulting from myelin degeneration in the central and peripheral nervous systems. Currently, no effective treatment is available for patients once symptoms are already present. Libmeldy©, an Ex vivo gene therapy, is the gold standard for pre-symptomatic MLD patients. Here, we investigated an innovative approach to deliver the recombinant ARSA enzyme by encapsulated-cell therapy. A cell-based device is capable of continuously delivering human ARSA compared to weekly intrathecal delivery of rARSA which is under clinical evaluation. Two constructs of genetically engineered cells have been tested to determine which one could target more efficiently the central nervous system. Moreover, a dose response evaluation has been done with 2 doses (cells number loaded) to evaluate the best therapeutic effect. MLD mice were implanted at 6 months once disease is well established. The device biocompatibility as well as the therapeutic efficacy have been evaluated 3 months after implantation. The device is well tolerated in animals. Moreover, we demonstrate a correction of sulfatide storage and significant improvement of neuroinflammation in all treated mice. Encapsulated, immortalized human myoblast genetically engineered to produce ARSA can deliver controlled, sustained, stable ARSA over months. After a proof of concept demonstrating therapeutic effect if subcutaneous capsule implantation in MLD mice we present here safety and biological activity of prolonged intracranial implantation for 5 months in non-human primates in MLD mice

MyoP devices, loaded with ARSA producing human myoblast cells were successfully implanted subdurally in 2 NHP. Over 5 months the tolerance was perfect with no adverse effect especially no neurological or behavioral changes.

NHP were sacrificed after 5 months and extensive biological/anatomical analysis were performed.

- Supernatants from all explanted capsules showed stable ARSA activity
- ARSA activity in neuronal tissues was doubled in both NHP compared to non-treated historical controls and or baseline (CSF)
- Hemagglutinin A, a tag attached to ARSA produced by the myoblast cell line, was detected in most area of the brain at necropsy; confirming the good release and biological processing of ARSA delivered by the encapsulated cells.

Beyond MLD treatment, these findings establish proof-of-concept for subdural protein delivery, unlocking therapeutic potential for CNS diseases where proteins face challenges crossing the blood-brain barrier. To advance towards clinical translation, we will:

- Establish GMP manufacturing process for clinical-grade Myo-P encapsulated-cell products,
- Conduct first-in-human phase I/II study in early symptomatic late infantile and juvenile MLD patients.

42 Definition of a Minimal Therapeutic Dose of *In Vivo* Liver-Directed Lentiviral Gene Therapy for Methylmalonic Acidemia

Elena Barbon[1], Amy Argabright[2], Chiara Simoni[3], Elisabetta Manta[4], Giancarlo La Marca[5], Francesca Sanvito[6], Angelo D'Alessandro[2], Julianne Smith[7], Alessio Cantore[8]
[1]SR-TIGET, Roma, C.F. e Partita I.V.A.: 04879781005, Italy, [2]University of Colorado, Aurora, [3]SR-TIGET, Milan, Milano, Italy, [4]SR-TIGET, Milan, Italy, [5]University Hospital Meyer, ITALY, [6]IRCCS San Raffaele Scientific Institute, MIlan, Milano, Italy, [7]Genespire, Milan, Italy, Italy, [8]SR-TIGET, Milan, Italy, Italy

Methylmalonic acidemia (MMA) is a severe metabolic disorder caused by mutations in the *MMUT* gene, resulting in a build-up of toxic methylmalonic acid (*MMAc*). Immune-shielded lentiviral vector (ISLV)-based liver gene therapy may provide a stable benefit in young children at the initial disease stage by virtue of vector integration into the genome of target cells. We have shown that administration of an ISLV expressing the wild-type *MMUT* transgene (ISLV.*MMUT*wt) into the MCK-*Mmut*-/- mice, an intermediate MMA mouse model, resulted in long-term (>1 year) amelioration of disease-related biomarkers, hepatic and extrahepatic detoxification from *MMAc*, and global rescue of the metabolomic profile. To increase the transgene expression per transduced cell and reduce the therapeutic ISLV dose, we tested a codon-optimized *MMUT* transgene under the control of a hepatocyte-specific expression cassette (ISLV.*MMUT*co), showing higher transgene expression and therapeutic efficacy when using it at similar doses compared to ISLV.*MMUT*wt. Reducing the effective LV doses facilitates manufacturing and alleviates potential dose-dependent toxicities. We administered ISLV.*MMUT*co to 2-week-old MCK-*Mmut*-/- mice at three different doses (1, 2, and 4×10^{10} TU/kg). We showed dose-dependent amelioration of disease biomarkers and hepatic and extrahepatic detoxification from *MMAc* with different kinetics depending on the ISLV dose. End-point RNA in situ hybridization analyses on the livers showed dose-dependent hepatocyte transduction efficiency, ranging from 20% to 80% of transgene-positive cells. We observed a substantial increase in transgene-expressing hepatocytes in livers collected at late (6 months) compared to early (6 weeks) time points after vector administration. This indicates a selective advantage of the transduced hepatocytes at the lowest tested ISLV dose. The progressive amelioration of the MMA-related biomarkers over time confirmed the selective advantage in this experimental group, with slower kinetics compared to mice administered at the two higher ISLV doses. These data highlight the potential for long-term therapeutic benefit, even when starting from sub-therapeutic doses. On the other hand, at the two higher doses, we found a rapid and sustained up to 8-fold reduction of circulating *MMAc* concentrations (mean of 276 µM and 1608 µM in treated and untreated MCK-*Mmut*-/- mice 2 weeks post-ISLV; mean of 157 µM and 1313 µM in treated and untreated MCK-*Mmut*-/- mice 20 weeks post-ISLV). To determine the ISLV dose required to achieve comparable transduction levels in human hepatocytes for clinical translation, we administered ISLV expressing a reporter transgene to liver-humanized Fah-/-Rag2-/-Il2rg-/- NOD mice (FRGN) with ≥70% human hepatocyte repopulation. We showed efficient and dose-dependent human hepatocyte transduction, achieving levels comparable to those observed in the MMA mouse model but at substantially lower doses (e.g., $1.9–7.5\times10^{9}$ TU/kg). The higher transduction efficiency achieved in this setting is due to the enrichment of human CD47, a phagocytosis inhibitor, on the surface of ISLV. This signal is recognized in FRGN mice because of the NOD background, protecting ISLV from macrophage uptake and thus increasing gene transfer into hepatocytes. These data provide critical insight into the minimal therapeutic ISLV dose required for first-in-human in vivo liver-directed ISLV gene therapy, supporting progression toward a clinical trial in MMA patients.

43 Neonatal AAV gene therapy provides long term rescue in mouse models of combined methylmalonic acidemia and homocystinuria, *cblC* type

Jennifer Sloan[1], Giuliana Lopez[2], Pauline Hoffman[3], Stefanos Koutsoukos[1], Kelsey Murphy[2], Madeline Arnold[2], Nathan Achilly[2], Gene Elliot[2], Victoria Hoffman[4], Charles Venditti[5]
[1]National Human Genome Research Institute, Bethesda, MD, [2]NHGRI, Bethesda, MD, [3]NHGRI, Philadelphia, PA, [4]National Institutes of Health, [5]NIH, Bethesda, MD

Combined methylmalonic acidemia and homocystinuria, *cblC* type (*cblC*) is the most common inborn error of intracellular cobalamin (vitamin B_{12}) metabolism caused by pathogenic variants in *MMACHC*. The protein encoded by *MMACHC* is responsible for the transport and processing of vitamin B_{12}. Early onset disease can be severe with symptoms including growth failure, anemia, heart defects, neurocognitive impairment, and progressive vision loss despite treatment. In order to further characterize manifestations of the disease and investigate AAV gene addition therapy as a possible treatment, we generated and characterized three *Mmachc* mutant alleles using gene editing: *Mmachc*^{del2} c.163_164delAC p.(Pro56CysfsTer4) , *Mmachc*^{del3} c.162_164delCAC p.(Ser54_Thr55delinsArg) and *Mmachc*^{del23} c.163_185del p.(Thr55ProfsTer42). *Mmachc*$^{-/-}$ mutants recapitulated the clinical phenotypes of *cblC* including embryonic and neonatal lethality, poor survival (median 5 days, with complete lethality by 1 month), growth impairment, neuropathology (hydrocephalus and thinning of the corpus callosum) and the hallmark biochemical features of elevated plasma methylmalonic acid, increased homocysteine and decreased methionine. We tested three AAV gene therapy vectors: rAAVrh10-CBA-*Mmachc* (AAVrh10), rAAV9-CBA-co*MMACHC* (AAV9) and rAAV9.PHP.eB-CBA-co*MMACHC* (PHP.eB). AAVrh10 and AAV9 were utilized to target liver, brain and other tissues and PHP.eB to target the central nervous system. The AAVs were delivered by a single intrahepatic injection at 1 x 10^{11} GC/pup P0-2. Neonatal treatment with all three AAV vectors [*Mmachc*^{del2} AAV9, PHP.eB; *Mmachc*^{del3} AAVrh10, AAV9; *Mmachc*^{del23} PHP.eB] resulted in long-term survival of mutants (n=7-11 per group, median >250 days) in all studies which was statistically significant compared to untreated mutants ($p<0.01$). Disease related metabolites (methylmalonic acid, homocysteine and cystathionine) remained elevated in mutants compared to wildtype and heterozygous controls: methylmalonic acid was greatly reduced in AAVrh10 (159.7 ± 7.5 uM; N = 3) and AAV9 treated *Mmachc*$^{del3/del3}$ mice (136.9 ± 47.5 uM; N = 3) vs untreated (503.3 ± 279.5 uM) $p<0.01$. Pathological examination of *Mmachc*$^{del3/del3}$ mutant mice treated with AAV9, one year after vector administration, indicated a mitigation of neuropathology. These *Mmachc* mouse models recapitulate key phenotypic and metabolic disease manifestations of severe cobalamin C deficiency and can be used to assess the preclinical efficacy studies of new genomic therapies. A single intrahepatic injection of an AAV gene addition vector, carrying either the mouse *Mmachc* or human *MMACHC* gene and pseudoserotyped with various capsids, led to increased survival and long-term rescue of *Mmachc*$^{-/-}$ mice. Systemic AAV gene therapy therefore holds promise as a potential therapeutic strategy to treat individuals with cobalamin C deficiency, the most common disorder of intracellular vitamin B12 metabolism.

44 ABO-101, a Novel Gene Editing Therapy for Primary Hyperoxaluria Type 1, is Efficacious and Well Tolerated in NHPs and Results in High Fidelity Editing in Primary Hepatocytes

Tia DiTommaso[1], Michael Kuefner[1], Anthony Garrity[1], Yurong Xin[1], Gabrielle Munoz[1], Ivan Kristanto[1], Lijun Liu[2], Florie Borel[1], Winston Yan[1], Daniel Ory[1], Pamela Stetkiewicz[1], John Murphy[1]
[1]Arbor Biotechnologies, Cambridge, MA, [2]Arbor Biotechnologies, Cambridge

Primary hyperoxaluria, or PH, is a group of rare genetic metabolic disorders characterized by the overproduction of oxalate by the liver. Oxalate builds up and accumulates in the kidneys and other organ systems, causing kidney damage and progression towards renal failure. PH1, the most common and clinically severe subtype of PH, results from a mutation of the *AGXT* gene that is expressed primarily in the liver. Here we present preclinical mouse and NHP *in vivo* data as well as genotoxicity data supporting ABO-101 as a novel CRISPR-Cas-mediated gene editing therapy for the treatment of PH1.

The current standard of care for PH1 is siRNA therapy that requires repeated lifelong treatments and targets *HAO1*, which encodes the glycolate oxidase enzyme (GO) and is upstream of the mutant *AGXT*. ABO-101 was designed to specifically inactivate the *HAO1* gene in liver hepatocytes and provide a durable reduction of oxalate levels through a single course of treatment. Here, we demonstrate durable reduction of hepatic GO protein expression in a rodent hepatectomy model (~88% GO knockdown pre- and post-hepatectomy) as well as long-term reduction of urinary oxalate to therapeutically meaningful levels (>30% reduction) for >6 months in a PH1 disease model. In addition to mouse pharmacology, we show that in NHPs treated with ABO-101, we achieved *HAO1* editing of approximately 60% in whole liver tissue, which indicates editing of the majority of hepatocytes and drives a greater than 2-fold increase in serum glycolate, a biomarker of knockdown of the pathway, all with a well-tolerated safety profile. Lastly, we highlight our genotoxicity and reproductive toxicity data packages demonstrating high fidelity of ABO-

101 across >1,500 candidate off-target sites; the maintenance of the chromosomal structure; and lack of germline transmission in vivo. Taken together, these results demonstrate signals of efficacy in mice and NHPs and safety at the genome-wide and organismal level, further supporting the advancement of ABO-101 into the clinic as a potential treatment for PH1.

45 RNA Switch-Regulated Biofactory Gene Therapies for Rare and Common Metabolic Disorders

Xiaojuan Tang[1], MENGJIA LU[1], Haimin Wang[1], Jun Xie[1], Guangping Gao[1], Hong Moulton[2], **Guocai Zhong[1]***
[1]UMass Chan Medical School, Worcester, MA, [2]Oregon State University, Corvallis, OR
**Corresponding Author*

AAV-transduced skeletal muscle cells can function as long-lived biofactories to continuously produce and secrete AAV-encoded biologics into the bloodstream. This approach has been demonstrated promising and is particularly attractive for biologics with short blood half-lives, such as protein/peptide hormones, which typically have blood half-lives ranging from minutes to hours. Genetic switches that enable precise temporal and dose control of transgene expression may improve safety and efficacy, and broaden the use of this approach, particularly for therapeutics with narrow therapeutic windows and/or major contraindications.

We recently developed a class of ultra-efficient RNA ON-switch systems (Z^{on}) that allow for switch regulator dose-dependent, monthly or less frequent repeated inductions of AAV transgene expression for more than a year, with regulatory ranges spanning five logs or more in mice. Here, we describe the utilization of Z^{on} to tightly regulate the expression of two short-lived protein/peptide hormones in two POC studies aimed at developing controllable biofactory gene therapies for (i) a rare genetic metabolic disease, congenital leptin deficiency (CGL), and (ii) multiple related common metabolic conditions, including obesity, insulin resistance, and metabolic dysfunction-associated steatohepatitis (MASH).

In the POC study for the treatment of CGL, administration of a switch regulator every six weeks to induce Z^{on}-controlled AAV-*leptin* resulted in (i) leptin protein production at physiological levels in circulation, (ii) a profound body weight-lowering effect, and (iii) normalization of hyperglycemia in leptin-deficient ob/ob mice. In the other POC study targeting obesity, insulin resistance, and MASH, Z^{on}-controlled expression of another short-lived protein/peptide hormone in genetically obese ob/ob mice led to (i) significant reductions in body weight, (ii) normalization of blood glucose and insulin levels, and (iii) substantial improvement in MASH-associated markers of liver injury and inflammation. These data demonstrate that Z^{on} RNA switch-controlled biofactory gene therapy is a promising approach for the treatment of certain rare genetic and common metabolic disorders.

Physical Delivery Methods and DNA/RNA Drug Development

46 The Tethosome Platform is a Non-Viral, Dual DNA/mRNA System That Facilitates Potent, Re-Dosable, and Durable Therapeutic Gene Expression

Will Olsen[1]*, Kathryn Kwant[1], **Ben Hawley[1]***
[1]Engage Bio, San Carlos, CA
**Corresponding Author*

Genetic medicine offers the potential to treat many currently incurable heritable or acquired diseases. Numerous viral DNA delivery systems have resulted in life-changing therapies, but challenges relating to immunogenicity, redosability, and manufacturability currently limit the utility of viral vectors. While non-viral gene delivery systems possess favorable manufacturability and redosability properties, several key challenges remain. Historically, gene expression from non-viral DNA vectors has been several orders of magnitude below therapeutic levels for most indications; this is attributed largely to the limited efficiency of DNA transport into the nucleus. In addition,

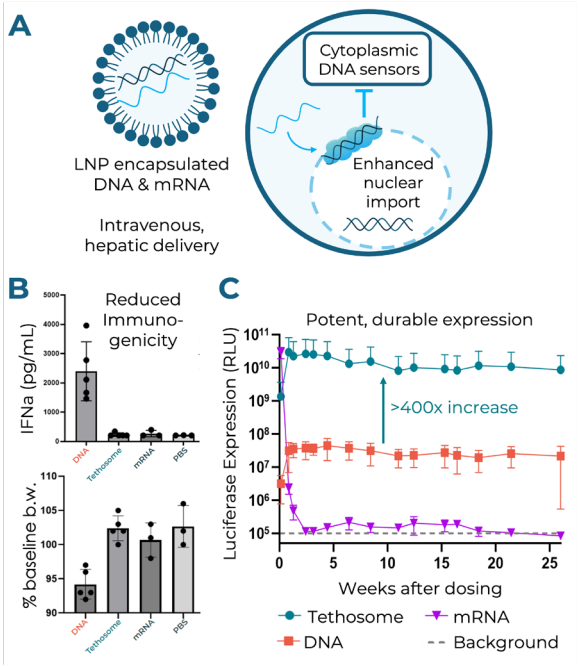
significant acute toxicity has been observed in animal models as a result of innate immune sensing of cytoplasmic DNA. The combination of low expression and immunogenicity has hampered the advancement of non-viral DNA medicines.

To enable DNA medicines to reach their significant therapeutic potential, Engage Bio has developed the Tethosome platform. Here, we co-encapsulate a modified DNA encoding one or more transgenes and an mRNA in lipid nanoparticles. The mRNA encodes our proprietary, engineered Tethosome protein which actively shuttles the DNA expression vector into the nucleus, while evading cytoplasmic DNA sensors including cGAS-STING and TLR9 (Fig. 1a).

To demonstrate these advantages, nucleic acids encoding firefly luciferase were delivered intravenously to the murine liver. Non-viral delivery of DNA resulted in pronounced increases in proinflammatory cytokines such as IFNα, as well as significant body-weight loss at day 1; in contrast, Tethosomes show no significant differences from nucleoside modified mRNA or PBS (Fig. 1b). By facilitating nuclear entry and abrogating innate immune activation, the Tethosome platform enables significantly higher and longer-lasting transgene expression, here leading to >400-fold increases in firefly luciferase expression relative to traditional DNA, and six months of durable expression (compared to <1 week with mRNA) (Fig. 1c).

We will also present data from several preclinical programs for monogenic gene replacement, biologics, and oncology. As a case study for monogenic gene replacement, a single dose of Tethosomes encoding full-length human Factor VIII (FVIII) was able to generate 50-100% of normal FVIII serum levels in mice, remaining consistent over the duration of the study (26 weeks). Crucially, the ability for Tethosomes to be safely redosed permits both titration to optimal levels, and "topping up" if expression wanes, ensuring that expression does not fall below therapeutic levels. As a case study for biologic drugs, a single dose of Tethosomes encoding a therapeutic GLP-1 receptor agonist peptide was able to elicit pronounced weight-loss in a mouse model of diet induced obesity, with months of durability and effect sizes comparable to clinically-approved GLP-1 drugs. Finally, in murine models of hepatocellular carcinoma (HCC), Tethosomes encoding a cocktail of clinically-validated, pro-inflammatory cytokines under the control of a HCC-specific promoter elicited >80% tumor growth inhibition and >250% median survival increase.

The Tethosome system offers a novel solution to the limitations that have held back non-viral DNA medicines, potentially enabling a new class of durable, redosable therapies to treat a wide range of diseases.



47 Next-Generation DNA-Based Delivery of Therapeutic Proteins Using MYO Technology: Preclinical Results on a Broadly Neutralizing Anti-Zika Virus Antibody

Andy Thompson[1], Andrew Cameron[2], Debnath Maji[3], Linda Sasset[4], Joseph Nkolola[5], Lauren Williamson[6], Xin Yao[7], Melanie Walker[2], Delcora Campbell[2], Carleigh Sussman[2], Luisa Rubinelli[2], Robert Miller[2], Robert Carnahan[8], James Crowe[9], Dan Barouch[10], Rachel Liberatore[11], Marek Drozdz[2]
[1]RenBio, Inc., Long Island City, NY, [2]RenBio Inc., Long Island City, NY, [3]Louisiana State University, Baton Rouge, LA, [4]RenBio, New York, NY, [5]Beth Israel Deaconess Medical Center, Boston, MA, [6]Vanderbilt University Medical Center, Nashville, TN, [7]RenBio Inc., New York, NY, [8]Nashville, Tennessee, [9]Vanderbilt Vaccine Center, Nashville, TN, [10]Beth Israel Deaconsess Medical Center, Harvard Medical School, Boston, MA, [11]RenBio, Long Island City, NY

Therapeutic proteins, a large class of drugs including antibodies, hormones, and enzymes, have seen a substantial increase in clinical development and use across many disease areas. Despite the broad applicability of these drugs, their more widespread use is often limited by high manufacturing costs and hurdles to delivery. Many therapeutic proteins are administered via time-consuming intravenous infusions. Others, regardless of administration route, need to be dosed frequently. Another drawback of many biologics is the requirement for maintenance in a low temperature environment prior to use. Such cold-chain dependencies can significantly hinder the ability to deliver therapeutics to large numbers of people, a problem that is amplified in resource-poor settings.

MYO Technology™, a DNA-based platform for the delivery of therapeutic proteins, was developed to overcome these barriers. The MYO Technology platform consists of therapeutic-encoding plasmid DNA (pDNA) and a proprietary medical device for the intramuscular injection of pDNA, followed by the delivery of very short electrical pulses to the muscle tissue surrounding the injection site. These pulses promote the in vivo electroporation of muscle cells and efficient uptake of pDNA, leading to production and secretion of the therapeutic protein, and ultimately release into peripheral circulation.

MYO Technology offers several advantages over standard delivery of therapeutic proteins, in part because pDNA manufacturing is a simpler and less specialized process compared to protein manufacturing, and pDNA is very stable and lacks most cold chain requirements. Furthermore, administration using MYO Technology takes only a few minutes, and the serum level of a therapeutic protein can potentially be maintained for many months without the need for redosing.

Zika virus (ZIKV), an arthropod-transmitted flavivirus, has been linked to severe neurological complications in humans, and prenatal exposure can cause congenital malformations including microcephaly. Although it remains a public health concern, no vaccines or specific treatments for ZIKV are approved for clinical use. ZIKV-117, a potent, broadly neutralizing human monoclonal antibody against ZIKV, was isolated from convalescent blood (Sapparapu et al., 2016, *Nature*), and has been demonstrated to prevent and treat ZIKV infection in animal models, including non-human primates (NHP) (Sapparapu et al., 2016, *Nature*; Nkolola et al., 2024, *J. Virol*).

Here, we present our preclinical studies on the DNA-based delivery of ZIKV-117 with MYO Technology. Proof of concept studies in mice show a single treatment driving antibody expression for longer than one year. ZIKV-117 protein produced in mice and rabbits in vivo following MYO Technology delivery shows comparable neutralizing activity to recombinant ZIKV-117 protein. Finally, we demonstrate that ZIKV-117 delivered by MYO Technology is protective against ZIKV infection in NHPs.

Through improvements in administration frequency and freedom from cold-chain requirements, MYO Technology has the potential to provide long-lasting protection from ZIKV, particularly in resource-poor areas. Furthermore, MYO Technology has the potential to confer the same advantages to a range of biologics, from other monoclonal antibodies to small therapeutic proteins.

48 Optimizing Focused Ultrasound Parameters for Enhanced AAV Delivery Across the Blood-Brain Barrier for the Treatment of Neurodegenerative Diseases

Bernie Owusu-Yaw[1], Yongzhi Zhang[1], Amanda Chisholm[1], Kimberly Kegel-Gleason[2], Nick Todd[3]
[1]Brigham and Women's Hospital & Harvard Medical School, Boston, MA, [2]Massachusetts General Hospital & Harvard Medical School, Boston, MA, [3]Brigham and Women's Hospital, Boston, MA

Introduction:
Rapid advancements in nuclease technology and gene-editing tools have created new opportunities for the treatment of neurodegenerative diseases. However, despite these developments in gene therapy technology, gene delivery to the brain remains a significant challenge due to the blood-brain barrier (BBB). Current methods of overcoming the BBB include intrathecal and intraparenchymal injections which are invasive and often result in limited diffusion beyond the injection site. Adeno- associated virus (AAV) vectors are widely used as delivery vehicles for in vivo gene therapy but BBB crossing ability of different capsids varies depending on AAV serotype and across species. Focused ultrasound (FUS) combined with microbubbles (MB) has emerged as a promising technique that can be used to temporarily disrupt the BBB to deliver AAV's to specific brain regions. FUS-mediated AAV delivery has been demonstrated in mice and non-human primates. There have not yet been any clinical trials to investigate the safety of using FUS for AAV delivery in patients. The efficiency of FUS-mediated AAV delivery can be enhanced by optimizing a range of treatment parameters including microbubble dose and FUS pressure. Here, we investigated the optimal FUS parameters for efficient FUS-mediated delivery of AAV9 to the striatum.

Methods:
FUS-BBB opening was targeted to the right striatum in C57BL/6J mice (N=4 per group). Treatment parameters were varied over microbubble dose (20, 40, 80 µL/kg) and harmonic dose, an integrated measure of microbubble response that is correlated with FUS pressure (51, 74,76, 89 a.u.). Other FUS parameters were fixed at 10 ms bursts and 1Hz repetition frequency for 120s, with resulting pressures ranging from 0.22-0.33 MPa (Table 1). Following sonications, mice were injected intravenously with 5.2×10^{11} vg/mouse (2.1×10^{10} vg/g) of scAAV9-hSYN-GFP. Gadolinium enhanced T1-weighted MRI images were acquired to confirm BBB opening in the striatum. Mice were euthanized three weeks after treatment and the brains were harvested for immunohistochemical analysis, with cell counting done based on confocal microscopy.

Results:
We were able to achieve successful BBB-opening in the striatum over the range of FUS-pressures used in this study (Figure 1A-C). BBB permeability was significantly higher in high pressure group compared to the low and medium pressure groups (Figure 1D). We did not observe any tissue damage using the more aggressive FUS parameters. In all groups, the percentage of neurons transduced was significantly higher in the FUS-treated striatum compared to the untreated side. There were no significant differences in neuronal transduction across the low, medium and high-pressure groups or across low, medium and high microbubble doses (Figure 2F and 2G).

Conclusion:
All parameters resulted in safe BBB opening with enhanced AAV delivery in the treated compared to untreated hemisphere. These findings suggest that the correlation between BBB opening volume as measured by gadolinium-based MRI and neuronal transduction following FUS-mediated AAV delivery is not direct. Further work needs to be done to elucidate the mechanism of FUS-mediated AAV delivery to improve transduction efficiency in FUS gene therapy studies.

Table 1. FUS parameters

	Gd/AAV Injection time from treatment	Harmonic Dose (a.u.)	Microbubble dose
FUS Pressure	0 hrs	51, 74*, 89	20 µL/kg
Bubble Dose	0 hrs	76	20*, 40, 80 µL/kg

**Indicates same group*

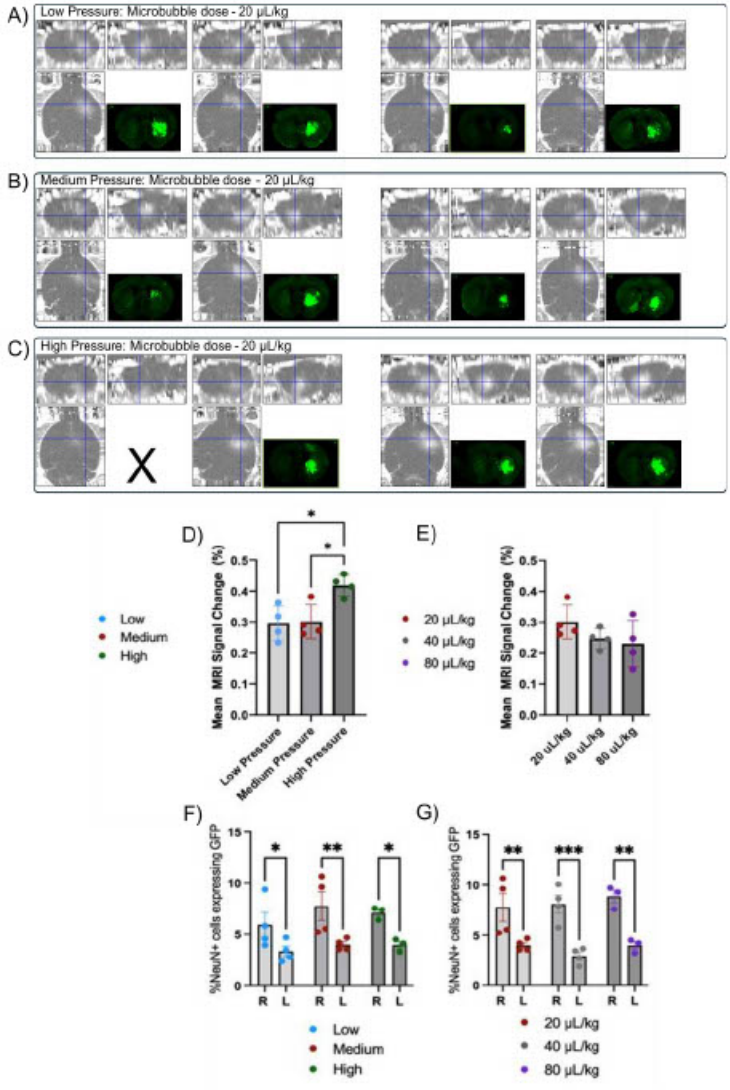


Figure 1. AAV delivery and neuronal transduction following FUS-BBB opening. Gadolinium enhanced T1-weighted MRI images and immunofluorescence images for GFP (green). Demonstrating BBB opening and GFP expression in the right striatum for the A) Low pressure, B) Medium pressure and C) High pressure groups receiving a microbubble dose of 20 µL/kg. MRI images were acquired using a preclinical T7 MRI scanner. D) Percent signal change in the striatum of the low, medium and high-pressure groups. E) Percent signal change in the striatum with a microbubble dose of 20 µL/kg, 40 µL/kg and 80 µL/kg. F) Percentage of Hoechst cells that are GFP+ and NeuN+ in the striatum of low, medium and high-pressure groups and G) Low (20 µL/kg), medium (40 µL/kg and high (80 µL/kg) microbubble dose groups. Data analyzed by two-way ANOVA followed by Tukey's multiple comparisons test. * $p < 0.05$, ** $p < 0.01$. **X- This animal was excluded from GFP analysis.*

49 Non-Viral Transcutaneous Fluoroscopy Guided Ultrasound-Mediated FVIII Delivery as a Promising Therapeutic Approach for Hemophilia A Treatment

Ting-Yen Chao[1], Feng Zhang[2], Yuanyi Xu[1], Timothy Nichols[3], Xiaohe Cai[4], Carol Miao[5]*
[1]Seattle Children's Research Institute, Seattle, WA, [2]UNIVERSITY OF WASHINGTON, Seattle, WA, [3]The University of North Carolina at Chapel Hill, [4]Seattle Children's Research Institute, [5]Seattle Children's Research Institute, Seattle, WA

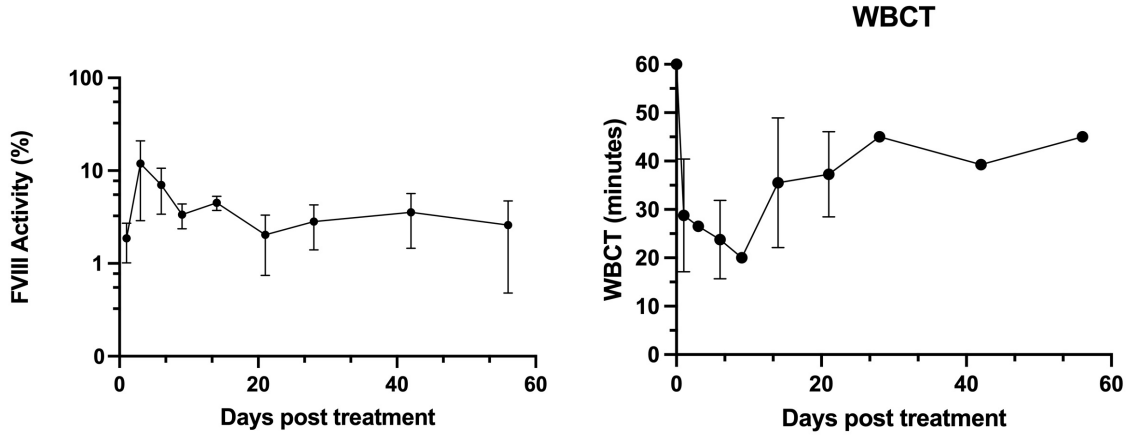
Hemophilia A (HA) is an X-linked clotting disorder characterized by a deficiency of functional factor VIII (FVIII) protein. Viral gene therapy is promising for treating hemophilia but currently there are safety concerns and challenges brought by the pre-existing antibodies against viral vectors. Ultrasound-mediated gene delivery (UMGD) has emerged as a promising non-viral method that utilizes therapeutic ultrasound (US) and microbubbles (MBs) to facilitate gene transfer.

Previously, we successfully performed UMGD of a human FVIII (hFVIII) plasmid in normal canines, achieving sustained hFVIII expression of approximately 20% over 60 days in two treated canines. In this study, we evaluated FVIII expression following UMGD with a canine FVIII (cFVIII) plasmid in HA canine models. A balloon catheter was inserted into the hepatic vein via jugular vein access of canines. A mixture of a high-expressing FVIII plasmid driven by the CAG promoter and RN18 microbubbles (MBs) was injected. Simultaneously, the ultrasound transducer, H114, was placed transcutaneously over the liver and administered pulsed US treatment. Each dog received treatment in two lobes, the left lateral lobe (LLL) and right lateral lobe (RLL), with four injections of the pDNA and MBs per lobe. Each lobe was treated for 2 minutes with the US transducer per injection, resulting in a total treatment time of 8 minutes per dog.

HA dogs (n=2) treated with the FVIII plasmid under UMGD, initially achieved approximately 10% activity, sustaining around 2.5% for two months. (Fig 1a). To confirm the improvement in coagulation function in the HA dogs, samples were measure by whole blood clotting time (WBCT) and Thromboelastography (TEG). The WBCT of non-treated HA dogs exceeded 60 minutes. In contrast, the treated HA dogs maintained a WBCT of less than 40 minutes within a month, (Fig 1b). TEG results also showed improvement. All dogs exhibited slight elevations in AST/ALT levels on the first day, but these levels returned to normal by day seven. Additionally, no significant changes were observed in any other parameters from the CBC and whole blood chemistry analysis in either dog.

The results of this study demonstrate that UMGD is a viable and effective method for delivering FVIII plasmids in HA canine models, achieving sustained FVIII activity with minimal adverse effects. This approach holds significant potential for advancing gene therapy for hemophilia A, offering a safer alternative to viral vector-based methods.



50 Safety, Tolerability, Biodistribution, Transgene Expression and Effectiveness of Image-Guided Laser-based Non-Viral Targeted Delivery of Multi-Characteristic Opsin in Retinae of African Green Monkeys

Saurav Mohanty[1], Najam Sharif[1], Sanghoon Kim[2], Michael Carlson[3], AMIR SINGH[4], SUBRATA BATABYAL[5], Samarendra Mohanty[6]

Dallas, [4]Nanoscope Therapeutics, Arlington, TX, [5]Nanoscope Technologies LLC, Bedford, TX, [6]Nanoscope Therapeutics Inc, Bedford, TX

Multi-characteristic opsin (MCO) is a trimeric fusion protein, containing three different light-sensitive proteins, which is responsive to ambient white light. Virally-delivered MCO is being evaluated in multiple clinical trials for retinal diseases causing photoreceptor degenerations. With the combined use of gold nanorods (GNRs), and near-infrared (NIR) laser wavelength tuned to the GNRs, non-viral delivery of MCO-020 plasmids is accomplished in a spatially-targeted manner. Upon intravitreal injection and laser delivery, MCO-020 expression in retinal neurons downstream to the dysfunctional/degenerated photoreceptors leads to visually-evoked signal. Here, we report the results of a GLP study evaluating the safety, tolerability, biodistribution, transgene expression, and effectiveness of MCO-020 delivery using an optical coherence tomography (OCT)-guided NIR laser procedure.

Specifically, high and low doses of MCO-020 plasmids mixed with GNRs were intravitreally injected into one eye of the sedated monkeys in 2 different groups (4-10 years old; both sexes; N = 3 / group), followed by OCT-guided scanning NIR laser irradiation in a 4 x 4 mm^2 area covering the macula. Another group of 3 animals received laser delivery of low doses of MCO-020 plasmids (and GNRs), which underwent laser redosing of a high dose of MCO-020 plasmids in the presence of a high dose of GNRs after 8 weeks of initial dosing. Control group eyes just received the vehicle buffer and the NIR laser irradiation. Several physiological, functional, and structural parameters were recorded through the 13-week study period, including measurements of intraocular pressure, slit lamp microscopy, fundus imaging, specular microscopy, OCT, confocal scanning laser ophthalmoscopy, and multifocal electroretinography (mfERG).

Regular ophthalmic exams did not show any adverse treatment-related toxicity or behavioral changes in any of the monkeys in any group. Mild, transient intraocular inflammation (attributed to the intravitreal injection procedure) was observed in all treatment groups but resolved on its own. No differences in IOP or central retinal thickness were observed between the MCO-020 treated and control groups over the 13-week study. Fundus autofluorescence imaging indicated higher levels of red fluorescence (attributable to mCherry, an active component of MCO-020) in the macula of the high-dose MCO-020 treatment group compared to the peripheral retinal areas. Similarly, there was a small but progressive increase in the mfERG amplitudes in monkeys that received the MCO-020 treatment. The increase in mfERG amplitudes above baseline values began at day-14 and continued through to day-28 and day-84.

In conclusion, the non-viral method described herein to deliver MCO-020 plasmids to NHP retinae was safe and well tolerated, and it effectively permitted transfection of the higher-order retinal neurons. Therefore, this OCT-guided NIR laser-based gene delivery procedure in targeted retinal cells offers an effective alternative to AAV-mediated transduction. Such a non-viral plasmid delivery platform can be used to help restore vision in patients suffering from degenerative retinal diseases, including geographic atrophy.

51 Single-dose electroporation delivery of plasmid-encoded incretin mimetics supports extended weight and blood glucose control in mouse models of diet-induced obesity

Ebony Gary[1], Yangcheng Gao[2], Casey Hojecki[3], Nicholas Tursi[4], Wujuan Zhang[2], Aaron Goldman[2], Martina Tomirotti[2], Mohammad Suhail Khan[2], Elizabeth Parzych[1], David Weiner[2]
[1]The Wistar Institute, Philadelphia, Pennsylvania, [2]The Wistar Institute, Philadelphia, PA, [3]Wistar Institute, Philadelphia, PA, [4]Wistar Institute

Obesity and obesity-associated diabetes affect millions of patients worldwide. Incretin mimetic drugs including glucagon-like peptide-1 (**GLP-1**) and glucose-dependent insulinotropic polypeptide (**GIP**), have advanced the treatment of diabetes and obesity. However, challenges such as short half-lives, protein production constraints, and increasing costs continue to limit the availability of these drugs. We developed plasmid-encoded long-acting incretin analogues (**pLincretin**s) by fusion of native and novel incretin molecules to IgG heavy chains. We evaluated the efficacy of these constructs in mouse models of diet-induced obesity (**DIO**). pGLP1-mFc and pGIP-mFc were detectable in mouse sera for four weeks. Treated mice exhibited significant weight loss, increased glucose tolerance, and decreased food intake compared to controls. Lipidomic analysis of serum identified differentially represented

lipid species between naïve animals and those treated with plasmid-encoded incretins. Similarly, Histological analyses revealed a reduction in liver fat droplets. A benefit of the nucleic acid platform is the ability to support the design of synthetic consensus molecules. We aligned several native and synthetic incretin molecules to design a plasmid-launched novel synthetic consensus incretin mimetic (**pSynCretin**) which also supported decreased body weight and food intake in DIO mice for four weeks following a single administration. These studies demonstrate that DNA-delivered incretin therapy can support weight and blood glucose control following a single *in vivo* administration and support the translation of nucleic acid approaches for incretin mimetic delivery.

52 Expanded Analysis of in vivo-delivered SARS-CoV-2 Plasmid DNA-encoded Monoclonal Antibodies (DMAb) in a Phase 1 Clinical Trial in Healthy Adults

Background:
dMAbs for Prevention of COVID-19 is an ongoing Phase 1 clinical trial in healthy human adults evaluating safety, tolerability, and pharmacokinetic expression of a synthetic plasmid DNA-encoded monoclonal antibody (DMAb) cocktail (NCT05293249). DMAbs are skeletal muscle expressed monoclonal antibodies, achieved through pDNA gene delivery of immunoglobulin genes and facilitated by CELLECTRA® *in vivo* electroporation technology. In this study, we evaluated in vivo gene delivery of a DMAb cocktail encoding AZD5396 and AZD8076, modified versions of the SARS-CoV-2 neutralizing mAb cocktail Evusheld. The most notable outcome of this study is the detection of durable in vivo DMAb expression >72 weeks, with further demonstration of a dose response and consistency within treatment groups. Ongoing efforts are therefore focused on the functional profile of DMAbs.

Methods:
The universal SARS-CoV-2 seropositivity in study participants (either by vaccination or natural infection) necessitated the development of unique assays that distinguish human IgG1 DMAb resulting from pDNA delivery from naturally occurring antibodies. In addition to development of a sensitive ELISA designed to specifically detect DMAb, bead-based isolation was optimized to maximize recovery from sera for additional functional analyses.

Results:
DMAbs expressed in serum demonstrated binding to the SARS-CoV-2 (RBD), including ancestral, Delta, and Omicron BA.2 and BA4/5 variants with a comparable profile to the parent Evusheld cocktail. Binding activity was detected longitudinally over >72 weeks, indicating consistent production of DMAb that functionally binds to target antigen. Serum-purified DMAbs potently neutralized in a sensitive, ancestral SARS-CoV-2 pseudovirus neutralization assay, with low ng/mL IC50 values, consistent with those observed with Evusheld. In-depth profiling of in vivo, muscle-produced DMAbs is underway and these protocols are being further optimized for large-scale purification from plasma apheresis.

Conclusions:
In parallel with the durable in vivo expression profile, these data highlight the biologic activity of an in vivo-expressed synthetic DNA-delivered mAb cocktail and are supportive of further development as a strategy for delivery of antibody-based gene-encoded biologic drugs.

Novel CAR-T Engineering Strategies for Hematological Malignancies

53 Efficacy, safety, and biological properties of Sleeping Beauty-engineered CAR T cells in patients with B-cell acute lymphoblastic leukemia

CAR T-cell therapy targeting CD19 has revolutionized the treatment landscape for B-cell acute lymphoblastic leukemia (B-ALL). To offer a more streamlined and cost-effective approach to achieve stable gene transfer, we utilized Sleeping Beauty transposon to engineer donor-derived anti-CD19 CAR T cells (CARCIK-CD19) for B-ALL patients relapsed after allogeneic hematopoietic stem cell transplantation (alloHSCT). Results from 36 patients in a pooled analysis of Phase 1/2, compassionate base use, and Phase 2 trials, sponsored by Tettamanti Center, Monza demonstrated encouraging safety and efficacy, with 83% remission rate and improved overall survival, associated with expansion, persistence, and high clonal diversity by integration site analysis of SB-engineered T cells. Despite these promising results, only 40-50% of B-ALL patients treated with any type of CAR T cells maintained a durable remission long term. In a considerable portion of treated patients, relapse occurs in the presence of CD19-expressing tumors, mainly because of CAR T-cell dysfunction. We hypothesized that the immunological niche of the BM reacts to CAR T cell-mediated inflammation by modulating the immune response through the activation of inhibitory pathways and molecules. To test our hypothesis, we performed transcriptional analysis of CAR T cells and the BM microenvironment from patients treated with commercial and our investigational CAR T-cell products and findings were validated by flow cytometry. We observed profound changes in the composition of BM after CAR T-cell infusion compared to pre-treatment samples, with an increase in the myeloid cells, and exhausted CD8+ T cells. Interestingly, myeloid cells displayed a higher resemblance to myeloid-derived suppressor cells (MDSCs) post-infusion. Significant enrichment in Interferon response, Hypoxia, and TGF-β signaling was associated with the expansion of MDSC, and exhausted T cells, detected by performing spectral flow cytometry of additional 20 matched BM samples pre and post CAR T-cell treatment. By modeling intercellular communications, we revealed that HIF1-α, VEGF and TGFβR2 are key players in the crosstalk between CAR T cells and the immune niche, leading to general immune suppression. These data were also validated in hematopoietic stem progenitor cell (HSPC)- humanized NSG mice engrafted with a human tumor, which recapitulated the human tumor microenvironment. PD1 expression in endogenous T cells post CAR-T treatment was associated with a lack of durable response. In conclusion, CAR T cells-mediated myeloid activation is associated with pathways of immune dysregulation that may dampen CAR T cell expansion and antagonize the effects of the therapy.

54 In Vivo Persistence and Function of CAR19 T-Cells for Pediatric B-Cell Acute Lymphoblastic Leukemia Are Impacted by Media, Cytokine, and Metabolite Bioavailability During Ex Vivo Expansion

Caitlin Hopkins[1], Amanda DiNofia[2], Shannon Maude[3], Gregory Chen[1], Maya Lavorando[1], Kwame Boateng-Antwi[2], Robert Bartoszek[1], Jessica Perazelli[2], Andres Mendez Corea[2], Alexander Shestov[4], Mercy Gohil[1], Yimei Li[2], Wei-Ting Hwang[4], Bakir Valentić[5], Shannon Christensen[4], Julie Jadlowsky[1], Regina Myers[2], Caroline Diorio[6], Megan (Suhoski) Davis[7], Theresa Colligon[1], Gabriella Plesa[8], Don Siegel[1], Bruce Levine[1], Carl June[1], Roderick O'Connor[1]*, Stephan Grupp[9]*, Joseph Fraietta[1]*

**Corresponding Author*

Chimeric antigen receptor (CAR) T-cell therapy targeting CD19 has been highly effective in treating pediatric B-cell acute lymphoblastic leukemia (B-ALL). However, responses are not durable in all patients, and up to 50% will relapse within two years of infusion. Relapse of CD19+ disease is likely due to inhibition or loss of functional CAR T-cells. There is interest in developing strategies to enhance persistence and function of CAR T-cells, but the exact mechanisms that drive functional persistence in patients are poorly understood. In two recent clinical trials performed at the Children's Hospital of Philadelphia evaluating a murine (NCT04276870) and humanized (NCT03792633) CD19/41BBz CAR for pediatric patients with B-ALL, we observed that two modifications made to the manufacturing process appeared to impact long-term functional persistence of CAR T-cells: base media formulation and cytokine supplementation. There are four manufacturing conditions across these trials—X-VIVO™-15 IL-2, X-VIVO™-15 IL-7/IL-15, OpTmizer™ IL-2, and OpTmizer™ IL-7/IL-15. Initial clinical response and expansion of CAR T-cells are similar across manufacturing conditions when compared to X-VIVO™-15 IL-2 manufacturing conditions used in prior murine (NCT02906371) and humanized (NCT02374333) pediatric CD19/41BBz CAR T-cell studies; however, cells produced in X-VIVO™-15 IL-2 demonstrate superior functional persistence in patients with 71% (95% CI: 64%,79%) of patients maintaining CAR T function—defined by B-cell aplasia—6-months post-infusion compared to 11% (1.8%, 71%), 43% (23%, 78%), and 36% (18%, 72%) of patients in other manufacturing groups. Patients treated with X-VIVO™-15 IL-2 CAR-T cells had a 2.7 to 6.7-fold increase in circulating CAR T-cells 3-months post-infusion compared to other manufacturing groups. Bulk and single-cell RNA-sequencing reveals that media formulation, but not cytokine stimulation, drives major transcriptional differences in patient CAR T-cells both pre-infusion and at peak expansion post-infusion. T-cells grown in X-VIVO™-15 have increased effector/effector memory signatures, larger cell volume, upregulation of cholesterol biosynthesis pathway, and increased CD8+ T-cells, suggesting an increased activation status. Deeper investigation into activation pathways reveals increased NF-kB activity in CAR T-cells grown in X-VIVO™-15 media compared to those grown in OpTmizer™. X-VIVO™-15 grown CAR T-cells demonstrate increased sensitivity to cytokines and a superior ability to grow and persist in the absence of target antigen in vitro. In vivo evaluation of donor-matched CAR T-cells cultured in X-VIVO™-15 shows increased CAR T-cell numbers and tumor control in a xenograft model of leukemia compared to OpTmizer™ cultured cells, resulting in increased survival. In a targeted metabolomics screen, we identified several differences in metabolite abundance across formulations. We note that X-VIVO™-15 was enriched with metabolites involved in TCA cycle activity, one carbon metabolism, as well as arginine, ornithine, and inosine metabolism, several of which have been implicated in T-cell stemness and mitochondrial function. Based on this data, we propose that metabolite bioavailability during manufacturing of CD19/41BBz CAR T-cells has a significant impact on the phenotype, transcriptional signature, and persistence of infused cells, which can determine long-term durability of responses in pediatric B-ALL patients.

Background:
Despite the success of BCMA-targeting therapies in multiple myeloma (MM), patients with high-risk features are more likely to suffer early relapse and need novel therapies. Using the MMRF CoMMpass database, we identified CD70 as a cell surface unpregulated in high-risk MM. Though CD70 was previously identified in MM (McEarchern et al, Clin Cancer Res (2008)), heterogeneous expression in newly diagnosed samples led to its later deprioritization as an immunotherapy target. In the post-BCMA CAR T era, anti-CD70 cellular therapies could be highly beneficial in high-risk MM patients at the highest risk of relapse.

Methods:
Primary patient samples were obtained under an IRB-approved protocol. CAR-T lentiviral transduction was performed on paired CD4/CD8 human T cells from at least 3 healthy donors. Effector function of CAR-Ts was assessed by cytotoxicity, cytokine secretion, and memory/exhaustion marker profiling. In vivo murine xenograft studies were assessed using survival and bioluminescence. ATAC-seq peaks were called using Promo and HOMER (data from Jin et al. Blood (2018)). Machine learning was performed using XGBoost approach applied to CoMMpass RNA-seq data with 80% of samples for training and 20% as test set.

Results:
We analyzed CoMMpass mRNA data (release IA19) for surface protein encoding-genes upregulated in tumors at relapse versus newly diagnosed. We focused on CD70 given its low or absent expression in normal tissues. CD70 was markedly elevated in high risk genotypes such as t(4;14) and gain 1q, as well as R-ISS 3 at diagnosis. Flow cytometry profiling of 8 myeloma cell lines, including t(4;14) models KHM11, KMS26, and LP1, as well as relapsed primary MM samples revealed increased CD70 protein expression with antigen density similar to BCMA. We engineered 10 anti-CD70 CAR-T binders, 9 of which used scFv-based formats, in to both 4-1BB and CD28-zeta CAR frameworks. For the tenth design, we used a structure-guided design based on the CD70:CD27 co-crystal structure (PDB: 7KX0) to identify a CD27-based fragment, which outperformed all tested scFv-based CARs in both CAR frameworks. All CD70 CARs were efficacious in in vitro cytotoxicity assays against MM cell lines (Fig. 1), with similar cytokine as well as memory and exhaustion cell marker profiling. Murine xenograft studies comparing scFv based-CARs versus our natural ligand (CD27) CAR-T demonstrated prolonged survival compared to empty CAR (n=5 mice/arm, $p<0.005$ by log-rank) in both MM.1S and LP-1 xenografts, similar to BCMA CAR-T controls. Our CD27-based CAR showed superior expansion (50-85x, $p< 0.0001$ by ANOVA) and persistence compared to scFv- and BCMA-based CAR in both the CD28z and 4-1BB frameworks (Fig. 2). We further investigated mechanisms of CD70 upregulation in high risk MM. We showed that knockout of NSD2 in t(4;14) cell line models led to significantly decreased CD70 surface expression, implicating epigenetic regulation of CD70 overexpression in this high-risk MM subtype. Analysis of ChIP-seq in ENCODE and primary MM tumor ATAC-seq was used to nominate a set of transcription factors that bind the CD70 locus. Extending from CoMMpass data, we built a predictive machine learning model for CD70 expression as a function of transcription factor gene expression, nominating key transcription factors TFAP2A, LEF1, MYB, and PAX5 as CD70 regulators.

Conclusion:
Together, these results highlight the promise of targeting CD70 with optimized CAR-Ts in myeloma

Introduction
CD123 is expressed in over 90% of acute myeloid leukemia (AML) cases, making it an ideal target antigen.

However, clinical trials have shown that CD123-specific chimeric antigen receptor (CAR)-T cells are associated with on-target, off-tumor toxicities, including severe myelosuppression and cytokine release syndrome, alongside limited clinical responses. To address these issues, we developed ligand-based CAR-T cells targeting the interleukin-3 receptor (IL3R CAR-T), leveraging IL-3's differential affinity for normal myeloid cells expressing CD123 alone versus AML cells co-expressing CD123/CD131. Using protein structure prediction, we extensively modified the CAR binder to create mutated ligand-based CD123 CAR-T cells. These IL3R CAR-T cells demonstrated improved tumor control *in vivo* and reduced toxicity toward neutrophils and myeloid precursor cells compared to scFv-based CD123 CAR-T cells.

Method

A ligand-based CD123 CAR plasmid was constructed by linking IL-3 to a spacer, a CD28 endodomain, and CD3ζ. Six IL-3 mutants (A–F) with varying affinities for IL3R were designed using biophysical calculations. CAR-T cells were generated via *piggyBac* gene modification. The efficacy and safety of these modified IL3R CAR-T cells were evaluated in co-culture experiments with AML cell lines (MV4-11, THP-1, and Kasumi-1) and neutrophils. Colony formation assays were conducted to assess hematopoietic toxicity following co-culture with bone marrow mononuclear cells. *In vivo* efficacy was tested using NSG mice intravenously injected with THP-1 cells expressing firefly luciferase (THP-ffLuc). Seven days post-inoculation, CAR-T cells were injected intravenously, and anti-tumor activity was monitored via an *in vivo* imaging system.

Results

Six CAR constructs with mutated IL-3 ligands were generated and evaluated. Three mutants (A, B, and E) supported successful generation of IL3R CAR-T cells, enabling favorable *ex vivo* expansion and CAR expression by day 16. CAR-T cells using high-affinity ligand E exhibited superior cytotoxicity against MV4-11 cells compared to those with wild-type (WT) IL-3. Consequently, ligand E-based IL3R (mutated IL3R) and WT IL3R CAR-T cells were selected for further experiments. Both mutated IL3R and scFv-based CD123 CAR-T cells exhibited similar *ex vivo* expansion, CAR expression levels, CD4/CD8 ratios, and exhaustion marker expression (PD1, LAG3). Both also showed comparable cytotoxicity against AML cell lines MV4-11, THP-1, and Kasumi-1. In a THP-1-ffLuc xenograft model, mutated IL3R CAR-T cells achieved better tumor control than scFv-based CD123 CAR-T cells, with significantly lower luminescence levels (1390 ± 22.5 vs. 2218 ± 177 p/s/cm²/sr, $p = 0.0017$) on day 35. Safety assessments revealed that mutated IL3R CAR-T cells caused less neutrophil toxicity compared to scFv-based CD123 CAR-T cells. Colony formation assays also demonstrated reduced hematopoietic toxicity for mutated IL3R CAR-T cells, with an improved safety margin compared to scFv-based CD123 CAR-T cells (1.72 ± 0.1885 vs. 1.00, $p = 0.019$).

Conclusions

We successfully developed ligand-based mutated IL3R CAR-T cells targeting $CD123^+$ AML, demonstrating enhanced safety and efficacy compared to scFv-based CD123 CAR-T cells. These findings highlight the potential of mutated IL3R CAR-T cells as a promising therapeutic approach for AML. A clinical trial for relapsed/refractory myeloid malignancies using these CAR-T cells is currently being planned.

Chimeric Antigen Receptor T-cell (CAR-T) therapy has achieved significant success in cancer treatment, particularly for patients with relapsed/refractory B-cell malignancies. However, about half of patients receiving anti-CD19 CAR-T ultimately experience disease progression. The effectiveness of this therapy depends on the intrinsic features of the drug product and individual factors present at or after infusion. Significant gaps remain in understanding the in vivo behavior of CAR-T and the absence of reliable biomarkers to address treatment efficacy and toxicity. These unmet needs hinder our ability to predict outcomes and mitigate treatment risks. For this reason, we developed a strategy combining clonal tracking and epigenomic monitoring via liquid biopsies, which are cell-free DNA (cfDNA) fragments released in body fluids from dying cells capturing dynamics changes in peripheral organs. Here, we profiled cfDNA in 16 patients who received g-retroviral or lentiviral-based drug products encoding an anti-CD19 CAR targeting B-cell tumors. All patients were relapsed/refractory to prior therapies, with half achieving a complete response (CR) 90 days after infusion, while the others experienced disease progression (NR). State-of-the-art methods for both qualitative and quantitative evaluation of engineered T-cells allowed the retrieval of integration sites (IS) from PBMC and cfDNA samples collected up to one year after infusion. A significantly higher number of IS ($p<0.024$) was found in CR patients (98,482 IS) compared to NR patients (2,906 IS) in both blood cells and cfDNA. Longitudinal analysis revealed higher clonality ($p<0.01$) and persistence of engineered cells in CR versus NR patients, both in cells and cfDNA, indicating greater CAR-T-cell activity and engraftment even in peripheral tissues. Beyond vector IS, cfDNA levels and dynamics significantly differed between the two cohorts ($p<0.02$). In CR patients, high cfDNA levels detected before treatment progressively decreased from the early days post-infusion, whereas in NR patients, these levels remained high or even increased. Methylation studies can identify the cell of origin of these fragments, as cfDNA retains the epigenetic signatures specific to its source cell. In healthy donors (HD) at steady state, leukocytes—as granulocytes, monocytes/macrophages, and megakaryocytes—account for the majority of cfDNA production (80%) while in diseased patients a shift in cfDNA composition is expected depending on the extent of tissue/cell damage. In CAR-T patients, a higher fraction of cfDNA fragments derived from B-cells (80-fold increase) was observed compared to HD, both before and for two weeks post-infusion, reflecting tumor burden and the cytotoxic activity of engineered cells. Furthermore, neuronal and liver damage were also detected in patients who developed cytokine release syndrome, immune effector cell-associated neurotoxicity syndrome, or other inflammatory responses, demonstrating that this epigenetic approach can capture systemic response after treatment, which may differ in CR and NR patients. Overall, our data suggest that cfDNA holds significant potential for monitoring CAR-T therapy's effectiveness and safety at both clonal levels by IS and at the organismal level through cfDNA-methylation, providing valuable insights into disease progression and treatment-related events post-infusion and uncovering mechanisms of therapeutic success and failure that have yet to be explored.

58 Increased Potency, Persistence, and Stem Cell Memory/Naïve Phenotype is Achieved with PRGN-3008 UltraCAR-T, an Overnight-Manufactured CD19 CAR-T Cell Expressing membrane-bound IL-15 and miRNA-based PD-1 Blockade from a Single Non-Viral Transposon

Cheryl Bolinger[1], Shamim Ahmad[2], Tim Chan[3], Afreen Sayad[4], Tikva Dadon[4], Pooja Chauhan[4], Carol Poortman[4], Aifen Wang[4], Jacques Plummer[4], Woo Joo[4], Christian Zinser[4], Bernward Klocke[5], Rutul Shah[4], Helen Sabzevari[4], Douglas Brough[4]
[1]Precigen, Inc., Germantown, Maryland, [2]Precigen, Germantown, MD, [3]Precigen Inc, Germantown, MD, [4]Precigen, Inc., Germantown, MD, [5]Precigen, Inc., Markt Schwaben, Bayern, Germany

Despite advances in CAR-T therapy for B-cell malignancies, challenges of durability, manufacturing complexity, high treatment cost, and treatment-related toxicities remain. Recent in-depth analyses across clinical studies agree that CAR-T with a Naïve or Stem-Cell Memory phenotype (Tscm) are the most likely to engraft, expand, and provide persistent anti-tumor activity, thus spurring the development of several approaches to address these challenges. A best-in-class therapy will need to provide several modifications to the therapeutic cell in order to maintain stemness and ensure product safety, all while keeping manufacturing time and cost as low as possible to ensure accessibility of CAR-T therapy to patients who need it.

Here, we describe preclinical development of PRGN-3008, a CD19-targeted cell therapy built on the NextGen UltraCAR-T platform. PRGN-3008 is manufactured by engineering of autologous T cells to express CD19 CAR, membrane-bound IL-15 (mbIL15) for enhanced persistence and maintenance of Tscm phenotype, a miRNA-based PD-1 blockade to avoid exhaustion, and a safety switch to allow cell depletion, all from a single non-viral transposon via an overnight, decentralized manufacturing process using the UltraPorator™ device.

In vitro analyses confirmed the co-expression of all transgenes and appropriate processing of the miRNA module for highly specific targeting of the PD1 transcript without significant impact on other genes or cellular miRNA processing machinery. In a repetitive antigen challenge assay designed to mimic the highly suppressive tumor microenvironment, PRGN-3008 demonstrated durable tumor killing in contrast to conventional CAR-T cells lacking mbIL15 and PD-1 blockade. Single-cell proteomics assay demonstrated up to 7-fold improvement in CAR-T polyfunctionality, a trait linked to improved clinical outcomes, with PRGN-3008 compared to conventional CAR-T cells. Transcriptome profiling demonstrated a robust impact of mbIL15 expression on genes linked to T cell functionality.

In *in vivo* tumor models, a single administration of PRGN-3008 manufactured overnight, without activation or *ex vivo* expansion, showed enhanced expansion and persistence, robust antitumor efficacy, and significantly longer survival compared to conventional CD19 CAR-T cells. Moreover, long-term antitumor immunity was observed when the resulting tumor-free mice were rechallenged 76 days later to simulate tumor relapse, which led to significant efficacy and overall survival without additional PRGN-3008 treatment. PRGN-3008 treatment resulted in a significant enrichment of Tscm/naïve cell population, associated with durable T cell memory and prevention of tumor relapse, compared to conventional CAR-T cells.

In summary, PRGN-3008 is engineered to address the limitations of conventional CAR-T, with the combination of intrinsic PD-1 blockade and mbIL15 potentiating CAR-T functions and providing a phenotype associated with clinical effectiveness. The decentralized overnight manufacturing process, where cells are delivered back to patients the day post-electroporation, is expected to contribute to the less-differentiated cell phenotype as well as reduce manufacturing costs and increase accessibility of the treatment. These results demonstrate that the PRGN-3008 has potential to be the best-in-class treatment.

59 Development of anti-CD21 Chimeric Antigen Receptor (CAR)-T Cells for T-Cell Acute Lymphoblastic Leukemia (T-ALL) - CAR engineering for a complex antigen.

Background:
Relapsed/refractory T-cell acute lymphoblastic leukemia (T-ALL) has a poor prognosis. While CD19-targeting CAR-T have revolutionized the treatment of B-ALL, progress in T-ALL has been slower. CD7-targeting CAR-T trials have shown promising results, proving the potential of CAR-T for T-ALL. However, targeting pan-T-cell antigens is limited by T cell aplasia and fratricide, requiring rescue stem cell transplantation. One alternative approach is to target T-lymphoblast restricted antigens. Here, we explore CD21, a pan-B-cell marker with a complex structure (Figure 1), as a novel CAR target in T-ALL.

Methods:
We validated CD21 expression in T-ALL and normal tissues using cell lines, patient samples, and healthy donors. We developed anti-CD21 CAR-T, optimized for potent activity against CD21-positive T-ALL cells. This involved testing various CAR architectures to address antigen-specific challenges.

Results:
CD21 RNA was expressed in 80% of T-ALL in a published dataset, in all molecular subtypes. Half (29/58) of newly diagnosed T-ALL samples expressed CD21, (mean ABC 1265). At relapse, 45% (5/11) of samples were positive for CD21, (mean ABC 820). CD21 in normal donors was restricted to B cells and ~10% T cells, with no expression on non-lymphoid tissues. Anti-CD21 single-chain variable fragments (scFvs) were derived via rat vaccination and immune phage library screening. Identified scFvs bound to CD21 membrane-distal epitopes. Initial 8-8-41BBz CAR-T cells did not show CD21-specific cytokine release or cytotoxicity in vitro. Further testing using an engineered cell line expressing only five distal CD21 epitopes, significantly improved cytotoxicity and cytokine release. A second binder campaign identified anti-CD21 scFvs that bound membrane-proximal epitopes. These CAR-T cells were active against CD21+ cells but exhibited high tonic signalling in CD21-KO Jurkat reporter cells. To address this, scFvs were reformatted into a 41BBz Fab CAR construct, which reduced tonic signalling significantly. Fab binders showed equivalent binding kinetics to scFvs but with increased thermal stability. One Fab binder, NM2, demonstrated particularly high thermal stability. NM2 Fab CAR additionally had lower surface expression. NM2 Fab CAR-T exhibited potent cytotoxicity against T-ALL cell lines and patient samples, even at low antigen density. In proliferation assays, NM2 Fab CAR-T expanded without fratricide. In a Jurkat Xenograft model, NM2 Fab CAR-T significantly improved tumor control and survival (median 41 vs 22 d). In two T-ALL patient-derived xenograft (PDX) models with low CD21 expression (<1000 ABC), NM2 Fab CAR-T prolonged survival and controlled tumor growth. To investigate enhancing efficacy in CD21 low density cases, we explored pharmacological upregulation of CD21. The dual αδ PI3K inhibitor copanlisib upregulated CD21 in T-ALL cell lines and PDX both in vitro and in vivo. In a T-ALL PDX with CD21 expression below a threshold anticipated to allow CAR-T activation, (ABC ~200), copanlisib pre-treatment before NM2 Fab CAR-T resulted in significant T-cell expansion and tumor control, which was not seen in the CAR alone group (Figure 2).

Conclusion:
Anti-CD21 Fab-CAR-T cells, targeting membrane-proximal epitopes, showed potent anti-CD21 activity. Pharmacological upregulation of CD21 can enhance efficacy in low antigen density. This novel approach avoids fratricide and T-cell aplasia, offering promise for treating T-ALL

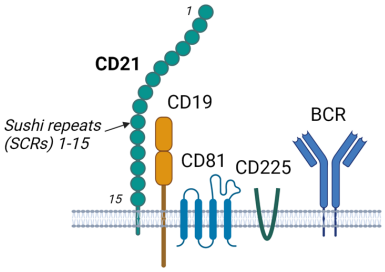

Figure 1: Structure of CD21. CD21 is a type 1 transmembrane glycoprotein found on the surface of B cells and follicular dendritic cells (FDCs) as part of the B cell co-receptor complex. CD21 has a large and heavily glycosylated extracellular domain consisting of 15/16 highly conserved short consensus repeats (SCRs).

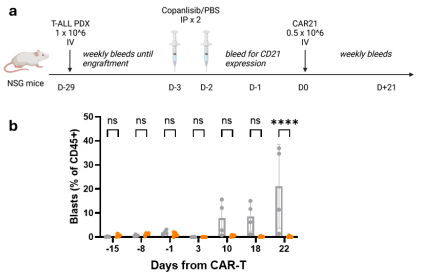

Figure 2: Pharmacological upregulation of CD21 enhances anti-CD21 CAR-T. (a) NSG mice were engrafted with very low CD21 expressing T-ALL PDX then treated with two doses of the Pi3K inhibitor copanlisib/control prior to anti-CD21 CAR-T. (b) % of T-lymphoblasts in peripheral blood at timepoints after CAR-T injection. Grey = CAR21 alone. Orange = copanlisib + CAR21.

474 CRG-023, A Tri-specific CAR T-cell Product Candidate, Demonstrates Strong and Durable Anti-Tumor Activity *In Vivo* Across Lymphoma Models

Introduction
CRG-023 is a novel tri-specific CAR T-cell product candidate that targets three B-cell surface proteins (CD19, CD20, and CD22). The construct design is intended to address factors that may limit CAR T-cell response against B-cell malignancies, such as tumor antigen escape and CAR T-cell exhaustion. Iterative engineering resulted in new scFv binders for CD19 and CD20 CARs that delivered optimized CAR performance, the selection of distinct costimulatory domains CD2, CD28, and 4-1BB for each of the three CARs, and the assemblage of the three CAR transgenes into a unique tri-cistronic vector format. Previous studies demonstrated that CRG-023 CAR T cells sustained durable anti-tumor activity despite repeated tumor challenge and had superior tumor control as compared to monospecific CAR T cells. Here we assessed the anti-tumor activity of CRG-023 CAR T against several disseminated and sub-cutaneous (s.c.) *in vivo* lymphoma models with varied antigen expression, different lymphoma histology, and in conditions that may require T-cell infiltration.

Results
A Burkitt lymphoma cell line (Raji) and two large B-cell lymphoma (LBCL) cell lines (SU-DHL-6 and SU-DHL-10), expressed all three target antigens at varying levels and were implanted into NCG mice. SU-DHL-10 and SU-DHL-6 cells expressed the highest and lowest levels of CD22 antigen respectively, and Raji cells expressed the lowest level of CD20 antigen, with the highest level of CD19 antigen. In a dose-response study, CRG-023 CAR T cells were able to clear Raji tumor cells in a dose-dependent manner and down to the lowest dose tested ($1x10^5$ tri-CAR^+ cells/mouse), despite an initial 100X increase in tumor burden at this lowest dose. The tri-specific CAR T cells also exhibited strong activity against both disseminated and s.c. models using SU-DHL-6 and SU-DHL-10 ($5x10^6$ tumor cells/mouse), demonstrating high levels of anti-tumor activity across histologies and capacity to traffic to the tumor site. CRG-023 CAR T cells exhibited superior anti-tumor activity as compared to single antigen (CD19, CD20 or CD22) targeting CAR T cells in a disseminated high tumor burden model (Raji 10^6 cells/mouse, day -4). Pharmacokinetic (PK) analysis of mouse blood in the dose-response disseminated Raji model and in both SU-DHL-6 and SU-DHL-10 s.c. models revealed measurable CAR T expansion at 2 weeks post-CAR T cell injection. CAR T cells were persistently detectable in spleen and bone marrow by the end of the study (Day 52).

Conclusion
I*n vivo* pharmacology studies reported here demonstrated effective and sustained anti-tumor activity for CRG-023 CAR T across several lymphoma models representing a variety of lymphoma histologies and expressing a variety of antigen levels. Additionally, CRG-023 CAR T cells were able to durably clear tumor burden in both disseminated and s.c. models, demonstrating CRG-023 CAR T cell ability to effectively traffic to tumor site in s.c. models. The significant, durable anti-tumor activity shown here suggests that CRG-023 offers a promising approach for the treatment of B-cell malignancies. The FDA recently cleared an Investigational New Drug (IND) application for this product candidate. A Phase 1 dose-finding study will enroll R/R LBCL patients who have received at least two prior lines of therapy, including both CAR T-naïve and CAR T-exposed patients.

Insights from AAV Engineering

60 Evolving Synthetic Membrane Associated Accessory Proteins (synMAAPs) for Enhanced AAV Vector Egress

Robert Fusco[1], Chenxuan Tong[1], Joshua Hull[1], Zachary Elmore[1], Sam Watts[2], Tobias Bonifert[3], Aravind Asokan[4]
[1]Duke University, Durham, NC, [2]Cytiva, Marlborough, MA, [3]Cytiva, Köln, Nordrhein-Westfalen, Germany, [4]Duke University, Durham, North Carolina

The infectious biology of Adeno-associated virus (AAV) has been widely studied with particular attention to receptors and intracellular trafficking, however unanswered questions surrounding capsid assembly, genome packaging, and viral egress remain. Our lab previously demonstrated that the membrane associated accessory protein (MAAP) functions as a viral egress factor. Structural analysis of different serotype-derived MAAPs revealed functional domains that are essential for protein expression, linker domains, membrane binding. Subsequent studies by other groups with natural and modified MAAP derived from AAV2 have indicated potential functional implications for vector genome packaging and yield. Despite these advances, one particularly striking aspect of MAAP / AAV biology are the structure-function correlates as evidenced by the serotype-specific sequence variability and distinct capsid secretion kinetics. This observation has remained unexplored to date.

Here, we employed a structure-guided library approach to evolve new and synthetic AAV egress factors through infectious cycling. We report newly engineered synthetic MAAPs (synMAAPs) with significantly improved secretion profiles, achieving up to an 8-fold increase in AAV secretion from HEK293 producer cells independent of serotype. SynMAAPs display remarkable structural convergence, as predicted by Alphafold3, showing improved amphipathic membrane binding domains. Compared to natural MAAPs, synMAAPs display strikingly distinct subcellular localization patterns characterized by nuclear exclusion and concentrated within the Golgi as evidenced by confocal microscopy. Proximity labeling experiments identified a cluster of membrane trafficking and fusion proteins mediated by SNAREs that are predicted to interact with MAAP, corroborating recent reports and providing new insights into how MAAP-host interactions facilitate AAV egress. Specific functional interactions of cellular host proteins hijacked preferentially by synMAAPs over natural MAAPs using a panel of knockout cell lines will be highlighted. In addition to dissecting the biology of AAV egress, we integrate these findings into engineered AAV vector production workflows, demonstrating the potential for improved secretion and streamlined manufacturing eliminating the need for cell lysis, reducing host cell contaminants and potentially enabling continuous perfusion systems.

61 CBN-1100: A Novel Recombinant Parvovirus Gene Delivery Platform with Enhanced Cargo Capacity, Immune Evasion, and Natural Liver Detargeting Properties

Samantha Smith[1], Michael Rak[1], Melvys Valledor[1], Yoshifumi Hashimoto[1], Carolyn Pelletier[1], Shu-hao Liou[1], Ryan Farrell[1], Po-Yi Ho[1], Brooke DeSimone[1], Derek Liberti[1], Alfred Tamayo[1], Brian Collins[1], Jeff Moffit[2], Joel Schneider[1], **Sebastian Aguirre Kozlouski[3]***
[1]Carbon Biosciences, Waltham, MA, [2]Carbon Biosciences, Hollis, NH, [3]Carbon Biosciences, Cambridge, MA
**Corresponding Author*

Gene delivery technology has advanced significantly over the past decade, with adeno-associated virus (AAV)-based vectors leading the field due to their favorable safety and durability profiles. However, traditional AAV vectors face substantial challenges, including significant off-target biodistribution and a high prevalence of anti-capsid antibodies in the human population, limiting their applicability in a large percentage of patients. To address these limitations, Carbon Biosciences has developed CBN-1100, a novel capsid derived from an autonomous parvovirus isolated from a non-primate mammal. CBN-1100 offers several key advantages over conventional AAV vectors, including an expanded cargo capacity of ~1kb greater than AAV), a pronounced lack of neutralizing antibodies in humans, and a unique biodistribution profile characterized by near-complete liver de-targeting. These attributes enable the efficient delivery of larger therapeutic transgenes and robust, specific promoters, surpassing the capacity and specificity limitations of existing AAV technologies. In this study, we show that CBN-1100 capsid supports encapsidation of AAV2 ITR-flanked cassettes of up to 5.9 kb while maintaining robust manufacturability. Vector production yields are consistent with industry standards across various scales, including up to a 40-liter bioreactor, achieving 85% filled capsid formation. Serological analyses showed significantly lower anti-drug antibody titers against CBN-1100 capsids compared to AAV9, consistent with the lack of exposure to the parental virus in humans. Systemic administration in mice and cynomolgus macaques revealed broad transduction efficiency and high transgene expression in therapeutically relevant tissues, including the heart, and the CNS, with over

10,000-fold lower liver biodistribution and gene expression compared to conventional AAV vectors. This liver de-targeting property substantially improved tolerability, as dose-escalation studies showed negligible elevations in liver transaminases, cytokines, and complement factors. Additionally, CBN-1100 was successfully enhanced through peptide insertions in two different variable regions (VRs) of its capsid, leading to a significant increase in potency in primary skeletal muscle cells and iPSC-derived cardiomyocytes. These modifications highlight its potential for improved tissue selectivity and potency. These unique pharmacological properties position CBN-1100 as a transformative platform for gene therapy, offering solutions for previously undruggable targets and indications. The combination of enhanced cargo capacity, immune evasion, and improved tissue specificity provide a new benchmark for next-generation gene therapy technologies.

62 Synthetic RNA Switches for Temporal and Dose Control of *In Vivo* Gene Therapies

Xiaojuan Tang[1], Chengzhi Du[1], MENGJIA LU[1], Haimin Wang[1], Jun Xie[1], Guangping Gao[1], Hong Moulton[2], **Guocai Zhong[1]***

In vivo gene therapy technologies, based on adeno-associated viral (AAV) vector delivery of genes encoding therapeutic proteins, noncoding RNAs, or genome/epigenome editors, could provide long-lasting (years of or even lifelong) treatments for various human diseases. Genetic switches that enable precise temporal and dose control of transgene expression may improve safety and efficacy, and broaden the use of these therapies, particularly for payloads with narrow therapeutic windows and/or major contraindications. However, to date, only a few genetic switches developed for this purpose function in animals, yet they exhibit significant leakiness and are typically controlled by switch regulators that have undesirable side effects and require frequent dosing (e.g., QD or BID).

Here, we describe a class of ultra-efficient RNA ON-switch systems (Z^{on}) that can be built in an AAV vector and allow for switch-regulator-dependent precise control of transgene expression. Z^{on} exhibits negligible to zero leakiness and regulatory ranges spanning five logs or more in cultured mammalian cells as well as in mice. The switch regulator is part of a class of oligonucleotide drugs safe for chronic use in humans; it can be administered once every four weeks (Q4W) or even less frequently in mice to maintain Z^{on}-controlled transgene expression. In a long-term repeated dosing study in mice, monthly administration of the regulator has consistently induced Z^{on}-controlled AAV transgene expression with near-flat expression kinetics for more than a year.

Z^{on} has broad potential applications. We have utilized Z^{on} in multiple POC studies in mice to develop temporal and dose-controllable biofactory gene therapies. These therapies leverage AAV-transduced skeletal muscle cells as biofactories to produce and secrete protein therapeutics into the bloodstream, targeting autoimmune diseases and metabolic disorders, respectively. Furthermore, since Z^{on} exhibits negligible to zero leakiness, it offers a unique opportunity to develop a 'suicide switch'-controlled, terminable AAV vector platform, as well as a leak-free, inducible AAV-genome-editor platform. This ultra-efficient, broadly applicable RNA switch technology has the potential to enable safer and broader use of AAV gene therapy in a variety of human diseases, including some common chronic disorders.

63 *In Vivo* High-Throughput Screening of Regulatory Elements to Distinguish AAV Transgene Expression Between Cardiac and Skeletal Muscle

Carson Key Taylor[1], Shanté Berry[2], Elizabeth Guilfoyle[1], Haasini Nandyala[1], Irene Kaplow[3], Garth Devlin[4], Caroline Yoon[1], Joel Bohning[1], Douglas Rouse[1], Aravind Asokan[4], Charles Gersbach[1]*

Engineering robust and safe gene delivery vehicles is critical to clinical translation of gene therapies. Adeno-associated virus (AAV) is well-established for *in vivo* delivery of gene therapies due to its widespread biodistribution and natural tissue tropism. However, transgene expression in unwanted tissues can result in toxicities

that can lead to adverse consequences in many studies. Tropism conferred by natural or engineered viral capsids provides some control over tissue expression, but greater specificity is needed for many applications. Regulatory elements within AAV vectors can be engineered to increase specificity of expression downstream of cell entry. Massively parallel reporter assays (MPRAs) have been used to screen for tissue-specific candidate regulatory elements (cREs). AAV vectors containing a library of cREs can be screened via MPRAs to identify elements that drive tissue-specific expression. In this study, we develop an *in vivo* AAV-MPRA to identify muscle-type-specific cREs that distinguish between striated muscle types and have low hepatic expression.

We designed a library of 1031 cardiac muscle-specific cREs, 668 skeletal muscle-specific cREs, 200 dinucleotide shuffled negative controls, and 30 fragments of muscle-specific gene promoters. Each 250 bp cRE was designed using human ENCODE data with the following criteria: 1) DNase-seq signal enriched in the target tissue, 2) presence of H3K27ac, H3K4me3, or H3K4me1 signal enrichment in the target tissue, and 3) proximity to a gene preferentially expressed in the target tissue. We then applied a binary classification CNN model to select cREs with the highest probability of tissue specificity. The AAV9-cRE library was delivered systemically into adult C57Bl6 mice. The hamstring, heart, and liver tissues were harvested for DNA and RNA isolation, followed by next-generation sequencing to determine relative transcription rates of each cRE.

In the hamstring, we identified 185 sequences with significant differential expression over both non-target tissues. Of these, 138 were designed to be skeletal muscle-specific, 37 were designed to cardiac muscle-specific, and 8 were shuffled controls. Additionally, 90 of those cREs had significant activity over shuffled controls. In the heart, 294 sequences had significant differential activity over both non-target tissues. Of these, 240 were designed to be heart muscle-specific, 39 were designed to be skeletal muscle-specific, and 8 were shuffled controls. 117 of those sequences had significant activity over shuffled controls. Significantly active cREs generally showed higher sequence conservation compared to the non-significant cREs. Motif analysis revealed enrichment for GATA motifs in heart-specific cREs and FOS/JUN and SIX motifs in hamstring-specific cREs.

In summary, we performed an *in vivo* AAV-MPRA that identified cREs driving muscle-type-specific transgene expression. Many identified cREs exhibited tissue-specific and high expression compared to shuffled controls, both of which are desirable qualities for use in a gene therapy vector and highlight their potential for therapeutic use in treating diseases that require distinction between muscle types, including certain muscular dystrophies. While our study focused on muscle tissues, this approach can be adapted for other tissues to advance gene therapy applications.

64 Understanding subcellular trafficking of natural and engineered AAV capsids by novel imaging techniques in skeletal muscle cells

Jeanette Zanker[1], Ai Vu Hong[2], Isabelle Richard[3]
[1]GENETHON, EVRY-COURCOURONNES, Essonne, France, [2]GENETHON, EVRY, France, France, [3]GENETHON, EVRY, Essonne, France

Adeno-Associated Viral (AAV) vector mediated gene therapies are at the forefront of novel treatments for muscular dystrophies. In recent years, the number of clinical trials and approved AAV-based treatments have increased. Nonetheless, certain roadblocks still arise during clinical trials, such as immune responses due to the high doses administered. While efforts to reduce the dose by capsid engineering are being made, investigating subcellular AAV trafficking would enable us to better understand the differences in transduction efficiency between natural and novel capsids to further develop efficient AAV capsids. Using 2D and 3D confocal imaging on either fixed sample or live-cell fluorescent microscopy, we aimed to investigate subcellular trafficking of a natural AAV9 and an engineered LICA1 capsid in immortalized human myotubes. The objective was to identify key difference between these two capsid variants. In fixed immortalized human myotubes, we saw that AAVs followed a time-dependent kinetic in known subcellular compartments and host factors such as early endosomes, AAVR, the Golgi, and the nucleolus. Surprisingly, despite the cellular monolayer, we observed significant differences in capsid accumulation between neighboring fibers, as well as myonuclei from the same fibers though no differences were observed in receptor presence. These findings were used to develop live-imaging techniques where AAVs were fluorescently labelled using covalently bound dyes. Differences in entry and movement between the two capsid variants were observed, and in combination with endo-lysosomal tracking, we were able to follow the cellular trafficking along the

myotubes. The development of novel methods to study subcellular trafficking paves the way to better characterize and understand the transduction efficiency of novel capsids without the need for specific antibodies. These techniques can be used to study AAV movement not only in immortalized cells lines, but also in isolated muscle fibers, which represent the targeted cell type in muscular dystrophies gene therapy much closer. This will allow us to have a better understanding of possible bottlenecks within a muscle fibers for efficient gene transfer, and could be further optimized for other applications.

65 Development of a Platform for Vectorized Expression of Secretory IgA

Arielle Gillies[1], Elena Campbell[1], Yanlong Pei[2], Jake Yates[3], Brenna Stevens[1], Madison Hughes[1], Jibraan Kadri[4], Cezar Khursigara[1], Matthew Miller[5], Sarah Wootton[1]
[1]University of Guelph, Guelph, ON, [2]University of Guelph, [3]Guelph, ON, [4]University of Guelph, Guelph, [5]McMaster University, Hamilton, ON

Most infections initiate at mucosal surfaces including the respiratory, gastrointestinal, and genitourinary tracts, where secretory IgA (sIgA) serves as a critical component of immune defense. Comprised of J-chain-containing IgA dimers plus the secretory component (SC) of the polymeric Ig receptor (pIgR), sIgA effectively neutralizes pathogens at mucosal surfaces through high-avidity antigen binding and agglutination. Despite its well-documented role in preventing and clearing infections, recombinant sIgA has yet to be translated to the clinic due to the complexity of its production, requiring plasma cells to synthesize IgA subunits and epithelial cells to add SC during transcytosis. One way to overcome these manufacturing hurdles is to use a gene therapy vector to deliver antibody genes to the host - an approach termed vectored immunoprophylaxis (VIP).

Adeno-associated virus (AAV) vectors represent a leading platform for safe and efficient in vivo gene transfer. AAV-mediated expression of pathogen-specific monoclonal IgG antibodies has provided durable protection against infectious diseases like Marburg, RSV, Ebola, and influenza in various animal models. The objective of this research is to develop a novel AAV platform that will promote prolonged in vivo expression of mAbs of the sIgA isotype at therapeutic levels within mucosal surfaces of the upper and lower respiratory tract and to validate the efficacy of vectorized sIgA expression using an influenza virus challenge model.

We have constructed five AAV genomes: two that express IgA with or without the J chain, one that expresses full-length pIgR and two that express different versions of the SC. Due to our use of influenza as a model pathogen for these studies, the IgA antibody was designed using the heavy and light chain variable domain sequences from FluA-20, a pan-influenza mAb that protects against all major influenza A subtypes that infect humans, and synthesized as a human IgA2 as it is more resistant to proteolysis than IgA1. The AAV6.2FF capsid, a triple mutant with enhanced tropism for lung and muscle tissues, enabling rapid and robust monoclonal antibody expression, was utilized as the AAV vector. In vitro expression of IgA, J chain, SC, and pIgR has been confirmed by western blot and antibodies secreted into the supernatant were confirmed to bind to the hemagglutinin (HA) target antigen by indirect ELISA. Human IgA was detected in the serum of Balb/c mice administered with different AAV vector combinations via either intranasal or intramuscular routes and the concentration of sIgA in lavage fluid will be quantified by ELISA. Next steps are to assess the therapeutic efficacy of vectorized sIgA in a PR8 influenza challenge model.

This study aims to establish a novel gene therapy platform for in vivo production of sIgA in the respiratory mucosa, offering protection against respiratory infections, reduced transmission, and the potential for sterilizing immunity- an achievement elusive with conventional vaccines for respiratory viruses.

66 Novel adeno-associated virus (AAV) vector production system is useful for gene therapy and analyzing the molecular mechanism of viral replication

Adeno-associated virus (AAV) vector is a promising tool for gene therapy, and various clinical trials are ongoing in the world. However, there are many issues which should be improved for further development. Among various issues, a number of empty capsids during AAV vector production are one of the big problems, meaning that costly multistep purification is required to remove empty capsids. It leads to increased price for AAV vector-based drugs.

To improve the efficiency of vector production, we have established new AAV vector production system controlling capsid (Cap) expression timing after separating replicase (Rep)/ Cap genes in conventional AAV vector production system. Our new AAV vector production system controlling Cap expression timing by the tetracycline(Tet)-dependent promoter significantly increased the yield of AAV2 vector and improved the empty/full capsid ratio. It is also applicable for various serotypes to improve the quantity and quality of viral vectors. Additionally, our system can show the same improvement of vector productivity even in scaled up culture sizes such as T225 and Cell Factory multi-layer flasks. Moreover, no difference in infectivity was observed between AAV vectors produced by conventional and new system in various serotypes, and there was no difference of tissue tropism in mice using AAV9 vectors. These indicate that new AAV vector production system can generally improve AAV vector productivity in various serotypes without changing the nature of AAV vectors. Further analyses showed that the improvement of AAV vector productivity was due to additive effect of the change of Rep expression pattern by individual expression of Rep and the Cap expression timing control.

As the other aspect, Rep and Cap expression is individually regulated by CMV or Tet promoters in our AAV vector system, so that Adeno helper genes are no longer required for these proteins expression. This suggests a possibility that our AAV production system can be used for screening of new essential host factors regulated by helper genes, which may be mainly involved in the late steps of viral production. We have identified about 60 genes from over 100 RNAs upregulated by helper genes. The expression of some genes, instead of helper genes, can increase vector yield in our AAV production system.

Our newly developed AAV vector production system has the potential to shed light on the reduction of cost for gene therapy and to identify essential host factors for AAV vector productions. Further analyses based on these findings would help not only elucidating the molecular biology of AAV but also solving various existing issues of gene therapy using AAV vector.

Cell Therapy Product Engineering I

67 Comparative Analysis of Lentiviral and CRISPR-Cas12i-Generated CAR T Cells: In Vitro and In Vivo Functional Outcomes

Felix Heider[1], Andreas Bosio[2], Stefan Wild[3], Sarah Kribben[4], Daniel Geray[4], Daniel Schäfer[4], Katrin Krischer[4], Ilia Kelmanson[4], Janina Brauner[4]
[1]Miltenyi Biotec B.V. & Co. KG, Bergisch Gladbach, Nordrhein-Westfalen, Germany, [2]Miltenyi Biotec B.V. & Co. KG, Bergisch Gladbach, (None), Germany, [3]Miltenyi Biotec, Bergisch Gladbach, Germany, [4]Miltenyi Biotec B.V. & Co. KG, Bergisch Gladbach, Germany

Chimeric antigen receptor (CAR) T-cell therapies have demonstrated remarkable clinical success, but the impact of the engineering method used for CAR integration has not been thoroughly investigated across different CAR receptors.

In this study, we compared CD318-CAR T cells generated via lentiviral transduction (random integration) with those generated using CRISPR-Cas12i-mediated targeted integration into the constant chain of the TCR beta receptor (*TRBC*). For both gene integration methods, an identical CD318 (CDCP1)-targeting CAR receptor was

used, and CAR T-cell functionality was validated using CD318-expressing AsPC-1 cells. Lentiviral- and Cas12i-generated CAR T cells were evaluated both *in vitro* and *in vivo* to assess efficacy, exhaustion, and persistence.

In vitro, CRISPR-generated CAR T cells exhibited reduced killing at lower effector-to-target (E:T) ratios, higher expression of exhaustion markers (e.g., PD-1, LAG-3), and reduced expansion following a tumor-killing assay compared to lentiviral-generated CAR T cells. *In vivo*, CRISPR-generated CAR T cells demonstrated slower tumor clearance and a 50-fold reduction in total CAR T-cell numbers in the blood two weeks after injection. The total CAR T-cell count in the blood of CRISPR-generated CAR T cells remained low for the entire duration of the study. Interestingly, CRISPR-generated CAR T cells isolated from the bone marrow and spleen exhibited reduced exhaustion markers, suggesting a potential reservoir of less-differentiated cells. Graft-versus-host disease (GVHD) was detected in NSG mice receiving lentivirus-generated CAR T cells. However, CRISPR-generated CAR T cells, which lack a functional *TRBC* gene, did not induce measurable GVHD until the study endpoint.

These findings highlight critical differences in CAR T-cell behavior based on the integration method, as well as the additional knockout of the T-cell receptor. While CRISPR-targeted integration provides precise genomic editing, it leads to functional differences in tumor clearance and persistence. Further research is needed to determine whether these differences present limitations or advantages for clinical translation. Collectively, this study provides insights into the trade-offs between lentiviral and CRISPR-based CAR T-cell generation, indicating that TCR gene disruption may affect the kinetics and potency of CAR T cells.

68 Development of a 1XX-Enhanced and Fully Non-Viral, CRISPR-edited BCMA CAR T Cell Therapy for Relapsed and Refractory Multiple Myeloma (UCCT-BCMA-1)

Jae Hyun Jenny Lee[1], Ke Li[1], Shanshan Lang[2], Alexis Talbot[3], Yasaman Mortazavi[4], Niran Almudhfar[5], Joseph Muldoon[1], Nechama Kalter[6], Michael Rosenberg[7], Krishnappa Netravathi[8], Shivangi Sachdeva[9], Shreya Shukla[9], Mindy Sadik[10], Dehui Kong[1], Derrick Houser[11], sreenivasan Paruthiyil[11], Mina Ahmadi[12], Yongchang Ji[13], Luis Acevedo[11], Brianna Liang[1], Emmanuel De Leon[1], Joshika Dantuluri[11], Petros Giannikopoulos[14], Ayal Hendel[15], David Oh[11], Tom Martin[11], Alexander Marson[16], Justin Eyquem[1]*, Brian Shy[17]*

B-cell maturation antigen (BCMA) targeting chimeric antigen receptor (CAR) T cell therapies have shown promising treatment outcomes for relapsed or refractory multiple myeloma (RRMM) patients with two approved therapies now commercially available. Currently, all of the approved CAR T cell therapies, as well as most others in clinical trials, utilize viral vectors to semi-randomly insert effector genes during the manufacturing process, leading to heterogeneous genomic composition and potential efficacy and safety variability. Lastly, shortages in lentiviral supply and high treatment costs have led to challenges with patient access, with only a fraction of eligible RRMM patients ultimately receiving commercial BCMA CAR products.

To address these issues at UCSF, we have internally developed a fully non-viral CRISPR/Cas9 engineering platform, enabling precise and efficient CAR integration at the T Cell Receptor Alpha Chain (TRAC) locus through hybrid ssDNA-mediated homology-directed-repair (HDR). The BCMA CAR construct includes the CD28 costimulatory domain and the modified 1XX CD3z intracellular signaling domain, which significantly enhances the product's potency and durability. Our Process Development team has developed a robust manufacturing process and demonstrated GMP compatibility across multiple engineering runs with a shortened manufacturing time, while maintaining consistently high CAR integration rates and yield, exceeding all proposed release criteria for purity, safety, potency, and quality (Figure 1).

Knock-in efficiencies from 7 full scale process development and engineering runs ranged from 38.2 to 72.7%, generating yields of 2.4e8 to 1.9e9 CAR+ cells, which is well above the maximum dose for the proposed clinical trial. Off-target analysis by GUIDE-seq and *in silico* nomination, followed by targeted amplicon sequencing identified two non-pathogenic off-target sites with low editing frequency (<0.2%). Residual Cas9 levels were monitored throughout the manufacturing process, which showed a rapid decay with minimal to absent levels in the final drug substance. Cryopreservation was optimized to improve post-thaw recovery and potency of the final drug products, demonstrating robust and durable tumor clearance *in vitro* and *in vivo*, with particular improvement for a subset of donors whose cells are more sensitive to cryopreservation.

Altogether, these results demonstrate a fully non-viral manufacturing process for generation of advanced 1XX BCMA CAR T cell therapies. We plan to make the manufacturing SOPs and critical study reports publicly available to enable widespread use of this platform and improve access to cutting edge therapies in the academic setting.

69 Establishing Microporous Particle Scaffolds as a Scalable, 3D Platform for Continuous Production of Immunomodulatory Mesenchymal Stromal Cell Extracellular Vesicles

Thomas Spoerer[1], Andrew Larey[1], Kanupriya Daga[1], Ross Marklein[1]
[1]*University of Georgia, Athens, GA*

Introduction:
Due to their immunomodulatory function, mesenchymal stromal cell-derived extracellular vesicles (MSC-EVs) are a promising therapeutic with the potential to treat neuroinflammation associated with neurodegenerative diseases. However, clinical translation has yet to be achieved due in part to the critical need for developing scalable manufacturing systems capable of producing consistent EV products. Existing large-scale systems provide limited control over key aspects of the cellular microenvironment, such as hydrodynamic forces, cell-cell communication, and substrate stiffness, that impact MSC growth and secretory function leading to poor reproducibility[1]. Three-dimensional (3D) hydrogel-based microporous particle (MP) scaffolds, in contrast, provide precise control over microenvironmental parameters, which has been shown to influence MSC growth and function[2,3]. Therefore, we aimed to investigate the ability of MP scaffolds to serve as a scalable, tunable platform for large-scale MSC-EV manufacturing.

Methods:
Scaffold void fraction was assessed by quantifying fluorescent dextran (2000kDa) using confocal microscopy (Zeiss LSM900). For expansion, cryopreserved adipose-derived MSCs (AD98, RoosterBio) were thawed and cultured in chemically defined media (CDM)[4] for 72 hours. For growth studies, MSCs were seeded in triplicate 25µL scaffolds

at three seeding densities (63, 125, and 250 cells/µL), and DNA content was assessed using PicoGreen assay. For EV manufacturing, MSCs were seeded into triplicate 75µL MP scaffolds (125 cells/µL), primed with pro-inflammatory cytokines (50ng/mL IFNϒ+TNFα) under hypoxia (2% O2) for 48 hours, and conditioned media was harvested for EV isolation at 72-hour intervals. EVs were isolated via ultracentrifugation and stored at -80°C, while particle count, CD63 expression, and lipid bilayer confirmation (MemGlow) were conducted using NanoFCM. Finally, EV bioactivity was assessed using our microglia morphology assay, as described previously[5]. *Results*: We observed consistent void fraction (33%) and cell seeding across replicate MP scaffolds (Figure 1A & 1B). MP scaffolds supported MSC expansion over a 15-day period, with a seeding density of 125 cells/µL exhibiting the greatest overall fold change (Figure 1C). Variability in MSC growth across scaffold replicates at each timepoint was minimal (CV < 20%), indicating that consistent scaffold preparation and the controlled 3D microenvironment provided by MP hydrogels support reliable MSC expansion (Figure 1D). MPs also supported production of MSC-EVs at each of the four cycles with positive tetraspanin CD63 expression and the presence of a lipid bilayer. MSC-EV yield increased over time and plateaued after the third EV harvest cycle (Figure 2A), agreeing with the trend of increased cell growth over time in Figure 1. Furthermore, EV preparations from each cycle differentially modulated microglia morphology, with preparations from later cycles showing higher bioactivity as evidenced by a significant shift in microglia morphology away from the stimulated positive control (Figure 2B).

Conclusions:
These findings establish MP scaffolds as a promising manufacturing platform for MSC expansion and production of bioactive MSC-EVs for treatment of neuroinflammation. *References*: [1] Thompson, W., Biotechnol. Adv., (2023). [2] Pfaff, B. N. Adv. Biol. (2023). [3] Caldwell, A. S., Biomaterials, (2020). [4] Spoerer, T.M., bioRxiv. (2024). [5] Daga K., J. Biol. Eng. (2024)

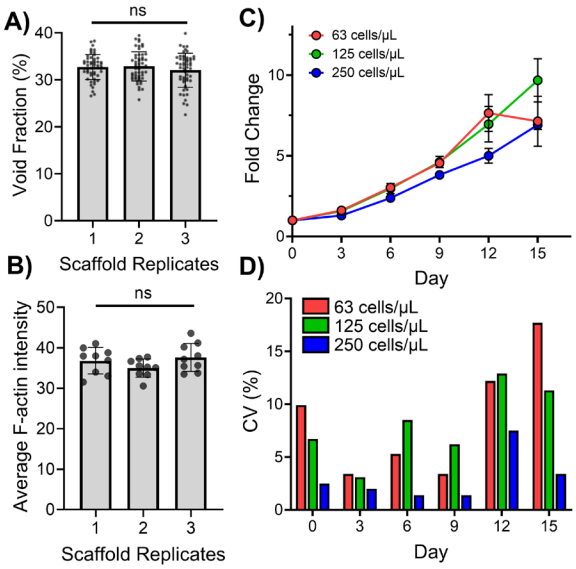

Figure 1: Consistent MP scaffold preparation allows for reliable MSC growth overtime. A) Mean VF across replicate MP scaffolds. n=54 images from z-stacks (18 slices, 13.5µm intervals) collected from three ROIs per replicate. B) Mean F-actin intensity across replicate MP scaffolds. n=9 ROI z-stack averages (20 slices, 40µm intervals) per replicate. C) Fold change in cell count over 15-day period for MSCs cultured at three different seeding densities in MP scaffolds. (n=3 scaffolds per seeding density group at each timepoint) D) CV (%) of fold change per group at each timepoint. ns = p>0.05, via one-way ANOVA with Tukey's multiple comparison test.

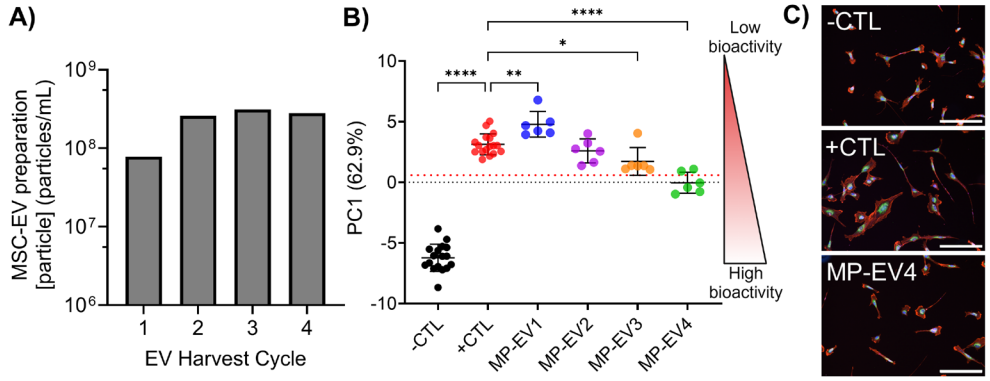

Figure 2: MP scaffolds support production of bioactive MSC-EVs across multiple harvest cycles. A) MSC-EV preparation concentration at each harvest cycle. B) Principal component 1 (PC1, 62.9% of variance) calculated using 21 morphological features of microglia treated with inflammatory signals and/or MSC-EVs *in vitro*. Each point represents a median of ~700-1000 cells/well with mean and standard deviation plotted for n=6 wells/group. Red line = historical data of microglia morphological response to treatment with EVs from 2D flask cultures. C) Representative images of microglia morphology (red=actin and Golgi apparatus, blue=nucleus, green=endoplasmic reticulum, magenta=mitochondria). Scale bar = 200µm. One-way ANOVA calculated using Dunnett's method where ****=p<0.0001, **=p<0.01, *=p<0.05.

70 Transcriptomic and Epigenomic Analysis of CAR Treg Stability

Treg (regulatory T cell) cell therapy shows promise for treating autoimmune diseases, but these might acquire effector T (Teff) phenotype upon destabilization by improper signaling. Here, we investigated this phenomenon using a tonic chimeric antigen receptor (CAR) Treg ex vivo model, subjecting cells from Treg production (D14) to a destabilizing protocol that included repetitive stimulation to induce destabilization defined by FOXP3^{lo}Helios^{-} expression with flow cytometry.

Flow cytometry analysis revealed an increased fraction of destabilized Tregs (FOXP3^{lo}Helios^{-}) after repetitive stimulation. In vitro suppression assay showed a decreased capability to suppress CD4+ and CD8+ Teff cell proliferation compared to D14 control samples, though the suppressive function remained distinct from that of Teff cells.

To assess the molecular changes beyond FOXP3 and HELIOS, underpinning the phenotypic alterations due to destabilizing conditions, we performed NGS molecular profiling using both bulk RNA sequencing (RNA-seq) and Enzymatic Methyl-seq (EM-seq). Key Treg genes (FOXP3, IKZF2 and IL2RA) showed consistently reduced levels of expression accompanied by increased DNA methylation at their respective promoter regions in destabilized cells. While D14 Tregs exhibited significant differences in gene expression, their methylome showed minimal changes as compared to D0 Tregs, indicating that the Treg product is epigenetic stable. However, under destabilization conditions, the molecular profiles of Treg and Teff became more similar, with reduced differences observed in both transcription and methylation. Scoring samples based on pre-defined Treg/Teff identity gene panels reflect the stability of the product. Additionally, we identified specific CpG regions that could serve as markers for tracking the stability of the Treg products after exposure to CAR target.

Together, our results demonstrate that Treg stability can be efficiently monitored through molecular profiling using expression or methylation panels, providing valuable insights for optimizing Treg-based cell therapies.

71 HDR gene correction of CD4$^+$ T cells approaching the clinic for the treatment of Hyper IgM1

Gene editing for Hyper IgM1
Mutations in the *CD40LG* gene impair the crosstalk between activated CD4+ T cells and effector immune cells, preventing the development of a robust immune response against pathogens. This defect underlies Hyper IgM 1 (HIGM1), an X-linked combined immunodeficiency with a median survival of 25 years. Furthermore, constitutive *CD40LG* expression leads to lymphoproliferation, emphasizing the need for a gene-correction strategy. We designed a knock-in gene editing (GE) strategy based on Cas9 and integrase-defective lentiviral vector (IDLV) template delivery, and developed a scalable good manufacturing practice (GMP)-compliant process for correction, selection, and expansion of CD4$^+$ T cells.

Tech transfer to academic GMP facility and biodistribution
The manufacturing process was transferred to the academic GMP facility of IRCCS San Gerardo. Three independent full-scale runs with healthy donors' cells were performed during the tech transfer, with a selection yield of 85% and a CD4+ purity >93%. *CD40LG* correction in the final product was around 90%, and dose requirements were met. Expecting graft-versus-host disease upon xenotransplantation of the drug product, in accordance with local regulatory authorities, a GLP biodistribution (but not toxicology) study was performed. The cell product engrafted similarly across groups, with preserved human CD4+ purity. Progressive maturation towards an effector phenotype was observed, in both treated and untreated groups, and editing efficiency remained stable.

Methods validation
We developed a panel of assays addressing identity, purity, potency and safety (cytokine-independent growth, genome integrity, RCL and process related impurities), and validated them according to EMA/CHMP/ICH/172948/2019 ICH guideline M10 and to FDA Bioanalytical Method Validation Guidance for Industry. We did not observe signs of exhaustion, cytokine-independent growth, or concerning genotoxic events. Edited patient cells restored regulated *CD40LG* expression, binding to CD40, and downstream signal transduction. No process related impurities were present.

Process performance with patient cells
Given differences in white blood cell counts and immunophenotype of HIGM1 patients as compared to the general population, we addressed potential concerns of reproducibility of our process with patient-derived cells from a cohort of 7 patients aged from 7 months to 54 years. Informed consent was provided to the attending physician by

patients or legal guardians and samples were pseudoanonymized. Patient cells were edited with high efficiency; purity and clonal diversity were maintained until the end of the process. Interestingly, the proportion of T stem cell memory cells was higher upon GE of patient cells as compared to the healthy donor counterpart. Moreover, patient cells displayed a slightly different proliferation kinetic, respectively faster in the early phases of culture and slower in the latter ones as compared to healthy donor cells. For this reason, a concomitant verification strategy for the clinical trial was agreed upon with Italian regulatory authorities (AIFA/ISS).

Outlook
We report on scientific, manufacturing, and regulatory challenges and success of academic development of an innovative drug product for the treatment of HIGM1, a rare pediatric disease with limited life expectancy and treatment options. Clinical trial enrollment is expected to start in the near future.

72 Comparative Analysis of Motixafortide versus Plerixafor for Autologous Stem Cell Mobilization and Collection in Multiple Myeloma: A Single Center Real-World Experience

**Corresponding Author*

Background:
Stem cell collection after 4-8 cycles of induction therapy remains standard for multiple myeloma (MM). These cells are used after high-dose melphalan as autologous stem cell rescue/transplant (ASCT). Growing demand for apheresis services upstream of chimeric antigen receptor and other cell therapies emphasizes a need for efficiency. FDA approval of Motixafortide (Aphexda®) and a phase III publication (Crees, Nature Med 2023) suggest this newer CXCR4 antagonist with longer-acting kinetics may be superior to plerixafor in MM stem cell collection.

Methods:
In this quality initiative, we compared a prospective cohort of 30 consecutive MM patients mobilized with motixafortide+G-CSF to 30 contemporary MM patients receiving plerixafor+G-CSF. Cohorts were matched for age, gender, race, and exposure to daratumumab and lenalidomide/pomalidomide (IMiDs). Primary outcome analyses included # of apheresis/collection days (enable more/other collections), shortening of apheresis sessions (allow same-day apheresis catheter removal), and adverse events requiring intervention. Local practice patterns included plerixafor (0.16- 0.24 mg/kg sc per renal function) for pCD34 <30 cells/mL at 6pm on day prior to collection (Day +4 of 5 G-CSF) or administration of motixafortide (1.25 mg/kg sc) regardless of pCD34 around 4-5pm, based on clinical logistics. Premeds for motixafortide were cetirizine, famotidine, montelukast, acetaminophen, prednisone 20mg, and lidocaine cream, with ice during a 1-hour monitoring period. Target is 4.0x10^6 CD34 cells/kg with minimum 12L collection for peripheral CD34 count (pCD34) $\geq$ 50 cells/mL and min 4 blood volumes for pCD34 <50 cells/mL. Historically, over 80% of MM patients target in one day with plerixafor+G-CSF.

Results: 29 of 30 patients were able to receive motixafortide. Fold-increase in pCD34 was not different after receiving either agent, though 3 super responders to motixafortide were noted. (Figure 1). We found a trend to superior increase in pCD34 after motixafortide in patients with Day 4 pCD34 $\leq$ 5, but sample size was limiting. Product CD34 yield did not differ. 27 motixafortide and 27 plerixafor patients completed collection in 1 day/procedure. Only 1 of 22 patients receiving motixafortide had his catheter removed the same day. Volume of blood processed and CD34 % product collection efficiencies were the same.

48% of motixafortide recipients required intervention (additional acetaminophen or famotidine or new administration of methylprednisolone IV, diphenhydramine or ketorolac) for pruritis (45%), tingling/burning or pain (34 and 31%), and erythema/rash or facial flushing (24% each). (Figure 2) No nursing or pharmacologic interventions were required after plerixafor. One motixafortide patient experienced painful nodules at injection sites for up to 3 months.

Conclusions: This initial real-world evaluation of motixafortide administration on feasibility, safety, and stem cell mobilization in MM patients at a single center (without changes in practice patterns) did not show superiority over plerixafor in pCD34, stem cells collected, or time/days required to target 4x10^6 CD34/kg. Our institution continues using plerixafor in initial ASCT mobilization procedures for MM. Ongoing investigations include cumulative daratumumab and IMiD exposure, financial and resource analyses, further observation of poor mobilizers with pCD34 of 1-2 cells/mL, and evaluation of post-transplant engraftment.

73 Use of IL-12, IL-15, and IL-18 Prior To Cryopreservation Confers a CIML Phenotype To CAR-NK Cells That Maintains Post Thaw Viability and CAR Functionality After Infusion

Leander Timothy[1], Ishwar Navin[2], Matthew Dysthe[2], Robin Parihar[2]*
[1]Starship Blood and Cancer Centre, Auckland, New Zealand, [2]Baylor College of Medicine, Houston, TX
**Corresponding Author*

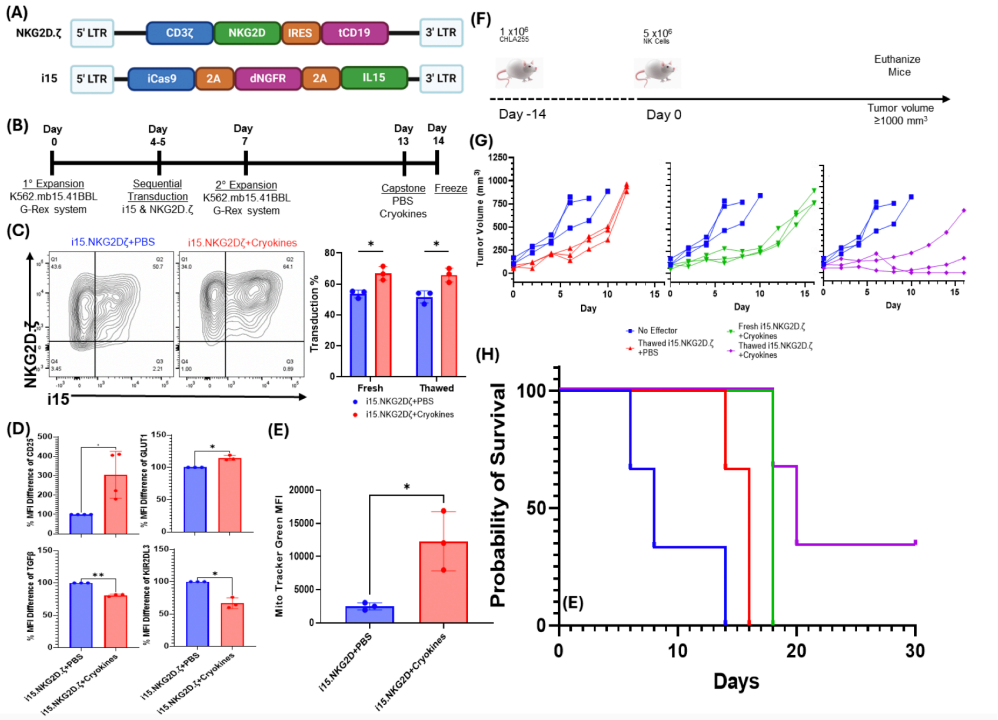
BACKGROUND AND AIM:
Cryopreservation of primary human NK cells modified with chimeric antigen receptors (CARs) has been problematic due to poor long-term viability and function post thaw. Recent methods to preserve activity of non-modified NK cells post thaw do not adequately apply to the unique features of peripheral blood-derived CAR-NK

cells. This barrier hinders use of CAR-NK cell products as truly “off-the-shelf” and may result from CAR-NK metabolic vulnerability during cryopreservation and thaw. Approaches that enhance metabolic fitness in CAR-NK cells during manufacture to decrease vulnerability and improve function post-thaw remain untested. Activation of NK cells with IL-12, IL-15, and IL-18 results in cytokine-induced, memory-like (CIML) NK cells with enhanced effector functions and metabolic fitness. We hypothesized that utilizing CIML cytokines in the terminal step of CAR-NK cell manufacture prior to cryopreservation could shift CAR-NK cell metabolism to a phenotype that maintains functional CAR-based killing post thaw.

METHODS:
Peripheral blood mononuclear cells obtained from healthy donors were cocultured with irradiated K562-mb15-41BB-L feeder cells at a 1:10 (NK cell:irradiated K562) ratio in G-Rex® culture devices for 6 days in medium supplemented with 10% FBS and 100 IU/mL IL-2. Cell suspensions on day 6 (containing 90-95% expanded/activated NK cells) underwent CD3 depletion, followed by sequential transduction with two separate retroviral vectors encoding IL-15 with an iCaspase9 safety-switch and an NKG2D.ζ CAR (Fig. 1A). The dual transduced cell population was secondarily expanded in G-Rex® devices at the same NK cell:irradiated K562 ratio with 100 IU/mL IL-2 for 7 additional days. 10 ng/mL IL-12, 10 ng/mL IL-15, and 50 ng/mL IL-18 (termed here as “cryokines” in this protocol) were added for the final 24 hours of secondary expansion (Fig. 1B). This 16-day human gene-modified NK cell production protocol resulted in >99% pure CD56+/CD3− NK cell population with avg. 62% dual-transduced NK cells (Fig. 1C). We examined post-thaw cell phenotypes, immediate and long-term CAR-NK viability, maintenance of transgene expression, mitochondrial mass as a marker of metabolic activity, and anti-tumor activity in a solid tumor xenograft model of CAR-NK cells manufactured and frozen with or without cryokines.

RESULTS:
Phenotypic evaluation post-thaw revealed maintenance of CAR and IL-15 transgene expression in cryokine treated CAR-NK cells compared to non-treated. Cryokine treatment increased expression of CD25, GLUT1, and decreased expression of TGFβ and KIR2DL3 on CAR-NK cells, consistent with CIML phenotype (Fig. 1D). Cryokine treated CAR-NK cells exhibited increased mitochondrial mass compared with non-cryokine treated CAR-NK (Fig 1E). This shift to a CIML-like phenotype corresponded with enhanced tumor control in vivo and improved survival in thawed cryokine treated CAR-NK group compared to controls, resulting in superior anti-tumor outcomes to even freshly infused CAR-NK cells (Fig. 1H).

CONCLUSION:
Cryokine treated CAR-NK cells share some properties consistent with a CIML-NK phenotype. Preserved functionality of cryokine treated CAR-NK cells is associated with increased mitochondrial mass, an indicator of increased metabolic activity. Addition of cryokines during late stages of CAR-NK cell manufacture represents an attractive option to maintain functionality in cryopreserved CAR-NK cells manufactured from peripheral blood.



Neurologic Diseases - Vectorology and Gene Therapy

74 CRISPR-hfCas12Max-Mediated Therapy HG303 Improves Neuromuscular Function and Survival in Amyotrophic Lateral Sclerosis Models

Dong Yang[1], Aiguo Guo[1], Tong Li[2], TJ Cradick[3], Alvin Luk[4], **Hui Yang[5]**, Linyu Shi[1]
[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China, Shanghai, Shanghai, China, [2]Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China, Shanghai, Shanghai, China, [3]HuidaGene Therapeutics, Clinton, NJ, USA; Cholgene Therapeutics, Middletown, DE, USA, Clinton, NJ; Middletown, DE, MA, [4]Huidagene Therapeutics Inc, Clinton, NJ, [5]HuidaGene Therapeutics Co., Ltd., Shanghai, China; Shanghai Institute of Meteria Medica, Chinese Academy of Sciences, Shanghai, China, Shanghai, Shanghai, China

Background:
Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease characterized by the loss of motor neurons, resulting in progressive muscular weakness, paralysis, and ultimately death within 2 to 5 years of symptom onset. Over 90% of ALS patients exhibit toxic aggregation of the mutated nuclear transactive response DNA-binding protein 43 (TDP-43) protein, a hallmark of the disease. Targeting *ATXN2*, a key gene associated with TDP-43 aggregation, has shown promise in reducing these toxic protein clusters. HG303, a novel CRISPR-hfCas12Max-based therapy, was developed to knock down *ATXN2* expression, providing a potential new treatment for ALS.

Methods:
A single AAV vector delivering hfCas12Max and *ATXN2/Atxn2* gRNA (gATXN2) was injected into the neonatal ALS mouse models (*TDP-43$^{Tg/Tg}$*) via intracerebroventricular (ICV) administration. Motor function (gait, tremor, and kyphosis) was assessed tri-daily between P15 and P21, and survival was monitored daily. The editing efficiency and Atxin-2 and p-TDP43 protein levels in the cortex (Ctx) and spinal cord (SC) of *TDP-43$^{Tg/Tg}$* mice were evaluated using next-generation sequencing (NGS), western blot (WB), and immunofluorescence (IF) 21 days after treatment (Fig. 1A). Additionally, HG303 was tested in wild-type (WT) non-human primates (NHPs) via intrathecal

(IT) administration to assess hfCas12Max DNA and mRNA biodistribution, safety, and editing efficiency of *ATXN2* 4 weeks after dosing in the central nervous system (CNS) (Fig. 2A).

Results:
Compared to PBS-treated *TDP-43*$^{Tg/Tg}$ mice, HG303 significantly improved motor coordination and neuromuscular function in HG303-treated *TDP-43*$^{Tg/Tg}$ mice in a dose-dependent manner, reducing gait impairment ($p<0.05$), tremors ($p<0.05$), and kyphosis ($p<0.05$) (Fig. 1B–D). Notably, middle- and high-dose HG303 treatments extended survival in *TDP-43*$^{Tg/Tg}$ mice, with 61% (8 out of 13) of high-dose-treated mice surviving beyond 160 days (Fig. 1E). qPCR results showed that hfCas12Max DNA and mRNA were distributed in the Ctx and SC (Fig. 1F and G). NGS results showed that the editing efficiency of *Atxn2* increased in *TDP-43*$^{Tg/Tg}$ mice from low-, to middle-, and high-doses, with 22.50±2.70%, 37.40±3.51%, 37.63±1.07% in Ctx and 2.92±0.44%, 8.18±1.06%, 14.70±0.42% in SC, respectively (Fig. 1H). After treating *TDP-43*$^{Tg/Tg}$ mice with low-, middle-, and high-doses, the Ataxin-2 protein in the Ctx and SC significantly decreased compared to the control mice (Fig. 1I and J). IF result also showed a significant knockdown of Ataxin-2 protein in the Ctx and SC (Fig. 1K and L). In WT NHPs, IT administration of HG303 (Fig. 2A) demonstrated efficient biodistribution of hfCas12Max DNA and mRNA across the SC and dorsal root ganglion (DRG) 4 weeks after injection (Fig. 2B and C), with *ATXN2* editing efficiency in SC ranging from 2.04-11.47% (4.82±2.28 %, mean±SD) (Fig. 2D). IF confirmed significant Ataxin-2 protein knockdown in the spinal cord (Fig. 2E). No adverse effects were observed in the CNS or peripheral tissues.

Conclusions:
HG303 offers a promising new approach to treating ALS by improving motor function, reducing toxic protein aggregation, and extending lifespan in preclinical models. Its successful application in NHPs supports the potential for translation into clinical trials, paving the way for transformative ALS therapy.

75 Systemic AAV Gene Therapy with Next Generation Engineered Capsid Demonstrates Expression Levels Supporting Potential Therapeutic Benefit for CNS, Cardiac, and Sensory Symptoms in Friedreich's Ataxia

Celeste Stephany[1], Ryan Kast[1], Miguel Chuapoco[2], Xiaojing Shi[3], Assaf Beck[4], Austin Kidder[1], Nicholas Flytzanis[5], Nicholas Goeden[6]*

**Corresponding Author*

Friedreich's Ataxia (FA) is a rare, hereditary, form of ataxia caused by an intronic trinucleotide repeat expansion that diminishes the expression of the frataxin (FXN) protein. Low FXN expression levels cause progressive deficits in cellular respiration and cell death, with pronounced impact to non-regenerative cell types (neurons, cardiomyocytes). There are no current treatments that directly address FXN deficiency, and investigational gene therapies to date do not cross the blood brain barrier to address CNS pathologies. Leveraging our high throughput directed evolution engineering platform, Capsida has identified a systemically administered (IV) capsid that achieves NHP brain-wide biodistribution, transducing >80% of neurons in key FA-related brain areas in addition to

delivering meaningful cardiac transduction. Moreover, identification of a novel human receptor for CAP-004 with complete homology between humans and macaques in the predicted binding pocket increases confidence in the clinical translatability of CAP-004 performance from NHP to humans.

In an NHP study dosing a small pool of capsids simultaneously (N=3 NHP), the engineered capsid drives RNA expression levels ~100x higher than AAV9 in CNS, while maintaining similar RNA expression in cardiac tissue, and ~10x de-targeting in the liver. In addition to evaluating the performance of engineered capsids relative to AAV9 in the pool study, multiple promoters were tested to establish their ability to limit overexpression of FXN, thus mitigating the risk for cargo-induced cytotoxicity. Capsida's proprietary endogenous human FXN promoter, miniFXN10, maintained steady levels of RNA enrichment across a range of DNA biodistribution levels suggesting that it successfully regulates FXN expression. When the drug candidate, CAP-004, was administered IV as a single variant at a low to moderate dose, the engineered capsid delivering hFXN transduced more than 80% of cerebellar Purkinje cells, dentate nucleus neurons, motor neurons in the cortex and spinal cord, and nearly 30% of cardiac left ventricle tissue area. Bulk protein levels in treated NHPs were 8.2x higher than endogenous levels in the motor cortex, and 1.7x higher in the left ventricle. Furthermore, substantial FXN RNA expression was detected in the retina (~1E6 copies/ug RNA) suggesting a potential benefit for sensory vision loss experienced by FA patients. Significant de-targeting of the liver and other non-target tissues contributed to the favorable safety profile characterized by no adverse immunogenicity, clinical pathology, and histopathology findings. Together, these data demonstrate that CAP-004 has the potential to become a best-in-class targeted gene therapy for the treatment of FA by providing therapeutic benefit for CNS and sensory manifestations of the disease that are not targeted by other approaches in addition to impacting cardiac symptoms with a single intervention.

76 Hematopoietic Stem Cell Lentiviral Gene Therapy for the Treatment of Angelman Syndrome

Christopher Luthers[1], Colin Juett[2], Samuel Cirigliano[2], Jason Quintos[2], Annika Mittelhauser[1], Xiaomeng Wu[2], Lindsay Lueptow[2], Irina Zhuravka[2], Servando Medel[2], Cesar Santana-Gomez[2], Mohamad Shamas[2], Linna Han[3], Albert Keung[3], Richard Staba[2], Andrey Mazarati[1], Jennifer Panagoulias[4], Allyson Berent[5], Roger Hollis[2], Donald Kohn[2]*

Introduction

Angelman syndrome (AS) is a rare non-degenerative neurogenetic disorder characterized by a universal lack of speech, impaired motor function and developmental delay. AS is caused by loss of function of the maternal copy of the Ubiquitin Ligase E3A (*UBE3A*) gene in neurons of the brain, where the paternal allele is silenced by a long noncoding RNA antisense transcript. A potential one-time treatment for AS is hematopoietic stem and progenitor cells (HSPCs) therapy overexpressing functional UBE3A via lentiviral vectors (LV) in the differentiated macrophage progeny of the bone marrow that traffic to the brain. UBE3A-overexpressing in myeloid cells in the brain secrete the protein into the extracellular space allowing for cross-correction, where UBE3A is taken up by neighboring neurons.

Methods

A preliminary in-vitro screen was conducted in both human and murine cells to identify candidate LV with high vector titer, gene transfer, UBE3A expression, secretion, and bioactivity. Upon identification of two lead candidate LV, murine lineage-depleted "Lin-" cells were transduced with these vectors then transplanted into busulfan-conditioned adult AS mice. 10-12 weeks post-transplant, AS mice underwent behavioral analysis to assess movement, balance, motor, anxiety and cognitive neurobehavior. Following behavioral analysis, mice underwent electroencephalogram (EEG) analysis to measure neurological electrical activity, specifically delta brainwave power, a robust translational biomarker in both AS patients and mice. AS mice were then euthanized and bone marrow, spleen, peripheral blood, and brain tissues were harvested to measure engraftment, vector copy number (VCN), UBE3A expression, and biodistribution.

Results

HSPC transplanted AS mice transduced with either of two lead candidate LV's showed statistically significant improvements in all neurobehavioral tests conducted: open field, novel object recognition, balance beam, and rotarod assays (Figure 1). Additionally, vector-containing mice showed detectable long-term donor-cell engraftment and VCN in all tissues up to 20-weeks post-transplant. EEG showed significant improvement in delta power in LV transplanted mice relative to non-transplanted mice. Confocal microscopy showed diffuse UBE3A protein expression in both engrafted immune cells of the brain and throughout neurons of the brain. This confirmed that the UBE3A protein as being secreted from the immune cells and taken-up by neighboring neuronal cells (Figure 2). Protein samples from each tissue are currently undergoing UBE3A bioactivity evaluation to confirm proper ubiquitin ligase functional activity, which has previously been documented after in vitro transduction.

Conclusions

Collectively, we have designed two lead candidates of UBE3A-expressing LV with high titers, effective gene transfer, and high UBE3A protein expression in-vitro. We were then able to validate the lentiviral gene therapy strategy in vivo in a robust adult mouse model of AS and showed comprehensive improvement of all well characterized neurobehavioral, electrophysiological, and biochemical AS phenotypes. These promising results serve as the critical preclinical experiments required to advance this program into IND-enabling studies and engage with the FDA to potentially bring the first LV gene therapy forward for a monogenic non-degenerative, non-lysosomal neurodevelopmental disorder, with a large clinical unmet need.

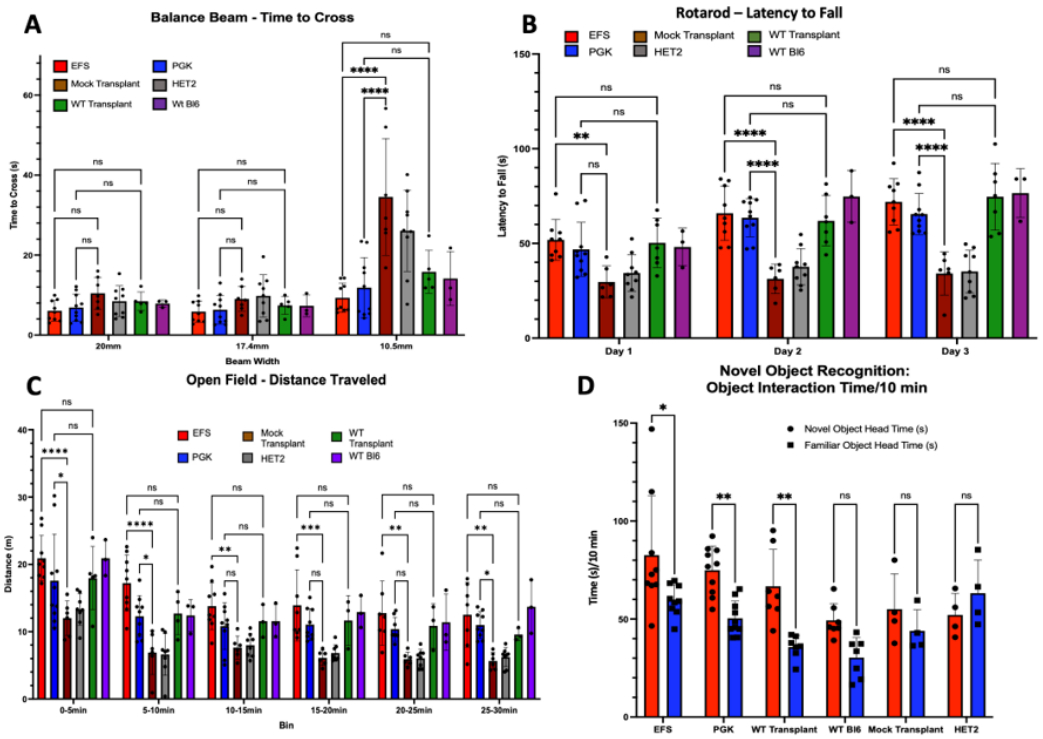

Figure 1. AS Mice which received Ube3a vectors show improvement in various behavioral phenotypes. (A) Mice underwent a balance beam assay in which time to cross beams of 3 different widths is measured. (B) Mice underwent a rotarod assay in which mice are placed on a rod with consistently increasing RPM's – data is displayed a latency to fall off of beam. (C) Mice underwent an open field assay in which mice are placed in a open field and allowed to roam – data is displayed as distance travelled in given 5 minute bins. (D) Mice underwent a novel object recognition in which they are trained with two familiar objects followed by replacement of one of the familiar objects with a novel object - data displayed is number of seconds each mouse spent interacting with the novel vs familiar object in a 10 minute window. **EFS/PGK** = AS mice transplanted with EFS/PGK-Ube3a vectors, **HET2** = AS Mice, **Mock transplant** = AS mice transplanted with unedited AS Lin- cells, **WT transplant** = AS mice transplanted with WT Bl6 Lin- cells. *p<0.05 **p<0.01 ***p<0.001 ****p<0.0001.

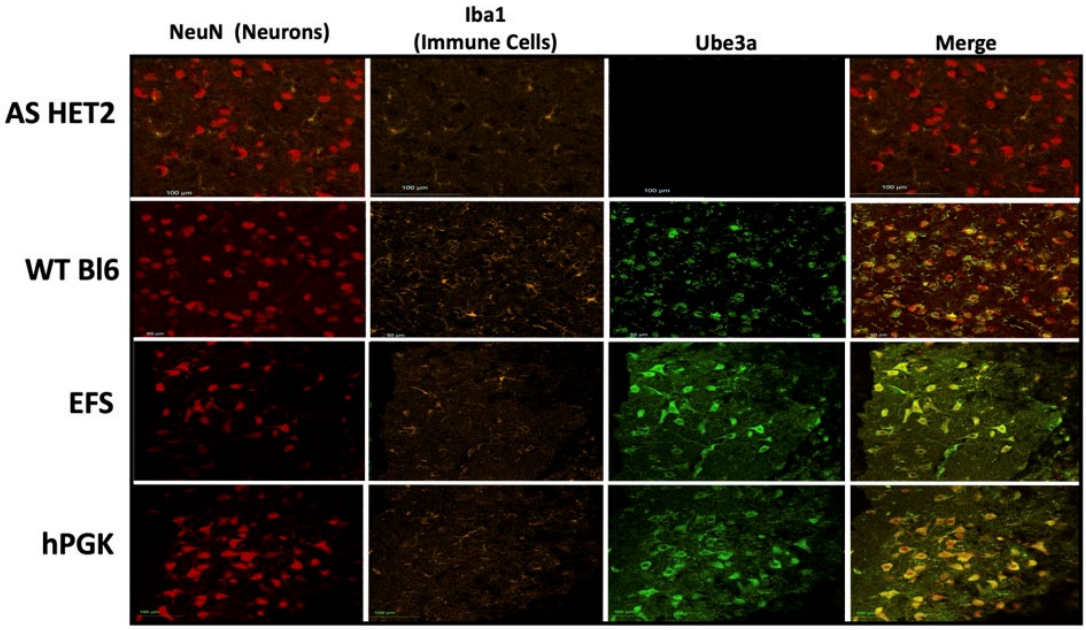

Figure 2. AS mice which received Ube3a vectors show restoration of Ube3a expression in immune cells and neurons. Mice were euthanized and brains were harvested, fixed, cryopreserved, and 30uM slices were generated. Brain slices were then stained with neuronal marker NeuN (red), Immune cell marker Iba1 (orange), and Ube3a (green). Stained brain slices were then imaged using super-resolution confocal microscopy. Images above show Neurons, Immune cells, Ube3a, and a merge of all three channels – displaying both a restoration of Ube3a expression in transplanted mice as well as Ube3a expression present in the neurons of edited mice.

77 ASPA Gene Therapy Increases Expression of Oligodendrocyte Transcription Factors, Correlating with Remyelination in Canavan Disease Animal Model

Anoushka Lotun[1], Morgan Mooney[1], Guangping Gao[1]*, Dominic Gessler[1]*
[1]*UMass Chan Medical School, Worcester, MA*

**Corresponding Author*

Gene therapy using recombinant adeno-associated viruses (rAAVs) has shown great promise in promoting therapeutic response and disease correction for CNS diseases, particularly for dysmyelinating diseases. Strategies such as gene addition are an effective means of restoring the wildtype (WT) gene for otherwise absent or mutated gene(s) of interest. Previously our group has demonstrated that a gene addition approach for Canavan disease (CD), a white matter disease, is efficacious in disease prevention and reversal in CD mouse models; this therapy is currently being evaluated in a clinical trial: NCT04998396. CD is caused by a loss-of-function mutation in aspartoacylase (ASPA), the metabolizing enzyme of N-acetylaspartate (NAA). CD mouse models lacking functional Aspa expression ($Aspa^{-/-}$) have elevated NAA levels, severe dysmyelination, and neurodegeneration, analogous to observed phenotypes in the developing CNS of CD patients. Systemic delivery of rAAV9.CB6-hASPA in neonatal and juvenile $Aspa^{-/-}$ mice can prevent and/or reverse the disease to a wildtype state, as determined by normalized ASPA expression, decreased NAA levels, and remyelination in the CNS. While these findings are encouraging, the underlying mechanism of how ubiquitous hASPA gene addition drives remyelination and corrects neurodegeneration in CD is not well understood.

Oligodendrocytes (OLs) play a critical and indispensable role in promoting efficient neuronal communication and health through the myelination of axons. The capacity for OLs to myelinate and/or remyelinate is contingent upon the proliferation of oligodendrocyte precursor cells (OPCs) and their lineage progression into mature myelinating oligodendrocytes (mOLs). In dysmyelinating diseases such as Multiple Sclerosis and Canavan disease, OPCs are abundant but fail to differentiate into mOLs. With our Canavan disease gene therapy we previously showed that

hASPA expression in Aspa$^{-/-}$ mice can surmount this differentiation block, leading to an increase of mOL cell populations which interestingly couples with increased NeuN^{+} neuronal cells. We hypothesized that this therapeutic potential is achieved through downstream effects of hASPA gene therapy on transcriptional factors (TFs) which drive OL and neural cell fate recovery. We found that protein expression of Sox2 and Olig1 transcriptional factors regulating cell proliferation and OL maturation decrease in Aspa$^{-/-}$ mice, but significantly increase post-hASPA reconstitution; this correlates with increased myelin basic protein (MBP) expression in hASPA-treated but not in untreated animals. These findings suggest a prospective avenue of using gene addition of transcriptional factors as a means to promote disease correction. We additionally discovered that phosphorylated Stat3 (pStat3), the active form of the Stat3 transcription factor, is upregulated in Aspa$^{-/-}$ brains but is normalized to wildtype levels after hASPA gene therapy. pStat3 activates transcription of cell survival and immune-related genes in response to cytokine and growth factor signaling. Therefore, the downregulation of pStat3 after hASPA gene replacement highlights the potential to either dampen immune response and/or promote cellular proliferation post-gene therapy via transcriptional factor activity. We are currently determining the cell-type distribution of these TFs before and after hASPA expression and how gene therapy could be leveraged to promote disease reversal through TF activity.

78 Preclinical Advances for the Translation of an AAV-Mediated Gene Therapy for CTNNB1 Syndrome

[1]Children's Medical Research Institute, Westmead, NSW, Australia, [2]National Institute of Chemistry Slovenia, Ljubljana, Slovenia, Slovenia, [3]Children's Medical Research Institute, Westmead, Australia, [4]Westmead, NSW, Australia, [5]Children's Medical Research Institute, AUSTRALIA, [6]GRANVILLE, NSW, Australia, [7]University Children's Hospital, Ljubljana, Slovenia, [8]Association of University Centers on Disabilities, Chicago, IL, [9]Asociacion CTNNB1 España and CTNNB1 Foundation, Gent, Oost-Vlaanderen, Belgium, [10]CTNNB1 Foundation, Ljubljana, Slovenia, [11]Sendatu Therapeutics, Westmead, NSW, Australia

CTNNB1 Syndrome is a severe and rare neurodevelopmental disorder caused by loss-of-function variants in the *CTNNB1* gene, which encodes for beta-catenin, a protein with essential functions in cellular properties, neurogenesis, and synapse formation. Consequently, loss of one functional copy of *CTNNB1* leads to developmental delay in 97% of cases, with patients mainly presenting intellectual and motor disabilities among other phenotypes. While there is no treatment for CTNNB1 Syndrome, the genetic cause could be addressed by delivering a functional copy of the gene to the affected cells. Our group developed a gene augmentation strategy mediated by adeno-associated viral (AAV) vectors.

For this purpose, we designed six AAV-CTNNB1(C1-6) therapeutic candidates, composed of the *CTNNB1* coding sequence accompanied by unique combinations of regulatory elements. Expression cassettes were individually packaged into AAV vectors and used for transduction of patient-derived cortical brain organoids. Based on comparative mRNA and protein expression analyses, we identified one construct, AAV-CTNNB1(C4) as the most promising candidate to significantly increase beta-catenin expression and function in patient-derived organoids without leading to the overexpression of Wnt-regulated genes associated with tumorigenesis, such as *MYC*. RNA sequencing analysis also confirmed the lack of activation of other oncogenic pathways.

We advanced the AAV-CTNNB1(C4) cassette for preclinical *in vivo* proof-of-concept studies in a *Ctnnb1*$^{+/-}$ murine model presenting motor and anxiety phenotypes, two symptoms frequently associated with CTNNB1 Syndrome. Four-week-old wild-type (WT) and *Ctnnb1*$^{+/-}$ mice were intracerebroventricularly (ICV) infused with a dose range comprised of 4.24e9, 2.12e10, and 1.06e11 vector genomes (vg) of test or control vector, and phenotypic outcomes were evaluated at 12 and 20 weeks of life (N=10-16 mice/genotype/dose level or control). Tests revealed normalization of anxiety-like behaviour and locomotor function in *Ctnnb1*$^{+/-}$ mice ICV-infused with the highest dose level. No differences were observed in general health, appearance and weight of mice across test cohorts through five months of life, and endpoint molecular analyses revealed normalization of mRNA and protein beta-catenin expression levels, consistent with patient-derived organoid findings.

To evaluate safety of AAV-CTNNB1(C4), WT mice were ICV-infused with 1.06e11, 2.25e11 vg of test or control vector and monitored weekly for changes in behaviour, appearance, and weight through 8 months of life. Biochemical markers of liver, kidney, and bile duct function measured from blood samples were normal in control and test vector infused groups, and comparable to non-infused mice. Brain and peripheral tissues revealed only age-related histopathological findings, independent of treatment. Together, these studies confirmed a lack of treatment-related toxicity.

Overall, this project demonstrated that AAV-CTNNB1(C4) could serve as an effective and safe therapeutic approach for CTNNB1 Syndrome. The vector, produced under current Good Manufacturing Principles (cGMP), is now in use for biodistribution studies in mice, as well as Good Laboratory Principles (GLP) toxicology studies in mice and non-human primates. These ongoing studies aim to support an investigational gene therapy clinical trial for CTNNB1 Syndrome, anticipated to commence in Europe and Australia in Q3 2025.

79 Treatment of Patients with Spinal Muscular Atrophy Using Covalently closed-end AAV

Several clinical gene therapies employ self-complementary adeno-associated viral (scAAV) vectors for improved efficacy by eliminating the need for second-strand formation that exists for natural AAV genomes. We recently developed an alternative self-complementary genome with a covalently closed-end inverted terminal repeat. Importantly, packaged genomes of these cceAAV vectors are markedly more intact than traditional scAAVs, which typically contain a large fraction of incomplete genomes, including many that lost their self-complementary configuration. Here, we report first-in-human experience with a cceAAV vector that was systemically administered to two pediatric patients with spinal muscular atrophy (SMA). In preclinical studies, cceAAV32 SMN1 achieved superior therapeutic outcomes than scAAV-SMN1 in SMA Δ7 mice, including substantially extended survival, higher body weight gain, and enhanced motor activity. Studies in non-human primates supported safety of clinical-grade cceAAV-SMN1 (NKG001). Clinical trial in two SMA patients at 12-24 months of age revealed no treatment-associated severe adverse events. Our strategy of initial treatment with RNA-splicing modifying drug during infancy enabled gene therapy in older SMA patients. Both patients showed rapid improvements in motor capabilities after gene therapy, as evidenced by substantial gains in motor function and electrophysiological parameters and capacity for independent mobility. These results strongly support clinical use of cceAAV vectors.

80 Endogenous MicroRNA Feedback for Dosage-Regulated AAV/SLC6A1 Gene Therapy

Introduction:
SLC6A1-related neurodevelopmental disorder (SLC6A1-NDD) is characterized by a spectrum of symptoms including seizures and intellectual disability. SLC6A1-NDD is caused by haploinsufficiency of the SLC6A1 gene, encoding a neuronal transporter for GABA (GAT1). Preclinical testing of an AAV9/SLC6A1 gene replacement therapy was capable of rescuing disease phenotypes, but revealed adverse consequences from mis-expression of

SLC6A1, by which too much or too little of SLC6A1 can cause an epileptic phenotype (Guo W et al, J Clin Invest, 2024). Therefore, we aim to develop a self-regulated gene therapy, to maintain SLC6A1 within its 'Goldilocks zone' of expression.

Objective:
In this work, we investigate how SLC6A1 expression is naturally tuned in the brain, to test the implementation of these features into an AAV/SLC6A1 gene therapy. Similar to a previous approach to utilize miRNAs to create a feedback regulation loop for the transgene (Sinnett S et al, Brain, 2021), we hypothesized that miRNAs might respond to varying levels of SLC6A1 expression, enabling a similar regulation scheme.

Methods:
MicroRNA (miRNA) responses to SLC6A1 were determined by small RNA-sequencing of the brain cortices of (n=3) wildtype, $Slc6a1^{+/-}$, $Slc6a1^{-/-}$, and AAV/SLC6A1-treated mice. Candidate SLC6A1-repressor miRNAs were identified by cross-referencing public HITS-CLIP datasets of miRNA-SLC6A1 mRNA binding in the brain with *in silico* predicted repressors of SLC6A1. A short genetic element containing the binding sites for putative feedback-regulator miRNAs was generated and appended to the AAV/SLC6A1 transgene. Functionality of the element was validated by a luciferase reporter assay.

Results:
We found that global miRNA expression levels adjust in response to the gene dosage of SLC6A1 in the cortex. Some of the top SLC6A1-binding miRNAs were up-regulated by SLC6A1. Gene ontology terms for these miRNAs were related to SLC6A1 function, including neurotransmitter regulation in GABAergic neurons. These miRNAs were confirmed to repress gene expression via elements in the SLC6A1 3'UTR. A compact minimal 3'UTR, comprised of these elements, was generated and incorporated into the transgene of AAV/SLC6A1.

Conclusions:
We have identified putative negative feedback loops between SLC6A1 and miRNAs, that may be exploitable for the dynamic fine-tuning of AAV/SLC6A1 gene therapy. A novel AAV/SLC6A1 variant, regulated by these miRNA binding sites, is next being tested in mice for improved safety and efficacy profiles for the treatment of SLC6A1-NDD.

Gene Therapy Clinical Trials

81 Revolutionizing Wilson's Disease Treatment: Clinical Safety and Efficacy of LY-M003, A Copper-Responsive AAV Gene Therapy Vector

Yi Chen[1], Yixiong Chen[2], Chao Lu[1], Zhe Shen[1], Jianyong Wang[1], Tianqi Jiang[3], Yuzhe Peng[4], Rihong He[4], Chenming Lu[4], Guofang Yan[5], Jian Wang[5], Juan Chen[4], Qing Lin[6]*, Chaohui Yu[1]*

**Corresponding Author*

Introduction:
Wilson disease (WD) is a rare autosomal recessive metabolic disorder primarily caused by mutations in the *ATP7B* gene. These mutations result in reduced ATP7B activity, leading to the progressive accumulation of copper in critical organs such as the liver, brain, and kidneys. LY-M003, an investigational adeno-associated virus serotype 8 (AAV8)-based gene therapy, was designed to produce a modified miniATP7B^{LY} protein, which retains comparable functionality to the wild-type ATP7B, primarily in the liver. The LY-M003 injection employs the Copper Responsive Engineering of ATP7B Expression (CREATE™) platform, which modulates protein expression based on hepatic copper levels. This innovative approach ensures both efficacy and safety in the treatment of Wilson's disease.

Method:
A clinical study (NCT06650319) to evaluate the safety and efficacy of a single intravenous infusion of LY-M003 in patients with WD is ongoing in First Affiliated Hospital of Zhejiang University, China. Stable treated patients with WD are eligible for inclusion. Patients are permitted to continue standard of care (SoC) therapy following LY-M003 administration until clinical symptom improvement is observed. A prophylactic immune management regimen including both steroid and immunomodulating agent is administered to all participants. The primary objectives of the study are to assess the safety and efficacy of escalating doses of LY-M003. Participants will be monitored for 52 weeks post-treatment, and subsequently enrolled in a long-term follow-up phase lasting five years.

Results:
Since September 2024, seven participants have received LY-M003 injections, with the treatment demonstrating a favorable tolerability profile across all dosage cohorts. No anti-drug antibodies (ADA) against ATP7B were detected, and no serious adverse events (SAEs) were reported. Instances of elevated liver enzyme were promptly managed and resolved through immune modulation therapy. Most participants demonstrated significantly elevated ceruloplasmin levels, with the peak values surpassing 50% of the normal range for one participant, suggesting reestablished hepatic copper transport functionality by ATP7B. Furthermore, several participants have either discontinued or reduced the standard of care (SoC) with normalized urinary copper levels. Notably, most participants began SoC reduction within one month post gene therapy administration. One individual from the high-dose cohort achieved complete discontinuation of SoC within six weeks of receiving LY-M003. For individuals exhibiting neurological symptoms improvement was observed with the administration of LY-M003, as evidenced by a reduction in UWDRS scores related to writing ability, language skills, and other functional capabilities.

Conclusion:
LY-M003 is a novel AAV8-based therapeutic approach for Wilson's disease currently under clinical investigation. Preliminary clinical data from various dosage groups thus far indicated a favorable safety profile and therapeutic efficacy on both peripheral and neurological symptoms, which underscores LY-M003's profound potential in revolutionizing the therapeutic landscape for Wilson disease, heralding a new era of treatment possibilities.

82 Updated Safety and Efficacy Results of RM-001, Autologous HBG1/2 Promoter-modified CD34+ Hematopoietic Stem and Progenitor Cells, in Treating Transfusion-Dependent β-Thalassemia

Rongrong Liu[1], Li Wang[2], **Hui Xu[3]**, Jianpei Fang[4], Sixi Liu[5], Xiaolin Yin[2], Junbin Liang[3], Xinyu Li[4], Yue Li[5], Gaohui Yang[1], Yaoyun Li[2], Yali Zhou[2], Yongrong Lai[1], Junjiu Huang[6], Xinhua Zhang[7]*

**Corresponding Author*

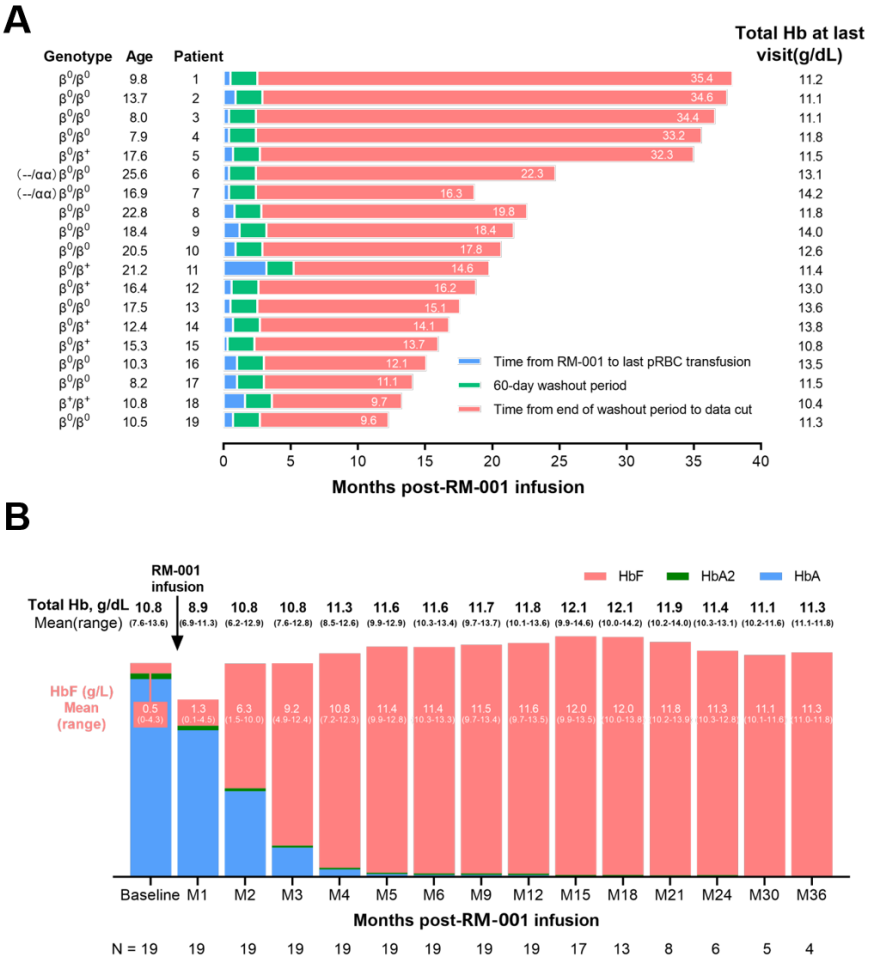
Background:
RM-001 is a novel non-viral cell therapy for β-hemoglobinopathies, which is designed to reactivate fetal hemoglobin (HbF) via ex vivo CRISPR-Cas9 gene-editing of autologous CD34+ hematopoietic stem and progenitor cells (HSPCs) at the binding site of BCL11A on the promoter of the γ-globin genes (HBG1/2). Here we report that in both investigator initiated trial (IIT) and phase I trial, all the patients (pts) with transfusion-dependent β-thalassemia (TDT) achieved transfusion-free after RM-001 treatment.

Methods:
Both IIT (ChiCTR2100053406 and ChiCTR2100052858, n =7) and phase I trial (ChiCTR2300069244, n =12) have been conducted to evaluate the safety and efficacy of RM-001 in treating TDT. Patients (6–35 y of age) with TDT and a history of ≥100 mL/kg/y or ≥10 units/y packed red blood cell (pRBC) transfusions in the 2 years before screening were eligible. Primary efficacy endpoint is transfusion independence defined as proportion of pts maintaining a weighted average hemoglobin (Hb) ≥9 g/dL without pRBC transfusion for ≥12 consecutive months (TI12). Key secondary endpoint is proportion of pts maintaining a weighted average Hb ≥ 9 g/dL without RBC

transfusion for ≥ 6 consecutive months (TI6). Evaluation of TI12 and TI6 started 60 days after last pRBC transfusion. Pts completing the 24-month trial will be enrolled in a long-term follow-up study.

Results:
As of Dec 31, 2024, 19 pts (mean age 15.9; 5 pts aged ≥18, 7 pts aged ≥12 to <18y and 7 pts aged ≥6 to <12y) have received RM-001, with a median follow-up of 19.8 (12.3-37.9) months. Pts received a mean of 53.0 (35.3-106.3) units/y pRBC transfusions before enrollment; 13 pts (68.4%) have the most severe genotype (β0/β0), 5 pts (26.3%) have β0/β+ genotype and the remaining one (5.3%) has a β+/β+ genotype. Following infusion, all pts engrafted neutrophils and platelets (median 15 and 21 days, respectively). All of 19 (100%) pts stopped transfusions and maintained transfusion-free ≥ 11 (11.6-37.4) months. Pts stopped transfusions at a median of 22 (10-95) days post-RM-001 infusion and achieved stable Hb ≥9 g/dL at a median of 31 (14-127) days. Of the 16 pts had ≥15 months of follow-up after RM-001 infusion, all of them (100%) achieved TI12. For all pts, the mean total Hb and HbF were 10.8 g/dL and 9.2 g/dL at Month 3, 11.6 g/dL and 11.4 g/dL at Month 6, 11.8 g/dL and 11.6 g/dL at Month 12, respectively. Proportion of edited HBG1/2 alleles was stable over time in bone marrow cells. The first 6 pts have finished 24-month follow-up and the first 3 pts have finished 36-month follow-up. No RM-001-related serious adverse event report. All of adverse events have been resolved. There were no deaths, discontinuations, or malignancies.

Conclusion:
The data from 19 TDT pts infused with RM-001 demonstrated clinically meaningful and sustained increases in total Hb and HbF, leading to transfusion-free in all of subjects. The safety profile of RM-001 is very well and no product-related serious adverse event was reported during the study. These results indicate that RM-001 has the potential to cure TDT with one-time treatment.



83 Phase 1/2 clinical trial of autologous hematopoietic stem and progenitor cell (HSPC) gene therapy for cystinosis

Stephanie Cherqui[1], Bruce Barshop[2], Edward Ball[3], Doris Trauner[3], Nadine Benador[3], Ranjan Dohil[3], Natalie Afshari[3], Donald Kohn[4], Frederic Bushman[5], Imama Ahmed[3]
[1]University of California, San Diego, La Jolla, California, [2]University of California San Diego, La Jolla, CA, [3]University of California, San Diego, La Jolla, CA, [4]Unversity of California, Los Angeles, CA, [5]University of Pennsylvania School of Medicine, Philadelphia, PA

Cystinosis is a lysosomal disorder characterized by cystine accumulation within the lysosomes of all organs caused by mutations in the *CTNS* gene encoding the transmembrane lysosomal cystine transporter, cystinosin. Major complications of cystinosis include early renal Fanconi syndrome, chronic kidney disease, renal failure, and ocular pathology that can lead to blindness. Cystinosis also affects the heart, thyroid, skeletal muscle, pancreas, and CNS, eventually causing premature death in early adulthood. Cysteamine delays, but does not stop, disease progression. Here we report results from the phase 1/2 open-label clinical trial (NCT03897361) evaluating safety and efficacy of CTNS-RD-04, consisting of autologous $CD34^+$ cells transduced with a lentiviral vector (LV) carrying the *CTNS* cDNA (CCL-EFS-CTNS-WPRE). Oral and topical cysteamine were withdrawn prior to infusion.

The trial is fully enrolled, and six participants (ages 20 to 46 years) have been treated with CTNS-RD-04 with follow-up ranging from 24 to 63 months. CTNS-RD-04 cell doses ranged from 3.63×10^6 to 9.59×10^6 $CD34^+$ cells/kg with vector copy numbers (VCNs) ranging from 0.59 to 2.5 copies/diploid genome. No adverse events related to drug product have been reported to date. Sustained and highly polyclonal hematopoietic reconstitution was observed in all patients with VCNs at 24 months ranging between 0.51 to 2.67. Patient 4 and 5 restarted low does cysteamine due to low level of VCN (<1). White blood cell cystine and tissue cystine crystals in skin and rectal mucosa decreased compared to baseline. Overall stabilization of the disease and improvement of muscle strength and motor coordination have been observed for patients 1 and 3 who have the longest follow up periods and VCNs $\geq$1. Updated data will be presented on patients infused to date. This is the first *ex vivo* gene therapy approach for a multisystemic disease due to a transmembrane lysosomal protein. The results in adults are encouraging with a good safety profile

84 First-in-Human Study of Autologous HBA2-Edited CD34+ Hematopoietic Stem and Progenitor Cells in Alpha-Thalassemia with Constant Spring Mutation

**Corresponding Author*

Background:
Hemoglobin H Constant Spring (HbH-CS) (--/αCSα) is the most common non-deletion α-thalassemia that can lead to severe health problems. The clinical severity of HbH-CS is widely variable and a considerable proportion of patients with HbH-CS need regular or irregular transfusion to support a normal growth, development and life. Currently, there is no cure for this type of disease worldwide. Because patients with HbH-CS has only a single base mutation in the Hemoglobin Subunit Alpha 2 (HBA2: c.427T>C) compared to that of asymptomatic carriers (--/αα), we speculate that repairing of the mutation by base editing may provide a potential cure for this type of disease.

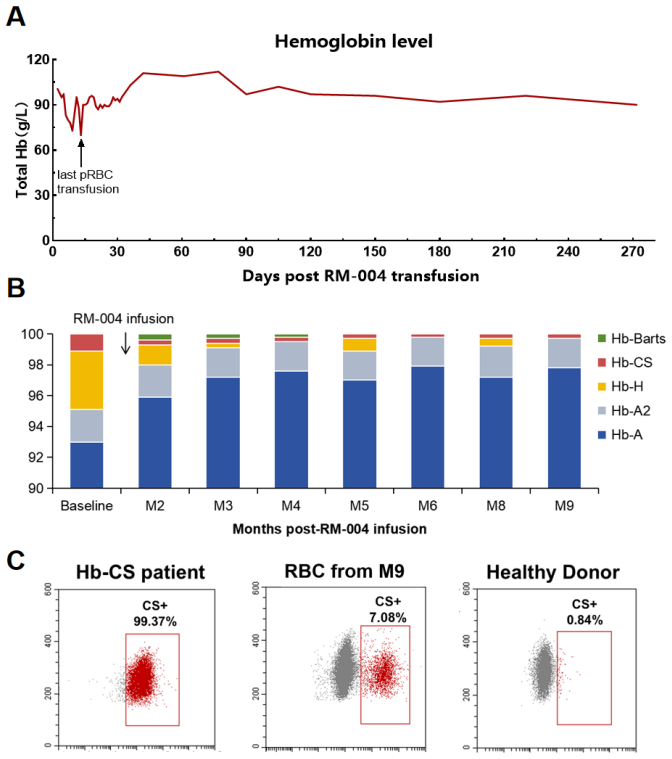
Aims:
To repair the CS mutation of HBA2 gene and increase the expression of normal α-globin chain in erythrocytes, we used ex vivo Cytosine Base Editor (CBE)–based gene editing to modify HBA2 gene in hematopoietic stem and progenitor cells (HSPCs), producing RM-004. NCT06107400 is an investigator initiated first-in-human study of

edited patient cells (RM-004) in transfusion-dependent HbH-CS. Here, we present the initial results from the first patient treated with RM-004.

Methods:
Patients (12–35 y of age) with HbH-CS receiving packed red blood cell (pRBC) transfusions of ≥100 mL/kg/y or ≥10 units/y in the previous 2 y were eligible. Peripheral CD34+ HSPCs were collected by apheresis after mobilization with G-CSF and plerixafor. CD34+ cells were edited with CBEs using a guide RNA specific for the CS mutation. Prior to RM-004 infusion, patient received myeloablative conditioning with busulfan form day-7 to day-3. Patient were monitored for stem cell engraftment/hematopoietic recovery, adverse events (AEs), Hb production, expression of HbA/HbH/Hb-CS, proportion of CS negative red blood cells and requirements for packed red blood cell (pRBC) transfusions.

Results:
The first subject was a 14-y female patient with HbH-CS, who received an annualized 29 units/y pRBC transfusions before enrollment. Patient received a single dose of RM-004 cells and engrafted neutrophils and platelets at Day14 and Day20 post-RM-004 infusion, respectively. The last pRBC transfusion was on Day13 after RM-004 treatment; and the patient has been transfusion-free over 8.5 months. The total Hb stablely over 9 g/dL on Day26 and maintained between 9~11 g/dL currently. Following the infusion of RM-004, the proportion of HbH and Hb-CS were dropped from 3.8% and 1.1% to 0 and 0.3%, respectively. Concurrently, the proportion of HbA1 increased from 93% to 97.8%.The proportion of CS positive RBCs significantly decreased from 100% to about 7%. The safety profile was generally consistent with busulfan myeloablation and autologous hematopoietic stem cell transplantation. No serious adverse event reported.

Conclusion:
The first patient treated with RM-004 demonstrated successful engraftment and clinical meaningful increase in Hb level. Although the follow-up time is relatively short, available data have shown that the patient has entered a transfusion-independence state. This is the first-ever clinical report of patients with α-thalassemia treated successfully with gene editing and indicates that RM-004 is a promising approach for the treatment of HbH-CS. Data will be updated for the presentation.



85 Use of Expanded Non-genetically Modified Natural Killer Cells (Troculeucel) with Enhanced Cytotoxicity in Patients with Alzheimer's Disease. Preliminary Clinical and Biomarker Results.

Paul Song[1], Lucia Hui[1], Yoonmi Kang[1], Sean Hong, Katia Betito[2], Blanca Isaura Acosta Gallo[3], Jesse Carr[4], Harry Chung[4], Cesar Alejandro Amescua[3], Clemente Humberto Zuniga Gil[3], Juan Mata[1], Rufino Menchaca Diaz[3], Sant Chawla[5], Hank Lee[1], Yongman Kim[1]
[1]NKGen Biotech, Inc., Santa Ana, CA, [2]NKGen Biotech, Santa Ana, CA, [3]Hospital Angeles, Tijuana, Mexico, [4]Behavioral Research Specialists, LLC, Glendale, CA, [5]Sarcoma Oncology Center, Santa Monica, California

Background:
Misfolded protein deposits whether it be amyloid in Alzheimer's, α-synuclein in Parkinson's, and Lewy Body dementia, or tau proteins in Frontotemporal dementia are known to illicit a cascade of autoreactive neuroinflammation and damage. Recent clinical studies have shown that removing these proteins by themselves will not fully address this complex process. The importance of Natural Killer (NK) cells of the innate immune system in neurodegenerative disease has largely been overlooked despite studies demonstrating their ability to reduce neuroinflammation (by eliminating activated T cells, degrading protein aggregates and secreting anti-inflammatory cytokines). Troculeucel is a first in-kind autologous non-genetically modified NK cell product with significantly increased cytotoxicity and over 90% activating receptor expression that can be consistently produced from any donor.

Method:
In this Phase 1 dose escalation study (NCT04678453), SNK01 was administered intravenously (IV) every three weeks for a total of 4 treatments using a 3+3 design in pts with mild, moderate or severe Alzheimer's Disease (AD) confirmed by complete evaluation including MRI and PET scans. The starting dose was 1 x 10^9 cells, and the highest dose was 4 x 10^9 cells. The primary endpoint was safety and secondary endpoints included changes in cognitive assessments, immune cytokines, and CSF protein levels. A second Phase I/IIa trial (NCT06189963), administering a dose of 6 x 10^9 every three weeks for one year, has completed the initial phase I portion.

Results:
In the initial dose escalation Phase I study, troculeucel was found to cross the blood brain barrier via a simple IV via CXCR3 and to identify and eliminate autoreactive T cells via NKG2D and DNAM-1. It was found to be very safe with no drug related adverse reactions. Despite 70% of subjects being treated at relatively low doses of troculeucel, 90% of all evaluable subjects had either stable or improved (±0.1) composite ADCOMS scores at Week 11 (one-week after the final dose). One-week post-final dose, improvement in CSF biomarkers were observed in 70% of subjects for p-Tau181, 60% for AB42/40 ratio, 60% for α-synuclein, 60% for GFAP, 40% for GDF-15, 30% for LTBP2, and 30% for NfL. Early data from a new phase I/IIa trial shows that after treatment with a dose of 6 x 10^9 cells every 3 weeks for three months, 2 of the 3 phase I subjects had already improved from a moderate to a mild AD rating on the CDR-SB scale and after six months, all three subjects had stable or improved CDR-SB, ADAS-Cog 11 and ADCOMS scores.

Conclusions:
Troculeucel has been shown to be very safe and well tolerated. It appears to have clinical activity in AD while also improving CSF protein levels and reducing neuroinflammation. A randomized phase II trial in moderate stage Alzheimer's patients is currently underway, and troculeucel is planned to be studied in Parkinson's Disease, Frontotemporal Dementia, and Lewy Body Dementia.

86 Lentiviral hematopoietic stem cell gene therapy (atidarsagene autotemcel) for late juvenile Metachromatic leukodystrophy (MLD): Interim analysis of a Phase III trial

[1]San Raffaele Telethon Institute for Gene Therapy (SR-TIGET), MILANO, Milano, Italy, [2]San Raffaele Telethon Institute for Gene Therapy (SR-TIGET), IRCCS San Raffaele Scientific Institute, Milan, Italy, Milan, Milano, Italy, [3]IRCCS San Raffaele Scientific Institute, Milan, Italy, Milan, Milano, Italy, [4]San Raffaele Telethon Institute, Milan, Milano, Italy, [5]San Raffaele Telethon Institute for Gene Therapy, Milano, Italy, [6]San Raffaele Telethon Institute for Gene Therapy, Milano, Lodi, Italy, [7]University of Perugia, Perugia, Italy, perugia, Perugia, Italy, [8]Orchard Therapeutics, London, United Kingdom, London, London, United Kingdom, [9]Self-employed, Pennington, New Jersey, [10]San Raffaele Telethon Institute for Gene Therapy, ITALY

Background
Metachromatic Leukodystrophy (MLD) is a rare, severely disabling lysosomal storage disease. Atidarsagene autotemcel ("arsa-cel") is a hematopoietic stem cell (HSC) gene therapy (GT) consisting of autologous CD34+ cells transduced ex vivo with a lentiviral vector encoding the human ARSA gene. These cells are infused following intravenous myeloablative busulfan conditioning. Arsa-cel has shown long-term favorable outcomes in early-onset MLD.

Methods
A phase III trial (NCT04283227) evaluates the safety and efficacy of "arsa-cel" in pre-symptomatic or early-symptomatic Late Juvenile MLD (LJ-MLD) patients. This report presents preliminary engraftment, pharmacodynamic and safety data from an ad hoc interim analysis

Results
As of January 2025, six patients enrolled in the study have been treated. Four were pre-symptomatic, and two were early-symptomatic. One patient had a prior allogeneic HSC transplant with myeloablative busulfan-based conditioning one year before enrollment, followed by autologous reconstitution. This patient met eligibility for HSC-GT under the protocol due to confirmed full-host chimerism and normal bone marrow (BM) findings. Among treated patients, the median age at GT was 10.4 years (range: 2.7 to 15.5 years). Stem cell source was mobilized peripheral blood collected after 6-8 doses of G-CSF and administration of Plerixafor 6-8 hours before leukapheresis. Median yield was 34.3×10^6 CD34+ cells/kg (range: 30.3-37.7×10^6 CD34+ cells/kg). The infused drug product median dose was 23.1×10^6 CD34+ cells/kg (range: 16.0-28.9×10^6 CD34+ cells/kg), with a vector copy number (VCN)/cell range of 2-5. The patient with prior allogeneic HSC transplant had CD34+ yield and graft characteristics comparable to other patients. All patients received myeloablative conditioning with busulfan as a single agent, with a cumulative target area under the curve of 85 mg×h/L. After a median follow-up of 27.8 months (range: 12.6 to 34.3 months), all patients are alive. Five patients remained neurologically stable, while one early-symptomatic patient experienced disease progression shortly after GT, followed by stabilization up to 30 months post-treatment. Short-term adverse events were consistent with busulfan's safety profile. Two patients required therapy to normalize platelet counts. No malignancies, abnormal clonal expansion, replication-competent lentivirus, immune responses against ARSA enzyme, or treatment-related serious adverse events were reported. Median neutrophil and platelet engraftment times were 33 days (range: 25-41) and 27.5 days (range: 24-48), respectively. All 6 treated patients showed rapid engraftment of transduced cells. In the five patients with available data at one year post-GT, the median VCN was 0.3 (range 0.2-0.9) and 0.8 copies/cell (range 0.3-2.5) in peripheral blood mononuclear cells (PBMCs) and CD15+ cells, respectively; the percentage of transduced BM progenitors ranged from 18.6% to 85.4%. ARSA activity increased to supranormal levels in PBMCs and normal levels in cerebrospinal fluid (indirect measure of functional ARSA enzyme in the CNS) at the latest follow-up.

Conclusion
This interim analysis suggests that the drug product characteristics, short-term safety profile, and pharmacodynamic efficacy of arsa-cel in LJ-MLD align with previous studies in early-onset MLD. Further follow-up is ongoing to assess brain imaging, clinical efficacy endpoints, and long-term safety

87 Autologous human peripheral blood B cells genetically engineered to express human iduronidase: Results from a first-in-human clinical trial in subjects with mucopolysaccharidosis type I (MPS I)

Paul Orchard[1], Jake Wesley[2], R. Scott McIvor[3], Christiane Hampe[4], Glen Grandea[2], Erik Olson[2], Kole Meeker[5], Cassidy Papia[6], Joell Solan[6], Robert Hayes[7], Sean Ainsworth[2], Robert Sikorski[2]
[1]University of Minnesota, Blood and Marrow Transplant & Cellular Therapy, Minneapolis, MN, [2]Immusoft Corporation, Seattle, WA, [3]University of Minnesota, Minneapolis, Minnesota, [4]Immusodt, Seattle, WA, [5]Immusoft Corporation, Tulalip, WA, [6]Immusoft, Seattle, WA, [7]Immusoft, Walnut Creek, CA

We report clinical outcomes from the first administration of genetically engineered B cells in a human subject. MPS I is a rare ($1/10^5$) lysosomal disease caused by a deficiency of a-L-iduronidase (IDUA), leading to systemic accumulation of glycosaminoglycans, organomegaly, skeletal dysplasias, cardiopulmonary complications and in severe cases neurologic impairment. Current treatments by enzyme replacement or by allogeneic hematopoietic stem cell transplant address some but not all of these manifestations. ISP-001 is an autologous B cell product engineered to express human IDUA for the treatment of MPS I. ISP-001 is generated from a non-mobilized peripheral blood apheresis product, enriched for the CD19+ fraction, expanded in culture and genetically engineered for human IDUA expression using the *Sleeping Beauty*transposon system. The first subject is a 25-year-old male who has been on enzyme replacement therapy (ERT; laronidase) for 13 years. He was infused with a low dose of ISP-001 (2.29×10^7 CD19/kg) in November 2023 while continuing ERT. No chemotherapy was administered. At 12 months post infusion no safety concerns have been identified, including a review of available data at 6 months by the FDA and an independent data and safety monitoring committee. Transposed cells were detected by quantitative PCR in marrow samples at 3 and 6 months. Urine glycosaminoglycans (GAGs) decreased into the normal range for the first time during the first six months post-treatment. Surprisingly, cerebrospinal fluid heparin sulfate levels also decreased post-treatment. Range of motion (shoulder flexion) improvement was noted through 48 weeks post treatment versus baseline. There was also continuous improvement in the subject's six-minute walk test, reaching the normal range at 12 months post-treatment. In summary, dosing of the first patient with genetically engineered autologous human B cells (ISP-001) demonstrated excellent safety to date and encouraging early pharmacodynamic and clinical activity in combination with ERT. These early results support both the dose escalation of ISP-001 to treat MPS I and the expansion of this new engineered B cell platform to treat other human diseases.

AAV Gene Transfer (A): Crossing the Blood-Brain Barrier

88 Widespread CNS Delivery With Best-In-Class Liver Detargeting Following Intravenous Injection of a Novel AAV

Mugdha Deshpande[1], Daniel Bloodgood[1], Barbara Diaz-Rohrer[1], Stephen Malina[1], Sarah Hilton[2], Samuel Wolock[1], Lindsey Campion[1], Amanda Miles[1], Carrie Maryak[1], Adithya Ramesh[1], Arpan Ghosh[1], Kathy Lin[1], Jamie Kwasnieski[1], Adrian Veres[1], Eric Kelsic[1]

Intravenous (IV) administration of AAV gene therapies is limited by the high burden of AAV to off-target tissues and the high doses required to achieve sufficient on-target delivery. Minimizing liver tropism while improving blood-brain barrier (BBB) crossing allows for the use of lower IV doses to achieve widespread CNS delivery, thus improving the safety and lowering the cost of CNS-targeted therapies. Using large datasets from multiplexed libraries tested in non-human primates (NHPs), AI model-based design enables the simultaneous optimization of on-target CNS and off-target liver delivery. Here we present characterization of a novel capsid designed with this AI-based approach showing best-in-class liver detargeting combined with broad delivery across the CNS after IV administration.

From a high-throughput library of ~100,000 synthetically designed capsids tested in two cynomolgus NHPs (M. fascicularis), we identified a capsid which achieved 335x greater aggregate brain transduction and 32x improved liver detargeting when compared with AAV9. Next, we evaluated the performance of this capsid individually in adult cynomolgus NHPs with a self-complementary transgene administered via IV delivery at doses of 4e12 and 3e13 vg/kg. At 3e13 vg/kg, this capsid showed widespread transgene delivery across the CNS, combined with strikingly improved liver detargeting, reaching vector genome biodistribution as low as 0.75 vg/dg in the liver. In

the CNS, we observed transduction in 14% of neurons in the motor cortex, in 19% of neurons in the premotor cortex and in 14-17% of neurons in the basal ganglia using RNAscope. In the liver, transgene protein IHC revealed transduction in 0.76% of hepatocytes at the 3e13 vg/kg dose, even though the payload used a strong ubiquitous promoter, thus highlighting the greatly improved safety profile. As compared to IV-administered AAV9 in NHP studies where the liver receives roughly ~1000X higher vector genome copies than the CNS, this capsid has a dramatic shift in biodistribution to only ~4X higher vector genomes in the liver compared to the motor cortex. In addition to characterizing in vivo properties in NHPs, we confirmed the interaction of this capsid with a candidate receptor that is expressed in the human BBB and whose human and NHP orthologs are highly conserved.

Together these data present an engineered AAV capsid that achieves substantial liver detargeting combined with improved blood-brain barrier crossing, making it an excellent candidate for clinical development of low dose IV-administered gene therapies targeting neurological diseases.

89 Rationally Designed Receptor-targeting AAV Variants Achieved Efficient CNS Transduction in both Mice and NHPs

Jingbo Liu[1], Jing Kou[1], Shaoyong Li[2], Qingzeng Wang[3], Yu Ding[1], Xin Xin[4], Mingwen Liu[1], Pengfei Yu[1], Ye Zhang[3], Zhongwan Li[3], Chunjuan Song[3], Guo-Jie Ye[5], Shuyuan Chen[6], **Zhenhua Wu[7]***

**Corresponding Author*

Intravenous administration of recombinant adeno-associated virus (rAAV) vectors delivering therapeutic payloads with broad distribution in the central nervous system (CNS) provides a non-invasive and promising treatment for many neurological diseases. Several engineered AAV9 variants have been demonstrated to penetrate blood-brain barrier (BBB) in mice but not in non-human primates (NHPs). We developed a Receptor-targeting AAV (RtAAV®) capsid engineering platform for efficient CNS distribution and cross-species translatability. A polypeptide library was incorporated into AAV capsids and screened for binding conserved transferrin receptor 1 (TfR1). Top-performing AAV capsids incorporated with different TfR1-targeting polypeptides were individually packaged with cynomolgus frataxin (FXN) transgene with tags driven by ubiquitous promoter. The capsids were intravenously injected into adult cynomolgus macaque at the dose of 2E13 vg/kg/capsid. Three weeks after injection, the animal was euthanatized, and tissues were collected for vector genome (vg) copy and transgene expression analysis by using ddPCR. One variant, RtAAV001 exhibited up to 14-fold and 12-fold improvements over AAV9 at vector genomic DNA (gDNA) level in the brain and spial cord, respectively. In an individual validation study, RtAAV001 capsid packaged with CMV-GFP-HA transgene expression cassette was intravenously administrated into adult cynomolgus macaque at dose of 5E13 vg/kg. Three weeks after administration, tissues were harvested and processed for vector gDNA and transgene mRNA analysis, as well as immunohistochemical (IHC) staining for protein expression characterization. High levels (6 – 25 vg/diploid genome) of vector gDNA were observed in all CNS regions examined. IHC analysis and immunofluorescent (IF) co-staining of NeuN and GFP-HA demonstrated efficient and broad neuron transduction by RtAAV001 in the CNS of NHP (Fig. 1A and 1B). About 17%, 30%, 42%, 58%, 61%, and 36% of neurons were transduced in the putamen, thalamus, cerebral cortex, hippocampus, lateral geniculate nucleus (LGN) and cerebellum, respectively. To test if RtAAV001 can penetrate BBB and transduce CNS across species, adult C57BL/6 mice were intravenously injected with RtAAV001 at dose of 1E12 vg/mouse. Compared to AAV9 control, RtAAV001 showed about 20-fold improvements at gDNA level in the CNS. About 42-fold and 62-fold enhancements over AAV9 at transgene mRNA levels were observed in the brain and spinal cord, respectively. The efficient and broad neuronal transduction of RtAAV001 in mice was also confirmed by co-staining of NeuN and GFP-HA (Fig.2). About 50%~90% of neurons in the mouse brains were transduced after intravenous delivery of RtAAV001. Interestingly, RtAAV001 showed diminished transduction in the liver. In conclusion, by rationally designing AAV capsids with incorporated TfR1 binding peptides, we successfully generated and validated novel AAV variants that can efficiently penetrate the BBB and transduce the CNS in both mice and NHPs following intravenous administration. These novel RtAAV® capsids represent more efficient and translatable delivery tools for AAV-based gene therapy for neurological diseases.

90 Cryo-EM unveils molecular mechanism of liver detargeting and neuronal tropism of CNS-enhanced AAV capsids

Seongmin Jang[1], Tyler Brittain[1], Jin Hyung (Alex) Chung[2], Gerard Coughlin[3], Izabela Giriat[4], Fiona Ristic[1], Yaping Lei[5], Zhe Qu[5], Nathan Appling[6], Camille Chossis[7], Timothy Shay[8], Viviana Gradinaru[4]
[1]Caltech, Pasadena, CA, [2]Caltech, Monterey Park, CA, [3]California Institute of Technology, Pasadena, California, [4]California Institute of Technology, Pasadena, CA, [5]Caltech, Pasadena, [6]Caltech, Pasadean, [7]California Institute of Technology (Caltech), Pasadena, CA, [8]CLOVER Center, Caltech, Pasadena, CA

Developing adeno-associated virus (AAV) vectors capable of crossing the blood-brain barrier (BBB) while minimizing liver transduction remains a key challenge in gene therapy for neurological disorders. The highly brain-enhanced capsid AAV-PHP.eB was developed by inserting a 7-amino acid (7-mer) sequence into variable region (VR)-VIII. Further refinement with an additional 7-mer substitution in VR-IV resulted in a highly liver-detargeted variant, AAV.CAP-B10.

Here, we report single-particle cryo-electron microscopy (cryo-EM) structures of CAP-B10 alone and in complex with AAV receptor (AAVR) domain PKD2 at resolutions of 2.03 Å and 2.30 Å, respectively. Our structural analysis revealed that CAP-B10 retains a VR-VIII configuration similar to PHP.eB, which facilitates binding to the BBB-transducing receptor LY6A while introducing steric hindrance that reduces AAVR affinity. Additionally, sequence changes in VR-IV alter the conformation of residues 454 and 456, further decreasing the affinity of CAP-B10 to AAVR-PKD2. Biochemical assays, including pull-down experiments and biolayer interferometry (BLI), confirmed that CAP-B10 exhibits significantly reduced AAVR binding compared to PHP.eB. Notably, substituting residues 454 and 456 in PHP.eB to match those in CAP-B10 resulted in a substantial reduction in AAVR interaction and liver transduction efficiency. These findings suggest that evolutionary modifications favoring liver detargeting are closely linked to the disruption of AAVR binding.

Reducing AAVR affinity also led to diminished astrocytic transduction, thereby shifting CAP-B10's cell tropism toward neurons. This indicates that altering AAVR interactions can modulate capsid tropism. We solved additional cryo-EM structures of AAV9-X1, AAV9-X1.1, and the AAV9-X1.1-PKD2 complex at resolutions of 3.10 Å, 2.40 Å, and 2.25 Å, respectively. AAV9-X1.1, which features the same VR-IV 7-mer substitution as CAP-B10, showed reduced AAVR binding relative to AAV9-X1, though the reduction was less than that observed for CAP-B10. This implies that effective liver detargeting results from synergistic steric effects of modifications in both VR-VIII and VR-IV.

Our findings suggest a dual-pronged approach for engineering brain-specific AAV capsids: reducing AAVR binding to minimize off-target transduction and introducing central nervous system (CNS)-specific receptor interactions to ensure efficient trafficking and transduction. This strategy provides a framework for tailoring AAV capsids to treat CNS disorders.

91 Discovery of AAV9-derived CNS capsids evading pre-existing neutralizing antibodies

Damien Maura[1]*, Jennifer Yu[1], Daniel Cox[1], Xiaoqin Ren[1], Matthew Child[1], Rupinderjit Kaur[1], Zachary Thorpe[1], Jiachen Liu[1], Alexandra Tsolias[1], Jeff Thompson[1], Amy Bruce[1], Joydeep Ghosh[1], Su Jing Chan[1], Roberto Calitri[1], Brett Hoffman[1], Tyler Moyer[1], Johnny Yao[1], Charlotte Chung[1], Chanchal Sadhu[1], Jeron Chen[1], Todd Carter[1], Mathieu Nonnenmacher[1]*

Adeno-Associated Virus (AAV) gene therapy holds significant potential for treating a broad range of human genetic disorders. However, its application is often constrained by the presence of pre-existing anti-AAV antibodies, which arise from previous exposure to natural AAVs. These antibodies hinder AAV biodistribution and tissue transduction, especially for systemically administered AAVs. Recent advancements in capsid engineering have not only enhanced AAV tissue tropism but also opened avenues for improving other key AAV characteristics.

In this study, we leveraged our proprietary RNA-driven TRACER evolution platform to detarget Voyager's 2nd generation AAV9-derived CNS-tropic capsids from neutralizing antibodies (NAbs). We evolved potential epitopes displayed on the capsid surface and screened the resulting libraries *in vitro* and *in vivo* in the presence of monoclonal NAbs and/or human intravenous immunoglobulin (IVIG) to maximize the clinical relevance.

We identified several capsid families with specific amino acids enriched by IVIG selection pressure at several mutation hotspots. The top capsid candidate was able to evade neutralization by 30% of NAb-positive human sera, while retaining mouse brain transduction properties of its CNS-tropic parent. Most importantly, this capsid was still capable of transducing the brain of Cynomologus macaque with pre-existing anti-AAV9 neutralizing antibodies,

whereas transduction by its parent was completely eliminated. Moreover, the mutations present in this capsid did not alter brain cellular tropism.

Additional mutations in a different capsid region further enhanced NAb evasion, achieving resistance to up to 43% of AAV9-neutralizing human sera; however these mutations adversely affected NHP brain transduction. Remarkably, a second generation of mutations in this region, identified using Machine Learning capsid modeling, enhanced both antibody evasion and brain transduction in pooled capsid library assays.

Overall, this study identified a 3rd generation of bioengineered AAV capsids with mutations conferring evasion from pre-existing neutralizing antibodies while retaining the improved CNS tropism of their 2nd generation parent. These novel capsids have the potential to significantly improve a key bottleneck in AAV treatments by increasing patient eligibility to receive AAV gene therapies.

92 Incorporation of Transferrin receptor binder and surface mutations into AAV enables efficient brain delivery and reduced liver tropism

Efficient intravenous delivery of adeno-associated virus (AAV) gene therapy for CNS indications in humans has been limited by a poor penetration of any AAV serotype across the blood-brain barrier (BBB) and is further restraint by frequently observed liver toxicity. To overcome these liabilities, we created AAVs with the following modifications: Firstly, we incorporated an expression cassette in the production plasmid for an AAV that encodes the transferrin receptor (TfR) binder previously used successfully to transport protein therapeutics into the CNS via receptor-mediated transcytosis. The TfR binder cross-reacts with cynomolgus monkey and human TfR, thereby easing the validation across species. Secondly, we modified several capsid domain encoding sequences in the production plasmid to investigate their influence of decreasing liver tropism.
For the initial validation in mice, we compared the efficacy of AAV9 or TfR-binder tagged AAV encoding green fluorescent protein (GFP) in the CNS transduction efficiency in human-TfR knock-in mice.
A 77-fold higher expression of GFP was observed in mice intravenously injected with the TfR-binder tagged and liver-detargeted AAV. Analysis of VG in liver revealed a 99% reduced tropism to the liver compared with AAV vectors that did not contain capsid modifications to reduce liver tropism. Immunohistochemistry against GFP revealed a homogenous expression of GFP in mice injected with the tagged virus.
Next, in an attempt to further increase brain transduction, we combined TfR-binder and another tag which targets a second receptor, and compared brain uptake in mice. We observed more than 2-fold increased transduction for the AAV containing binders for two separate receptors compared to TfR-binder tagged AAV.
We then validated the technology in non-human primates (NHP) and intravenously injected a cynomolgus monkey with untagged AAV9 encoding mCherry and dual tagged, liver-detargeted AAV encoding mRuby2. Tens to hundreds-fold increase of transduction was observed across regions of the brain in NHPs injected with the modified dual tagged AAV. Analysis of VG in liver revealed more than 90% reduced tropism of the modified dual tagged AAV compared with AAV9. Transduction of dorsal root ganglia, which can be a safety concern, was also reduced more than 90% compared with AAV9.
We finally validated the technology on a mouse model of CLN2 (Batten's type 2). In this model, mice lack the enzyme TPP1 which leads to the accumulation of toxic substrate lipofuscin in several parts of the body, including the CNS. Untreated TPP1 KO mice had a life span of ~160 days, which was barely increased with TPP1 enzyme replacement therapy. Infection of TPP1 KO mice with tagged AAV encoding TPP1 led to a functional cure as indicated by survival and absence of tremor.
We conclude that our modified AAV capsids may provide an invaluable tool for the safe and efficient delivery of gene therapy to the CNS.

93 Identification of Multiple Novel Blood-Brain-Barrier Receptors for CNS Gene Therapy and Other Drug Modalities via an Integrated AAV Capsid Engineering Platform

Significant progress has been made in recent years targeting novel therapeutics to the CNS by leveraging known blood-brain-barrier (BBB) shuttling mechanisms like the transferrin receptor. Building upon this work, we have leveraged our high-throughput AAV directed evolution platform to screen for novel shuttling proteins localized to the BBB that enable more efficient and specific CNS delivery. Leveraging Capsida's high-throughput capsid engineering platform, we designed viral libraries with targeted peptide insertions and substitutions across multiple surface-exposed loops that converge to form a binding pocket. We then systematically screened capsid libraries derived from multiple AAV serotypes across >100 non-human primates (NHPs) and identified at least 5 novel binding proteins that mediate CNS shuttling, to date. Notably, these receptors stand out for their diverse advantages in CNS delivery, demonstrating higher expression specificity in brain vasculature compared to known BBB receptors, and demonstrating the ability to bias delivery towards certain cell types within the CNS like neurons or glial cells.

In characterization studies, the novel BBB shuttling mechanisms have demonstrated the ability for their AAV binders to transduce >80% of neurons throughout the CNS, with >99% specificity for neurons relative to other cell types, showcasing the capability of these novel BBB shuttling proteins to mediate greater efficacy and specificity for CNS-targeted therapies. Sequence analysis has revealed high sequence identity across rodents, NHPs, and humans, and in vitro assays have confirmed cross-species capsid protein binding, enabling a more predictive path from discovery to the clinic. Taken together, these findings demonstrate the capability of our integrated capsid engineering platform to identify both CNS-tropic AAVs and an unmatched portfolio of BBB shuttling mechanisms, paving the way for not only highly targeted AAV variants but also the development of non-viral CNS drug modalities that mediate greater CNS efficacy and specificity.

94 Engineering Second-Generation Human Transferrin Receptor 1 (TfR1)-Targeting Capsids with Enhanced Brain Transduction via Differential Directed Evolution and Site Saturation Mutagenesis

Mengying Zhang[1], Nadia D'Lima[2], Samneet Kashyap[1], Margaret Kelemen[1], Darryna Guy-Williams[1], Pete Clarner[1], Xiaodong Lu[1], Misha Chittoda[1], Harini Sampath[1], Samantha Desmarais[1], Shawn Bourque[3], Aditya Utturkar[1], Ankur Thomas[2], Bin Wang[2], Deeptha Gokul[1], Neil Shah[1], Caitlin Meeks[1], Junghae Suh[1], Yuan Yuan[1]

Achieving safe and efficient gene delivery remains a significant challenge for central nervous system (CNS)-targeted gene therapy. Recombinant adeno-associated viruses (rAAVs) developed through directed evolution have shown potential as CNS-targeting vectors. However, these novel capsids may face limitations in human translatability due to genetic differences between humans and model organisms. To address this, we have developed Differential Directed Evolution, a method designed to engineer capsids that can penetrate the blood-brain barrier (BBB) by binding to human receptors. This technique involves screening peptide-insertion AAV libraries in parallel using a humanized knock-in (KI) mouse model and wild-type (WT) mice, allowing us to identify human transferrin receptor 1 (TfR1)-dependent CNS capsids through bioinformatic analysis. Utilizing this approach, we successfully identified our first generation (Gen1) of hTfR1-targeted capsids, which demonstrate enhanced CNS targeting in hTfR1 KI mice.

To identify additional hTfR1-targeting capsids, we designed an optimization library from two separate initial libraries. The resultant optimization library was then screened in WT and hTfR1-KI mice. Several promising capsid variants exhibit strong hTfR1-dependent CNS transduction. A subset of these were selected for further validation and characterization. Top second-generation (Gen2) capsids show hTfR1-dependent transduction in a cell-based assay, confirming their interaction with the human TfR1 homolog. When evaluated in hTfR1 KI and WT mice following intravenous injection, Gen2 capsids exhibit hTfR1-dependent widespread CNS transduction in KI mice.

In summary, we identified additional hTfR1-targeting capsids through optimized Differential Directed Evolution (Gen2 capsids) with enhanced CNS transduction. These capsids may provide new options as gene delivery vehicles for neurological disorders.

Translational Applications of Base and Prime Editors

95 *In Vivo* Delivery of HBG1/2 Promoter Editing Cargo to HSC of Humanized Mouse and Non-Human Primate with Lipid Nanoparticle

Introduction
Induction of fetal hemoglobin (HbF) by editing DNA regulatory elements to reactivate γ-globin gene (HBG1/2) expression is a clinically validated therapeutic strategy for sickle cell disease (SCD) and β-thalassemia. Ex vivo–based autologous genome editing of the HBG1/2 promoter of hematopoietic stem and progenitor cells (HSPCs) for hematopoietic stem cell transplantation (HSCT) has shown promising results in clinical trials of renizgamglogene autogedtemcel (reni-cel). Patients receiving reni-cel in these trials were observed to have rapid and sustained increases in HbF, early correction of anemia, and durable normalization of total hemoglobin. The patient journey for ex vivo genome-edited HSCT, requiring both HSPC mobilization and collection and myeloablative conditioning, is burdensome and limits patient access to the therapy. Thus, an in vivo–based genome editing approach using the clinically validated HBG1/2 promoter–targeted gene editing strategy offers potential to significantly decrease patient burden and provides an opportunity for global access.

Methods
We developed targeted lipid nanoparticles (tLNPs) that deliver green fluorescent protein (GFP) mRNA and editing cargos in vivo to HSPCs and/or hematopoietic stem cells (HSCs) in bone marrow (BM) of NBSGW mice engrafted with human CD34+ HSPCs (hNBSGW mice). The potency of the editing machinery was improved with a multi-pronged approach, including targeting moiety and lipid composition optimization. We tested a leading tLNP carrying GFP mRNA and HBG1/2 editing cargo in an hNBSGW mouse model and non-human primates (NHPs; Cynomolgus macaques).

Results
Switching targeting moiety on the base LNP formulation increased GFP expression and HBG1/2 editing in HSPCs in BM of hNBSGW mice after a single intravenous (IV) administration. This targeting moiety enabled higher editing of HSCs (Lin-CD34+CD38-CD45RA-CD90+). With B2M gRNA editing cargo, B2M knockout was achieved in 16% of HSPCs and 72% of HSCs based on flow cytometry analysis of human leukocyte antigen 1 week after dosing. Systemic delivery of this tLNP containing GFP mRNA resulted in GFP expression in ~90% of HSPCs (Lin-CD34+CD38-CD45RA-CD90+) in hNBSGW mice. Further optimization of the tLNP composition described

above led to B2M knockout in 42% of HSPCs and 84% of HSCs in hNBSGW mice. Editing levels for the HBG1/2 promoters with this optimized tLNP were 29% in HSPCs after 1 week and ~40% in HSCs after 4 weeks. Corresponding HbF induction was observed upon editing the HBG1/2 promoters; HbF-positive red blood cells in BM increased from 2% in controls to ~23% (13.1%–41.2%) in the treatment group at 4 weeks. Using the tLNP, delivery and editing were evaluated in NHPs after a single IV injection. tLNP containing GFP mRNA showed ~75% of the HSCs (CD34+CD90+CD45RA-) were GFP+. A single IV injection of this tLNP carrying surrogate HBG1/2 gRNA editing cargo resulted in editing levels of up to 26% in HSCs 1 week after tLNP treatment. Evaluation of the more optimized tLNP composition in NHPs is ongoing.

Conclusion
Our data from humanized mouse and NHP models represent a significant advancement in developing in vivo gene editing therapies for treating β-hemoglobinopathies. As ~30% donor chimerism can significantly ameliorate disease symptoms in patients with SCD, the editing level and percentage of HbF-positive cells achieved with in vivo editing of HBG1/2 promoters may be therapeutically relevant and supports further

96 In Vivo Prime Editing Rescues Alternating Hemiplegia of Childhood in Mice

Alternating hemiplegia of childhood (AHC) is a neurodevelopmental disorder that presents within the first 18 months of life with recurrent paroxysmal attacks that include hemiplegia (paralysis affecting one side of the body), dystonia (painful involuntary muscle contractions), abnormal eye movements, and seizures. Patients with AHC also exhibit non-paroxysmal hypotonia (low muscle tone), developmental delay, and intellectual disability. AHC is exceptionally rare, with an estimated incidence of 1 in 1,000,000, and no disease-modifying treatments have been reported. Approximately 75% of AHC cases are associated with pathogenic variants in *ATP1A3*, which encodes the catalytic α_3 subunit of the neuronal Na^+/K^+ ATPase protein complex.

Here, we report prime editing (PE) and base editing (BE) correction of AHC mutations in human cells and in two mouse models of AHC. In engineered HEK293T cells and iPSCs derived from patients with AHC, we developed PE and BE strategies that efficiently correct (40-90% in treated cells) five *ATP1A3* mutations that together cause more than 65% of *ATP1A3*-linked AHC cases (Figure 1). To investigate how gene editing can mitigate the pathology of AHC *in vivo*, we engineered PE strategies to efficiently correct the mouse *Atp1a3* D801N and E815K mutations—orthologous to the two most prevalent human pathogenic variants—in two AHC mouse models. Dual AAV-mediated delivery to the mouse CNS as a P0 intracerebroventricular injection efficiently corrects the *Atp1a3* D801N and E815K mutations (up to 48% efficiency in cortex), significantly rescues a survival defect in D801N mice (Figure 2), and rescues clinically-relevant behavioral phenotypes, including stress-induced paroxysmal episodes, in D801N and E815K mice. Collectively, these findings establish efficient and precise genome editing strategies that correct the most prevalent AHC mutations and the first durable multi-phenotype rescue of AHC in animals. Our work provides a proof-of-concept for in vivo prime editing in the CNS of an animal model to rescue a neurological disorder, and suggests the feasibility of a one-time gene editing treatment that can mitigate the pathology of AHC through direct, efficient correction of AHC-causing mutations.

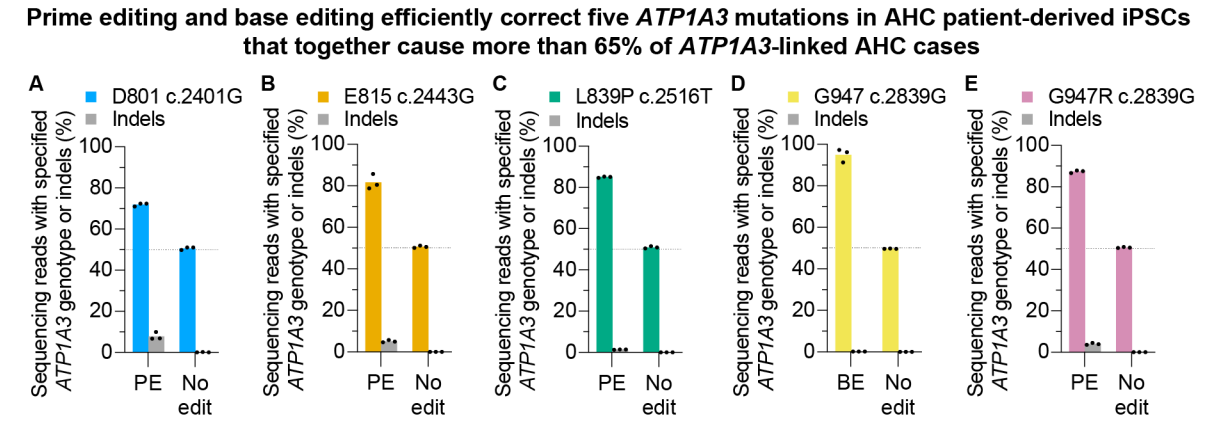

Figure 1. Monoclonal iPSCs derived from AHC patients with heterozygous *ATP1A3* mutations were used to evaluate correction with prime editing (PE) and base editing (BE). X-axis labels identify conditions treated with PE, BE, or control conditions in which cells were not edited ("No edit"). Because iPSCs derived from AHC patients are heterozygous for pathogenic *ATP1A3* mutations, all samples start from approximately 50% wild type genotype. Data represent the mean of n = 3 independent biological replicates and dots show individual replicate values. **(A)** PE correction of D801N c.2401A to D801 c.2401G. **(B)** PE correction of E815K c.2443A to E815 c.2443G. **(C)** PE correction of L839P c.2516C to L839 c.2516T. **(D)** BE correction of G947R c.2839A to G947 c.2839G. **(E)** PE correction of G947R c.2839C to G947 c.2839G.

Figure 2. Introduction:
Mucopolysaccharidosis Type 1 (MPS-1H, Hurler Syndrome) is a progressive, multisystem disorder caused by the alpha-L-iduronidase (IDUA) G◊A (W402X) point mutation, resulting in IDUA deficiency and lysosomal accumulation of glycosaminoglycans (GAGs). Previous studies have demonstrated efficient liver and heart editing in a murine model of MPS-1H (Idua-W392X) following adeno-associated virus serotype 9 (AAV9) mediated delivery of an adenine base editor (ABE) *in utero* via intravenous (IV) injections, but brain editing was minimal. This study aims to evaluate *in vivo* AAV9/ABE delivery via intracerebroventricular (ICV) injection for treatment of MPS-1H.

Methods:
Idua-W392X mice were injected at postnatal day 0 (P0) with split-intein AAV9 vectors containing ABE 8.8 and *Idua*-W392X-gRNA via IV, ICV, or dual IV/ICV injections. Age-matched, uninjected Idua-W392X mice and age-matched healthy mice (B6) served as controls. Terminal analysis was performed at 6 months, at which time mice underwent neurobehavioral testing. Mice were then euthanized and organs were harvested for DNA sequencing, IDUA enzyme activity and GAG analysis.

Results:
All injected mice survived until terminal analysis at 6 months (n=31). Survival rate of uninjected W392 mice was 80%. Liver editing was on average 39.9% in the IV group (n=11; $p<0.0001$), 25.7% in the ICV group (n=10; $p<0.0001$), and 42.5% in the IV/ICV group (n=10; $p<0.0001$) greater than the W392X control (n=7). In the heart, average editing was 9.0% in the IV group ($p=0.0006$), 6.6% in the ICV group ($p<0.03$), and 9.9% in the IV/ICV group ($p=0.0002$) greater than the W392X control. Average editing in the left cortex was 14.2% in the ICV group and 13.9% in the IV/ICV group compared to 0.4% in the IV group ($p<0.001$). The degree of editing correlated with increased tissue IDUA enzyme activity; higher IDUA activity was demonstrated in the livers and hearts of mice in the IV and IV/ICV groups compared to ICV injected mice and W392X controls. Correspondingly, IDUA enzyme activity was highest in the brain in ICV and dual IV/ICV injected groups compared to the IV group and W392X control. GAG analysis revealed a similar trend. GAGs were significantly lower in the IV and IV/ICV groups in the liver and heart compared to ICV injected mice and W392X controls, while the brain had significantly lower GAGs in the ICV and IV/ICV groups compared to the IV and W392X control groups. IDUA activity and GAG levels were improved in the liver and heart in the ICV group. Rotarod testing for sensorimotor coordination and motor learning demonstrated significant improvement in ICV and dual IV/ICV groups compared to the IV and W392X control groups.

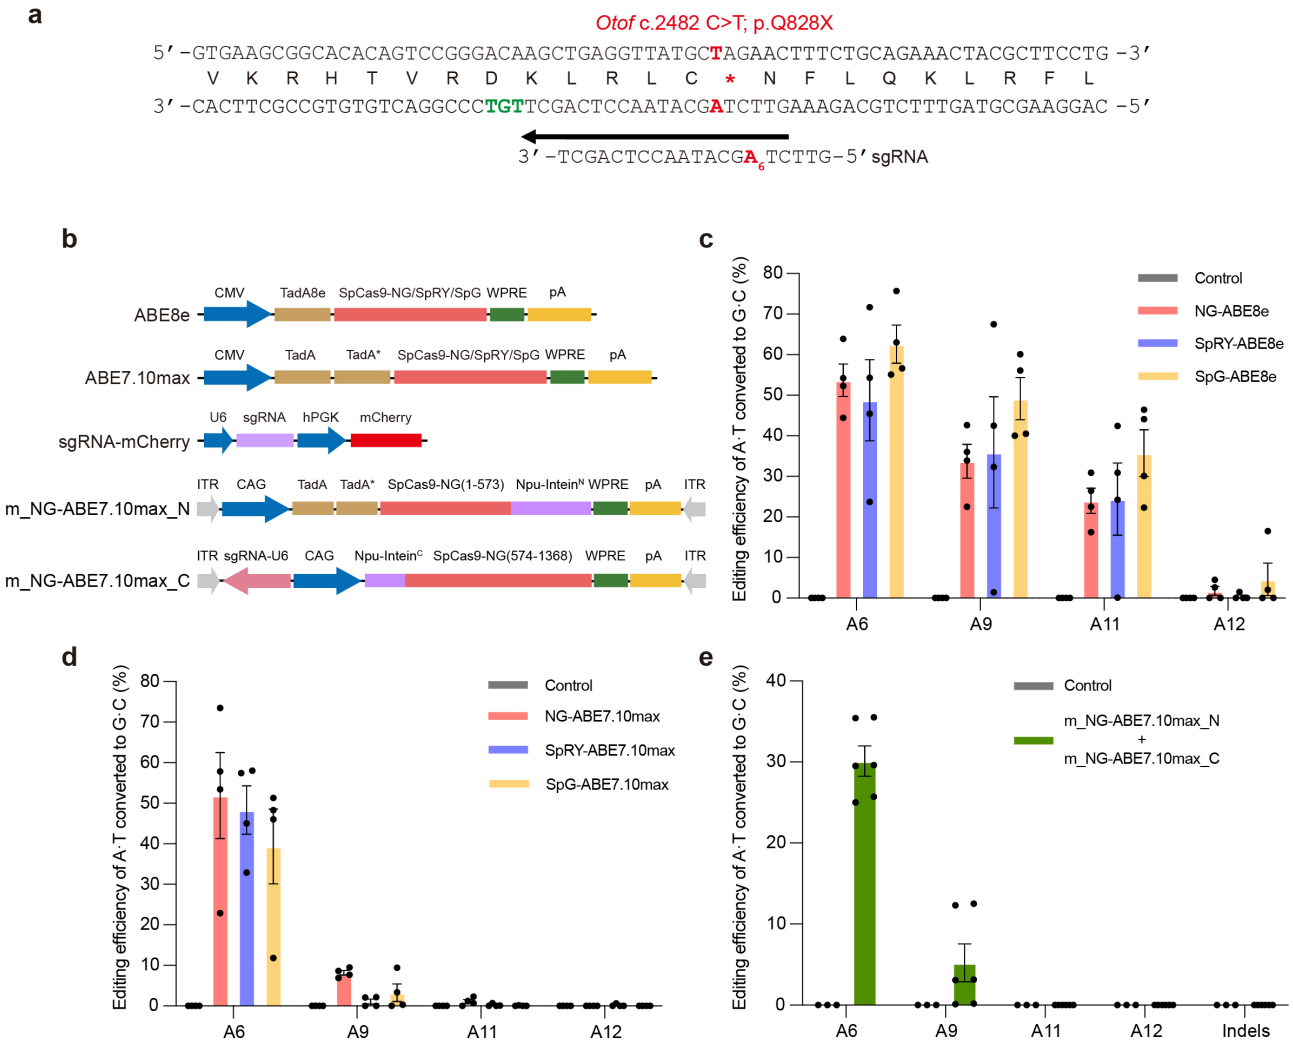
Conclusions:
ICV-mediated injections result in greater brain editing efficiency compared to IV injections. Both IV and ICV injections lead to liver and heart editing. Higher editing correlates with improved survival, increased IDUA activity, decreased GAG accumulation, and neurobehavioral improvements. Our findings demonstrate the potential for ICV-mediated base editing as a therapeutic model for MPS-1H and other neurologic disorders.

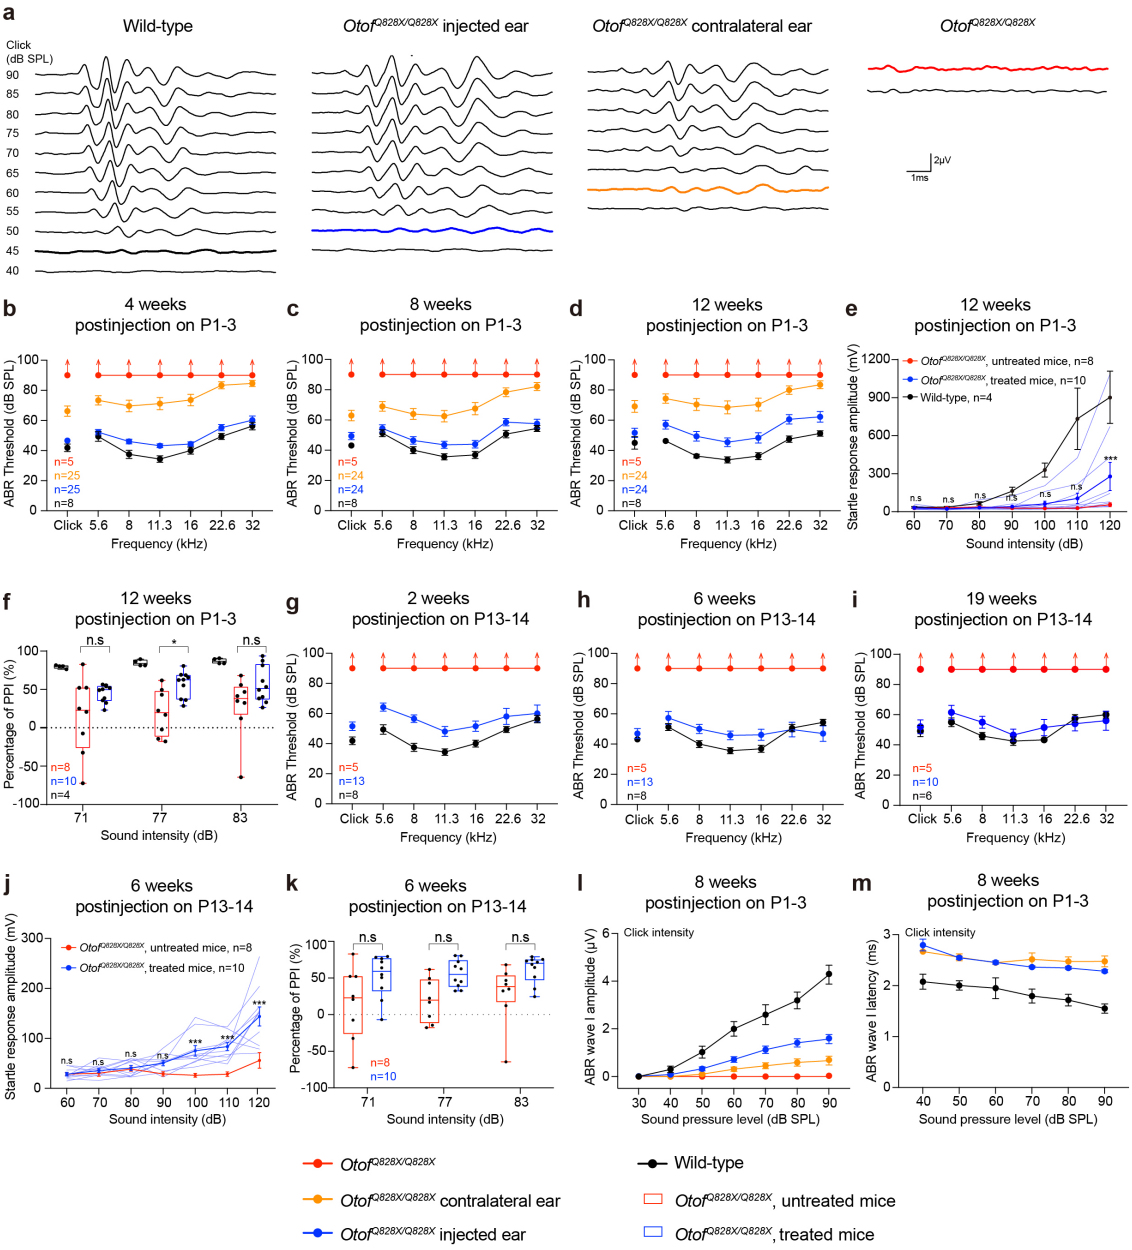
98 A base editor for the long-term restoration of auditory function in mice with recessive profound deafness

Daqi Wang[1], Chong Cui[2], Shengyi Wang[3], Yilai Shu[4]
[1]Eye & ENT Hospital of Fudan University, Shanghai, Shanghai, China, [2]Fudan University Eye Ear Nose and Throat Hospital, CHINA, [3]ENT Institute and Department of Otorhinolaryngology, Eye and ENT Hospital, Fudan University, Shanghai, China, [4]ENT Institute and Otorhinolaryngology Department of Eye & ENT Hospital, NHC Key Laboratory of Hearing Medicine, Key Laboratory of Gene Editing and Cell Therapy for Rare Diseases, Fudan University, Shanghai, China, Shanghai, China

A prevalent recessive mutation (c.2485C>T, p.Q829X) within the OTOF gene leads to profound prelingual hearing loss. Here we show that in Otof mice harbouring a mutation (c.2482C>T, p.Q828X) homozygous to human OTOF that faithfully mimics the hearing-loss phenotype, a base editor (consisting of the deaminase ABE7.10max and the Cas9 variant SpCas9-NG) packaged in adeno-associated viruses and injected into the inner ear of the mice via the round-window membrane effectively corrected the pathogenic mutation, with no apparent off-target effects. The

treatment restored the levels of the otoferlin protein in 88% of the inner hair cells and stably rescued the auditory function of the mice to near-wild-type levels for over 1.5 years while improving synaptic exocytosis in the inner hair cells. We also show that an adenine base editor that targets the prevalent human OTOF mutation restored hearing in humanized mice to levels comparable to those of the wild-type counterparts. Base editors may be effective for the treatment of hereditary deafness.





99 Rescue of Zellweger Spectrum Disorder in Mice and in Patient Cells by Base Editing

Zellweger spectrum disorder (ZSD) is a disease continuum caused by biallelic loss-of-function variants in *PEX* genes required for peroxisome biogenesis and critical for cellular metabolism and signaling. The *PEX1*-p.G843D (c.2528G>A) allele, present in approximately 30% of ZSD patients, frequently results in chronic liver disease that can progress to cirrhosis and hepatocellular carcinoma and also impact neurological health. Here, we report the development and application of an adenine base editing strategy to correct metabolic abnormalities in an established homozygous *Pex1*-p.G844D ZSD mouse model that manifests liver pathologies and metabolic dysfunction found in patients. Through intravenous delivery of AAV9 encoding ABE8e-V106W into both neonatal and four-week-old mice, we achieved up to 60% allele correction in the bulk liver, consistent with the correction of most hepatocytes. By restoring peroxisome function, base editing eliminated the accumulation of very long-chain fatty acids and potentially neurotoxic C27-bile acid intermediates. Elevated levels of phytanic acid, a neurotoxic branched-chain fatty acid substrate of peroxisomal catabolism, were normalized in blood, liver, and brain tissue. Treated mice showed rescue of liver pathologies, normalized liver transcriptomes, and normalized body weights in a dose- and time-dependent manner. Non-viral lipid nanoparticle (LNP) delivery of ABE8e-V106W mRNA to four-week-old mice also yielded correction of the *Pex1*-p.G844D allele correction in 27% of bulk liver cells. In patient-derived fibroblasts, base editing corrected >80% of *PEX1*-p.G843D alleles and restored peroxisome biogenesis. Genome-wide experimental and computational off-target analysis found minimal off-target editing in either mouse or human genomes. Collectively, these findings suggest that liver base editing over a range of ages may benefit a significant proportion of ZSD patients, and provide a foundation for developing precision gene correction treatments that address the root cause of a wide range of peroxisomal disorders.

100 A Type I CRISPR adenine base editor with a guide-length-tunable editing window and its application in correcting CFTR-G542X null mutation

[1]University of Michigan, Ann Arbor, MI, [2]Qi Biodesign, Beijing, Beijing, China, [3]Harvard University/Broad Institute, Cambridge, MA, [4]Harvard University, Boston, MA, [5]Helmholtz Institute for RNA-based Infection Research (HIRI), Würzburg, Germany, [6]Harvard and MIT, Boston, MA, [7]University of Michigan Medical School, Ann Arbor, MI, [8]Harvard University and HHMI, Cambridge, MA

Base editors typically use a DNA deaminase fused to a Cas9 nickase to install single nucleotide conversions without causing double-stranded genomic breaks. They are emerging as a promising platform in human gene therapy, due to their high efficiency in correcting single nucleotide variants and better safety profile. However, the targeting scope of a base editor is confined by an editing window that covers a specific range of nucleotides within the R-loop, and measured from a nearby suitable 2-3-nt PAM.

To overcome this editing window rigidity, we developed a sliding-window type I CRISPR adenine base editor (T1ABE) through extensive protein and crRNA engineering. We first fused a TadA-8e deaminase to the Cas11 subunit of *N. lactamica* (Nla) I-C Cascade and engineered the NlaCas3 nuclease into a ssDNA nickase. The resulting first-generation T1ABE v1 introduces up to 45% A•T-to-G•C edits across multiple endogenous genomic sites and in various human cell lines. T1ABE displayed an unconventional 8-nt activity window on the PAM-distal, target-strand DNA that lies outside the R-loop region.

Exploiting the “Cascade remodeling” property inherent to type I CRISPR, we achieved editing window tunability over a 40-nt range (relative to a fixed PAM) through spacer/guide length extensions. Moreover, through structure-guided engineering and TadA8e-Cas linker optimization, we arrived at a hyper-activity variant T1ABE v3, which can access hard-to-edit sites in the human genome. The prominent features of T1ABE v3, including high-efficiency, a guide-length-tunable window, and T/C-rich PAM preference, should facilitate targeting to a wide range of most genomic sites. Indeed, our computational analysis of the ClinVar database revealed that approximately 95% of the all pathogenic and likely pathogenic G•C-to-A•T mutations in ClinVar would in theory be targetable by T1ABE.

To demonstrate the therapeutic potential of T1ABE's tunable window, we pursued a preclinical application to correct the cystic fibrosis *CFTR(G542X)* null mutation, which lacks small molecule drugs or a current base edit strategy. In an induced pluripotent stem cell (iPSC) model, all-RNA delivery of T1ABE v3 successfully corrected the pathogenic adenine into guanine with a ~32% editing efficiency. The T1ABE-installed edit (resulting in a G542R variant) can restore robust CFTR channel function in our CFTR-dependent organoid swelling assay.

Lastly, we showed that T1ABE exhibited minimal off-target effects at the transcriptome level, and genome level. Our results highlight the potential of type I CRISPR-Cas system to support precise gene correction applications. These findings advance Type I CRISPR as a platform for precision base editing applications.

101 AI-Assisted Development of Compact Base Editors for Enhanced Efficiency and Specificity with Broad Targeting Range

Background:
Base editors provide a revolutionary approach to correcting genetic mutations without causing double-strand breaks (DSBs), minimizing possible adverse effects associated with traditional genome editing tools. While SpCas9-based base editors achieved excellent efficiency and fidelity, their large size hinders their use in the in vivo single AAV delivery systems. Conversely, previous small IscB-delivered base editors enable single AAV delivery but suffer from limitations such as low efficiency, strict TAM requirements, and increased off-target risks due to short spacer lengths (14–16 bp) (Fig. 1C). To address these challenges, we applied artificial intelligence (AI) to develop eMM101ABE8e, a compact and efficient adenine base editor optimized for single AAV delivery.

Methods:
We utilized a computational AI pipeline to analyze bacterial genomes and identified a group of novel Cas proteins, designated MM101 to MM109 (600-800 amino acids). Functional screening using an EGFP-reporter system (Fig. 1A) identified MM101 as a strong candidate. AI-assisted protein engineering enhanced MM101, resulting in eMM101, with 11-fold higher activity (Fig. 1D and E). Based on eMM101, we developed eMM101ABE8e, an adenine base editor (Fig. 1F), and compared its editing efficiency with other base editors derived from IscB, SlugCas9, CjCas9, Nme2Cas9, and SpCas9 across multiple therapeutic targets in HEK293T cells. Additionally, we assessed the efficiency of eMM101ABE8e in induced pluripotent stem cells (iPSCs) through mRNA electroporation. We also evaluated its in vivo performance in a humanized Duchenne muscular dystrophy (DMD) mouse model. Editing efficiency, dystrophin recovery, and therapeutic potential were evaluated using qPCR, immunofluorescence staining, and Western blot analysis. This DMD model was created by deleting mouse exon 51 and replacing mouse exon 50 with its human counterpart (Fig. 2B and C).

Results:
Our study identified MM101 as a promising candidate due to its compact size (2.3 kb), suitable spacer length (19–23

bp), and broad NGG PAM targeting range (Fig. 1B and C). Through protein engineering, we developed eMM101, which exhibited approximately 11-fold higher activity than wild-type MM101 (Fig. 1E). The eMM101ABE8e base editor demonstrated significantly higher editing efficiency compared to IscB-, SlugCas9-, CjCas9-, and Nme2Cas9-based base editors, with performance close to SpCas9ABE8e (Fig. 1G). In iPSCs, eMM101ABE8e achieved comparable editing efficiency to SpCas9ABE8e across therapeutic target loci such as PDCD1 and CD52 (Fig. 2A). In the DMD mouse model, eMM101ABE8e achieved efficient single AAV delivery, modified the splice donor site, and restored dystrophin protein expression to functional levels (Fig. 2D–G).

Conclusions:

The AI-engineered eMM101ABE8e is a compact and efficient base editor with a broad target range and high specificity. Its compatibility with single AAV delivery and successful application in iPSCs and in vivo DMD model underscore its transformative potential for both research and therapeutic applications, paving the way for next-generation precision medicine.

Wilson disease (WD) is a monogenic autosomal recessive disease caused by loss-of-function mutations in the *ATP7B* gene, encoding a copper-transporting ATPase critical for copper homeostasis. Current therapies are supportive, life-long with side-effects and require intensive management. Clinical trials of AAV-mini-*ATP7B* are underway, and the safety, efficacy and durability are still under evaluation. Prime Editing offers the opportunity to correct *ATP7B* mutations back to their wildtype sequence thereby retaining normal gene regulation and full protein function. The *ATP7B* p.H1069Q and p.R778L mutations are highly prevalent and found in more than 40% of patients in the US & EU. Correcting these mutations by Prime Editing offers a potentially curative and one-time therapeutic strategy to address a significant unmet medical need.

We established an iterative high-throughput screening platform to rapidly and robustly optimize all components of Prime Editing *in vitro*, including pegRNA, ngRNA, mRNA and Prime Editor (PE) protein resulting in the discovery of several lead candidates for validation *in vivo*. To model WD *in vivo*, we utilized humanized-*ATP7B* mouse models that carry either p.H1069Q or p.R778L mutation and recapitulate WD patient phenotypes. Following further optimizations to all components of our liver-targeted LNP and RNA cargo, we demonstrated dose-dependent editing in p.H1069Q fully humanized mouse models, achieving >70% precise editing of hepatocytes leading to >75% reduction of copper in the liver. Gene correction and phenotypic rescue were durable 12 weeks after treatment. Further studies are underway to characterize copper homeostasis. Using Prime's suite of biochemical and targeted sequencing assays, no off-target editing was detected in human hepatocytes and WD patient-derived cells, underscoring the precision and accuracy of Prime Editing.

To achieve safe and precise gene correction to the liver, we developed a universal liver-targeted LNP that contains N-acetylgalactosamine or GalNAc conjugated to a PEG-lipid, positioning the GalNAc moiety on the surface of the LNPs. GalNAc facilitates selective uptake by the hepatocyte-abundant ASGPR receptor, enabling precise liver targeting via IV injection. To assess the impact of the universal LNP distribution to liver and testes, rats were administered LNP formulated +/- GalNAc lipid. Tissues were collected at multiple time points and mRNA cargo was assessed as a measure of biodistribution. Based on AUC, the relative liver-to-testes distribution was improved from 36X to 495X with LNPs containing the GalNAc lipid. Notably, mRNA distribution to testes was reduced 5 to 8-fold while mRNA levels in the liver were increased by 60% with addition of the GalNAc lipid.

To demonstrate the safety and effectiveness of our universal LNP platform in large animals, we developed surrogate PEs that target either the *ATP7B* p.H1069 or the *SLC37A4* gene. These surrogate PEs encapsulated as RNA cargo in LNPs, when delivered by IV injection, result in >50-80% precise editing in cynomolgus monkey hepatocytes. Additional NHP studies using these Prime Editors will be presented.

Based on these data, we have initiated IND enabling studies to develop the drug candidate PM577 for the treatment of Wilson disease. Thus, Prime Editing offers the potential of a one-time safe and effective curative approach for Wilson disease patients.

103 Engineering an Endoplasmic Reticulum (ER) Stress Responsive RNA Structural Switch for mRNA and Gene Therapies

Roza Ogurlu[1], Joshua Hull[1], Eliya Sanchez[1], Sophia Fergione[1], Alan Rosales[2], Vivian Yudistyra[1], Gabriela Webb[3], Helen Wu[4], Heather Vincent[5], Jonah Sacha[3], Aravind Asokan[5]
[1]Duke University, Durham, NC, [2]Duke University, Durham, [3]Oregon Health & Science University, Beaverton, OR, [4]Oregon Health & Science University, Beaverton, [5]Duke University, Durham, North Carolina

Protein misfolding and aggregation in the ER leads to ER stress and triggers the unfolded protein response (UPR) pathway, which in turn can activate the innate immune system. Upon activation, 'adaptive UPR' promotes a series of transcriptional and translational events to re-establish ER homeostasis. However, if ER stress persists, an alternate 'terminal UPR' program induces apoptosis. Overexpression of Factor VIII (FVIII), a blood clotting factor, and related derivatives following AAV liver gene delivery for treatment of severe hemophilia A has been linked to ER stress induction in preclinical studies and hepatotoxicity in clinical studies. Similarly, other endogenous or exogenous secreted proteins, such as monoclonal antibodies, can elicit ER stress upon over-expression exceeding critical thresholds, thus decreasing efficacy. Consequently, there is an unmet need to circumvent pro-apoptotic UPR, while maintaining sufficient long-term protein expression in mRNA and gene therapies. One strategy is to take advantage of UPR-linked cell survival promoting mechanisms to preserve an optimal rate of protein production from delivered genes.

Here, we exploit an endogenous feedback loop that involves RNase-mediated rearrangement of X-box binding protein 1 (XBP1) mRNA during adaptive UPR to engineer an ER stress responsive switch. To deploy unconventional XBP1 mRNA splicing in gene delivery, we first incorporated XBP1 mRNA fragments (XBP1F1-5) upstream of reporter genes to validate mRNA splicing and protein expression regulation under chemically induced ER stress. We designed the fusion mRNA in a way that XBP1F splicing introduces stop codons preceding the reporter gene sequence. Then, we replaced reporter genes with therapeutically relevant ER stress causing FVIII and Leronlimab (an anti-CCR5 monoclonal antibody being evaluated for HIV treatment). For both therapeutic proteins, we observed efficient splicing of XBP1F constructs and a significant decrease in ER stress markers in various cell lines when expression was modulated by XBP1F splicing. We also demonstrate a potential application for the XBP1F switches in mRNA therapy by evaluating XBP1F splicing efficiency and ER stress marker expression in cells transfected with in vitro transcribed XBP1F1-Leronlimab mRNA. Notably, key structural domains based on XBP1F stem loops were essential for optimal attenuation of ER stress levels. In order to assess this technology in a preclinical proof-of-concept study, we packaged Leronlimab and XBP1F-Leronlimab into AAV8 and administered vectors to mice intravenously. Including XBP1F in the cassette design reduced interindividual variability of therapeutic mRNA expression and ER stress marker levels in the liver.

To conclude, by leveraging an unconventional splicing mechanism during UPR, we developed an RNA-based gene switch to control expression from delivered nucleic acids (mRNA or DNA) encoding ER stress causing proteins. Further testing and refinement of XBP1F modified therapeutic constructs in animal models with the goal of developing mRNA and gene therapies with decreased immunotoxicity and improved safety profiles is underway.

104 A Hybrid AAV PiggyBac Transposon and mRNA-LNP Transposase System for Arginase Deficiency: Long-Term Survival and Arginine Control, with a 50-fold Dose Reduction Compared to AAV Alone

Kiran Singh[1], Rachel Xu[1], Taryn Diep[1], Stuti Bakshi[2], Isabel Day[2], Blair Madison[3], Bonnie Jacques[3], Joshua Rychak[3], Sang Lee, **Gerald Lipshutz**[4]*
[1]UCLA, Los Angeles, CA, [2]University of California Los Angeles, Los Angeles, CA, [3]Poseida Therapeutics, San Diego, CA, [4]David Geffen School of Medicine at UCLA, Los Angeles, CA
**Corresponding Author*

Introduction:
Arginase Deficiency is a rare metabolic disorder of the urea cycle that results in neurodevelopmental abnormalities

including intellectual disability, progressive neurological decline, and a characteristic gait termed spastic diplegia. While patients have at times elevated ammonia, they characteristically have persistent hyperargininemia and the marked presence of guanidino compounds (e.g., GAA). The main therapy today is dietary which, at best, is only partially effective. Traditional AAV-based gene therapy in a mouse model prevents the disorder with moderate to high doses of a liver-specific AAV vector.

Methods:
We sought to develop an approach that allowed for substantial dose reduction with normalized biochemical characteristics in afflicted mice and potential for durable genomic integration in young mice during liver growth. We applied a hybrid approach in which an AAV9 transposon expressing an ARG1 cDNA is co-administered with a super piggyBac (SPB) transposase as an mRNA-lipid nanoparticle (LNP) to provide rapid, transient SPB transposase expression for genomic integration of the DNA cargo. Adult (8-week-old) conditional arginase 1 knockout mice were divided into 5 groups and followed for 9 months. To initiate arginase deficiency, all mice received Cre Recombinase-mRNA LNP at 1 mg/kg. Negative control mice received vehicle and positive control mice received traditional AAV8 expressing ARG1 under a liver-specific promoter at a dose of 5e13 gc/kg. Transposon/transposase experimental mice were divided into two groups: one receiving active SPB transposase and the other receiving catalytically dead (CD, i.e., inactive) transposase LNP RNA. Along with active or CD-SPB, mice received varying doses of transposon AAV encoding ARG1. All groups included male & female mice (n = 3 each).

Results:
Mice were followed for 9 months with daily weighing (surrogate for health) and monthly blood collection. Vehicle control mice demonstrated substantial weight loss and all perished by day 50 (6 of 6 dead) after administration, while all traditional AAV8.TBG.ARG1 mice survived (6 of 6 alive). While 1 male having received the highest dose of AAV transposon + CD-SPB survived for the length of study, all others perished early (8 of 9 dead) with substantial weight fluctuation. With catalytically active SPB, male mice of all 3 doses survived to the end of study (except one 1e12 dose mouse lost due to anesthesia overdose) (i.e., 8 of 9 alive) as did female mice of all 3 doses (i.e., 9 of 9 alive). While in vehicle control & CD-SPB mice GAA, ammonia, and arginine increased, these were low & stable in active SPB mice. Ammonia challenging (6 mmol/kg ammonium chloride) demonstrated marked improvement of ammonia control with the transposon-based approach compared to classical non-integrating AAV. In a follow-up ongoing study, additional mice were similarly administered an even lower dose of AAV.ARG1-transposon + SPB. Presently at 8 months, 5 of 6 mice are alive with stable weights; analysis of blood ammonia and arginine is underway.

Conclusions:
These studies in aggregate demonstrate promising results of a transposon/AAV carrying ARG1 and mRNA-LNP for hepatic transduction and long-term hepatic arginase expression producing ammonia, arginine, and GAA control at significantly lower AAV doses. Next steps are to examine the approach in a neonatal model with actively growing liver and dividing hepatocytes.

105 Identifying Novel Single Amino Acid Substitutions of Human Factor VIII with Enhanced Cofactor Function for Next Generation Hemophilia A Gene Therapy

Introduction:
Hemophilia A (HA) is a monogenic bleeding disorder that causes prolonged or spontaneous bleeding due to insufficient activity of clotting factor VIII (FVIII). FVIII is integral in the clotting cascade as a cofactor to factor IX (FIX), binding to both activated FIX and factor X (FX) to increase the rate of FX cleavage. The use of AAV gene therapy to permanently treat HA has been impeded by insufficient levels of FVIII expression or the loss of FVIII

expression over time after treatment. While the underlying mechanism for this lack of durable expression has not been elucidated, we have hypothesized that HA gene therapy outcomes can be improved with the use of a FVIII transgene with enhanced activity, similar to the improvement seen in hemophilia B gene therapy with the use of the hyperactive FIX-R338L transgene. Here, we used domain-restricted evolution-directed gene engineering (DREDGE) technology to design and screen single amino acid substitutions of human FVIII to identify individual substitutions that significantly increase FVIII cofactor activity for use in a next generation gene therapy for HA.

Methods:
We have developed the DREDGE technology for protein engineering by focusing on highly conserved amino acids that are not known to cause any reduced function when mutated within a specific domain of a protein of interest. We selected over 50 amino acid positions in human FVIII protein and designed over 200 variants. Substitution variants were generated on a B domain deleted FVIII-SQ backbone, which were then individually transfected into Huh7 cells. The resulting conditioned media was tested for FVIII activity by one-stage activated partial thromboplastin time (aPTT) assay and for FVIII antigen by ELISA. The ratio of activity to antigen was then used to determine changes in the specific cofactor activity of the resulting FVIII protein.

Results:
Initial screening of the over 50 chosen positions found 3 positions at which the substitutions had a positive effect: K570, R571, and K707. Testing every amino acid substitution at each of these 3 positions via site saturation mutagenesis revealed that changes at positions K570 and R571 increased cofactor activity. Changes at position K707 increased FVIII concentration in the media without an increase in specific cofactor activity. Single amino acid substitutions at either position K570 or R571 enhance the specific cofactor activity of FVIII. At position K570, K570V is the most active substitution with an approximate 3-fold increase in cofactor activity. At position R571, R571S is the most active substitution with an approximate 5-fold increase in cofactor activity. One variant of note, R571A, that was identified in our in vitro screen with a ~3-fold increase in specific activity, has just been reported in a human subject showing ~600% specific activity, validating the effectiveness of DREDGE.

Conclusions:
We have efficiently identified and created hyperactive FVIII variants using DREDGE. The variants generated have increased FVIII activity to antigen ratios, allowing for providing high levels of activity at low expression levels. While work is ongoing to validate these variants in vivo and precisely define their specific activity and mechanisms of action, we believe these variants could provide more durable therapeutic benefit in next-generation HA gene therapy. Further, the DREDGE technique could be a useful tool to identify enhanced transgenes for other indications.

106 Development of a Novel Non-Viral Genetic Therapy for Hemophilia A Utilizing Durable, Redosable, and Titratable Approach of Ultrasound-Mediated Delivery of an Oversized Episomal hFVIII DNA Vector

Ivan Krivega[1], Surabhi Rao[2], Victor Foster[3], Margarita Krivega[4], Julia Poniatowski[4], Elizabeth Del Greco[4], Katie Benthall[4], David Kim[5], Nana Ingram[4], Shubhangi Singh[6], Julia Suffoleta[6], Gwendolyn Austin[4], Charles Levine[4], Bert Frederich, Jon Chan[4], Divia Mehra[4], Glenda Arauz[4], Celia Ortiz[4], Anagha Rao[6], Oliver Chen[4], Tanaya Ghosh[4], David Satyadi[4], Jessica Canzolino[6], Matt Lindeblad[4], Sherry Bullens[6], Steven Feinstein[7], Ken Greenberg[4]
[1]SonoThera, Burlingame, CA, [2]SonoThera Inc, San Francisco, CA, [3]SonoThera, San Francisco, CA, [4]SonoThera, South San Francisco, CA, [5]SonoThera, Inc, South San Francisco, CA, [6]SonoThera, South San Francisco, [7]SonoThera, Highland Park, IL

Introduction:
Hemophilia A (HemA), the absence or deficiency of Factor VIII (FVIII) protein is associated with episodes of uncontrolled bleeding resulting in marked increases in morbidity and mortality. Current treatment paradigms require serial injections of recombinant FVIII protein or bispecific antibodies. Recently FDA-approved, viral-mediated, gene therapies offer an alternative one-dose treatment option, albeit with uncertain durability. Once treated, patients may experience variable FVIII therapeutic expression levels and the ability to redose is not an option should the FVIII expression level become subtherapeutic. Transcutaneous ultrasound-mediated gene delivery (UMGD)

represents a novel, targeted, therapeutic option permitting serial redosing as required to sustain therapeutic FVIII levels. As designed, UMGD offers a safe, individualized, and durable treatment option for patients with HemA.

Methods:
SonoThera provides unique genetic engineering expertise in the development of next-generation DNA payload designs including optimized DNA constructs encoding an oversized FVIII transgene (FVIII-ST). Previously, transgenic FVIII expression measurement was performed in vitro using human and mouse cells and subsequently, in vivo in mouse plasma to compare the activity of FVIII-ST with the clinically validated FVIII-V3. The next-generation DNA constructs were coupled with SonoThera's UMGD platform technology for targeted and non-invasive delivery to the subject liver in combination with ultrasound contrast agents and externally applied ultrasound.

Results:
Based on in vivo testing of wild-type mice, Hemophilia A disease model mice, and non-human primates (NHP), SonoThera's FVIII-ST vector revealed superior expression resulting in enhanced efficacy and durability of human FVIII as compared to FVIII-V3. With ongoing optimization of UMGD parameters, FVIII-ST expression levels exceeding 175% of normal were achieved in mouse blood, persisting for over six months following a single treatment without significant elevation of safety endpoints. Further, using serial treatments, marked increases in transgenic FVIII were observed, providing potential dosing regimens to maintain clinical efficacy of FVIII levels. Recently, NHPs undergoing serial UMGD therapy demonstrated reproducible, elevations of human FVIII in blood upon ultrasound-mediated delivery of FVIII-ST to the liver.

Conclusion:
Based on in vitro and preclinical safety and efficacy data in wild type, Hemophilia A mice and NHPs, SonoThera offers a non-viral treatment paradigm as a potential genetic therapy for patients with Hemophilia A.

107 Liver Fibrosis Negatively Impacts *in Vivo* Gene Transfer to Hepatocytes

Liver fibrosis is a pathological process occurring in several genetic and acquired diseases. The fibrotic damage impacts liver architecture and the metabolism of hepatocytes and may negatively affect gene therapy approaches. Adeno-associated viral vectors (AAV) demonstrated clinical efficacy and safety for many inherited diseases. Lentiviral vectors (LV) represent an alternative that allows stable long-term transgene expression in preclinical models of liver disorders. Recently, lipid nanoparticles (LNP) have emerged as promising non-viral vehicles to deliver RNA-based therapeutics or genome-editing agents to the liver. Here, we perform a detailed characterization of the impact of liver fibrosis on *in vivo* gene transfer to hepatocytes by AAV, LV, and LNP in four mouse models. We exploited two chemically induced mouse models that mimic common fibrosis types. Repetitive carbon tetrachloride (CCl_4) administrations for 3 or 6 weeks cause mild or moderate toxic fibrosis in the pericentral area, while diet supplementation with 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) for 3 or 5 weeks leads to moderate or marked biliary fibrosis in the periportal area. We exploited CCl_4- and DDC to induce liver fibrosis in wild-type (WT) and floxed-tdTomato mice. We intravenously administered LV or AAV encoding for reporter genes (human factor IX or mCherry) to WT mice or LNP carrying the CRE-recombinase mRNA to floxed-tdTomato mice. Both pericentral and periportal fibrosis negatively affected LV and LNP-mediated hepatocyte gene transfer. On the contrary, the efficiency of AAV transduction was reduced just in case of periportal fibrosis. Moreover, we employed *Abcb11*$^{-/-}$ and *Agl*$^{-/-}$ mice, which recapitulate features of progressive familial intrahepatic cholestasis type 2 and glycogen storage disease type III, as representative models of genetic disorders characterized by liver fibrosis. We observed mild and minimal periportal fibrosis in the liver of 6-month-old *Abcb11*$^{-/-}$ mice and 9-month-old *Agl*$^{-/-}$ mice, respectively. We administered them with LV or AAV encoding for mCherry and observed slightly reduced

transduction in *Abcb11*$^{-/-}$ mice, while we did not find changes in *Agl*$^{-/-}$ mice. These data suggest that the type and extent of damage determine the impact on gene transfer efficiency. The different gene transfer outcomes may depend not only on the deposition of extracellular matrix but also on blood flow alteration, inflammatory cell infiltrate, or specific cell responses caused by the underlying pathogenic mechanisms. However, we did not detect any alteration in LV clearance and biodistribution in other organs or liver cell types in the presence of CCl_4 or DDC-induced fibrosis. Interestingly, we observed an overall change in the efficiency of gene transfer in different zones of the liver lobule (zonation) in the various models. In the presence of liver damage, LV periportal transduction bias was always reduced, while AAV pericentral transduction bias was modified just in *Abcb11*$^{-/-}$ and *Agl*$^{-/-}$ mice. LNP gene transfer zonation was altered with both CCl_4 and DDC-induced fibrosis. Overall, this work shows that hepatic fibrosis generally reduces hepatocyte gene transfer efficiency but never completely abolishes it. This study has relevant implications for developing liver-directed gene therapies and highlights the need to evaluate delivery vehicles, vector doses, time of administration, and patient selection depending on the underlying liver damage.

108 Steatosis increases human hepatocyte susceptibility to AAV vector transduction

Background & Aims:
Adeno-associated virus (AAV) vector therapies that target the liver have emerged as transformative approaches to deliver systemic proteins for diseases such as hemophilia A (FVIII deficiency) and are under development for many liver conditions. However, for reasons that remain poorly understood responses vary widely between individuals. Metabolic dysfunction-associated steatotic liver disease (MASLD) affects approximately 30% of the global population including 44-57% of hemophilia patients. Given the widespread MASLD prevalence, understanding the impact of human hepatocyte steatosis on liver-targeting AAV transduction efficiency may help optimizing therapeutic outcomes.

Methods:
For in vivo studies, primary human hepatocyte (PHH) engrafted (huFNRG) mice were fed a hypercaloric Western diet (WD) and/or 10% sucrose water for one month to induce liver steatosis or maintained on control chow. Mice were then injected with AAV3B capsid-derived vectors expressing either mScarlet or codon-optimized (co)F8 from a chicken beta-actin (CBA) promoter, and liver tissues or isolated PHH were analyzed for vector uptake and transgene expression two weeks later. For in vitro studies, PHH isolated from huFNRG livers were cultured, treated with oleic acid (OA) to induce steatosis, transduced with AAV3v4 vectors expressing fluorophores from a CBA promotor or FVIII variants from a transthyretin (TTR) promoter, and fluorescence or FVIII activity in supernatants were quantified over weeks.

Results:
A greater proportion of human hepatocytes in steatotic huFNRG mice expressed mScarlet compared to those on control chow, ranging from 1.7-fold higher for mice on 10% sucrose water to 3-fold higher for those on a WD+10% sucrose diet. Higher transduction of steatotic hepatocytes was consistent across various AAV3B-derived capsids. Steatotic livers also demonstrated increased vector DNA uptake and mRNA expression compared to chow-fed mice, with a 3-fold increase for AAV3v4-CBA-mScarlet and a 5-fold increase for AAV3v4-CBA-coF8 vector DNA. OA-treated PHH cultures showed significantly higher fluorophore expression than controls as early as day 3 post-transduction with self-complementary AAV vectors. Similarly, steatosis led to higher FVIII activity levels in AAV3v4-TTR-coF8 transduced PHH cultures starting from day 9 and persistent through day 18, with this effect observed across several variants, including coF8-X5, which exhibited the highest activity.

Conclusion:
Steatotic primary human hepatocytes are more susceptible to productive AAV vector transduction with AAV3B-derived capsids. These results suggest that MASLD may affect AAV gene therapy transduction and highlight the need for optimizing therapeutic strategies for individuals with hepatic steatosis.

CAR T-Cells for Solid Tumors

109 Armored anti-macrophage CAR T cells remodel the tumor microenvironment and control metastatic ovarian and lung tumor growth.

Jaime Mateus-tique[1], Ashwitha Lakshmi[2], Alfonso Sanchez-Paulete[3], Rhea Iyer[4], Alessia Baccarini[5], Brian Brown[6], Chiare Falcomatà
[1]Icahn School of Medicine, New York, NY, [2]University of Illinois Urbana-Champaign, Champaign, IL, [3]Boehringer Ingelheim, New York, NY, [4]mount sinai Icahn School of Medicine, New York, NY, [5]Mount Sinai School of Medicine, New York, NY, [6]Mount Sinai Medical Center, New York, New York

Background
Despite advances in CAR T cells (CAR-T), anti-tumoral efficacy remains elusive for solid tumors. This is primarily due to a lack of specific and persistent antigens on tumor cells and the highly immunosuppressive tumor microenvironment (TME) dominated by tumor-associated macrophages (TAM). To address this problem, we sought to develop CAR T cells that would specifically target and kill immunosuppressive TAMs and deliver immunostimulatory cytokines into the cold tumor.

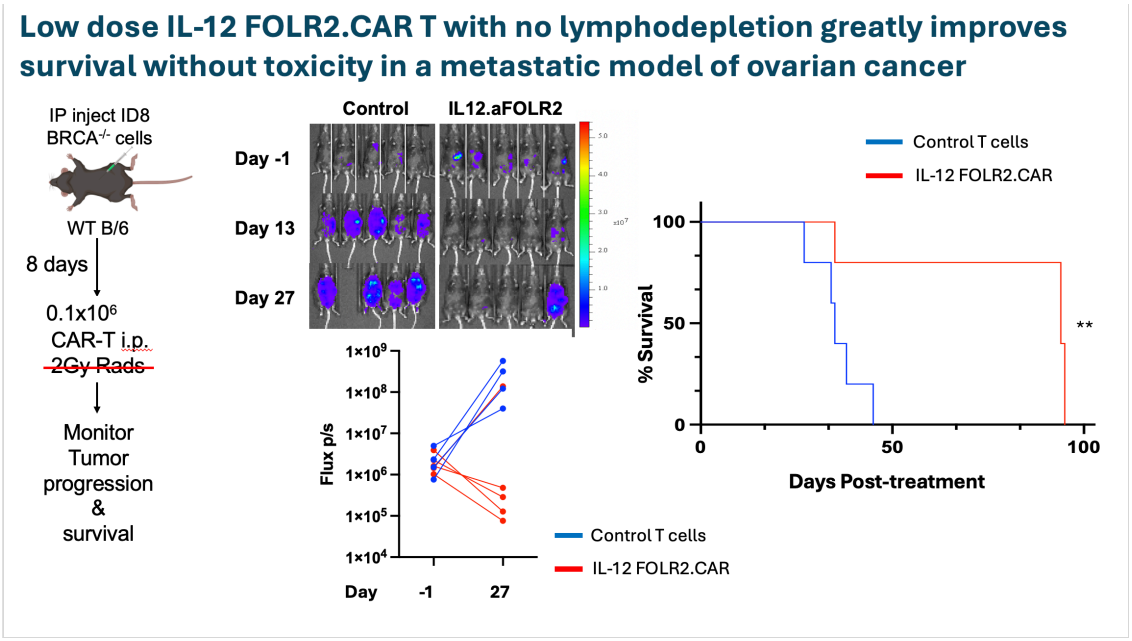
Methods
We generated chimeric antigen receptor (CAR) targeting FOLR2 and TREM2, two cell-surface molecules that are highly and specifically expressed on TAMs found within many human tumors and not expressed by non-macrophages or even most healthy tissue macrophages. We also engineered the vectors to express IL-12, a pro-inflammatory cytokine. IL-12 has been shown to benefit T cell therapies but has also been challenged by high toxicity, necessitating that its delivery is localized to tumors. We tested the IL-12 anti-FOLR2 CAR T cells and IL-12 anti-TREM2 CAR T cells in syngeneic, orthotopic mouse models of metastatic ovarian and lung cancer,

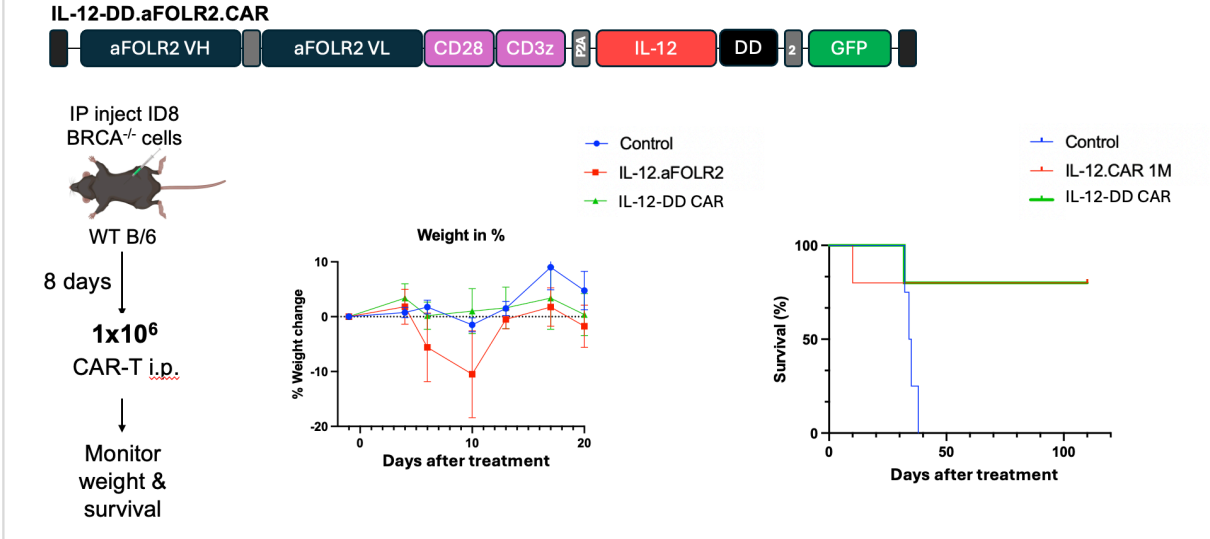
respectively. Mice were treated with control or CAR T cells after tumors had formed in the peritoneal cavity (ovarian) or lungs. We studied how the armored anti-TAM CAR T cells remodeled the TME and impacted animal survival.

Results
In mice with disseminated ovarian tumors, the transfer of control T cells had no impact on tumor growth, and animals died within 35 days of implantation. In striking contrast, when we injected IL-12 armored anti-FOLR2 CAR T cells, ovarian tumors shrunk within 3 weeks, and the mice survived >90 days. Importantly, this was achieved with only 105 CAR T cells, without any pre-conditioning, and little to no toxicity was observed. This result depended on the anti-macrophage CAR allowing the localization of the secreted IL-12, as transfer of IL-12 expressing T cells did not provide survival benefit. Similarly, survival was almost doubled when we treated immunocompetent mice with aggressive lung tumors with 1.5x105 IL-12 anti-TREM2 CAR T cells (no pre-conditioning) compared to the control T cell treated group. Examination of the tumors in both the ovarian and lung cancer models found that expression of IL-12 from the CAR-T led to a significative infiltration of activated endogenous T cells and a shift in macrophage to an immunostimulatory phenotype, indicating TAMs had been reprogrammed and an endogenous T cell response was promoted. Notably, IL-12 induced upregulation of FAS on tumor cells, facilitating FAS-dependent killing. Incorporation of a destabilization domain for IL-12 enabled conditional control of cytokine release while preserving anti-tumor efficacy.

Conclusions
These results demonstrate that targeting tumor-associated macrophages (TAMs) with IL-12 armored CAR T cells

enables significant and lasting anti-tumoral effects in preclinical models of two aggressive cancers. Anti-TAM CAR-mediated local delivery of IL-12 represents a promising approach for solid tumor therapy by resetting and reprogramming the TME, inducing FAS-mediated killing, and activating endogenous immunity with limited toxicity. The incorporation of a controllable IL-12 secretion system enhances safety and clinical translatability. With continued refinement, these therapies hold the potential to overcome the barriers of solid tumor treatment and provide durable outcomes for patients with aggressive cancers.





110 Peptide Drug-Secreting CAR T cells Targeting the VIP/VIPR Pathway Display a Novel Phenotype and Superior Antitumor Efficacy

Heather Lin[1], **Dejah Blake[2]**, Kory Wells[3], Ruby Freeman[3], Subir Goyal[3], Tongrui Liu[2], Christopher Funk[3], Bradley Heller[4], Tenzin Passang[3], Christopher Porter[3], Chrystal Paulos[5], Anupam Patgiri[3], Lily Yang[2], Edmund Waller[3], Sarwish Rafiq[3]*

Chimeric antigen receptor (CAR) T cell therapy is a highly potent cellular immunotherapy that still faces significant obstacles that limit clinical success. Novel approaches to improve the CAR T cell phenotype, metabolic fitness, and the engagement of endogenous immunity are necessary to create effective products. Herein, we target the vasoactive intestinal peptide (VIP) pathway to enhance CAR T cell therapy efficacy. VIP, a neuropeptide that binds to VIP receptors, plays an immunosuppressive role by dampening adaptive immune responses, including CAR T cells. VIP is produced by activated T cells and by several hematological and solid tumors, as a mechanism to suppress T cell activity. To counteract this, we engineered CAR T cells that secrete a novel synthetic short peptide drug antagonist of VIPR (CAR/VIPRa). This design enables localized delivery of antagonistic peptide drug to enhance CAR T cell function.

CAR/VIPRa T cells exhibit reduced exhaustion, improved viability, and enrichment of stem/ central memory phenotypes after manufacturing. By RNA sequencing, antigen-stimulation induces cellular pathways in CAR/VIPRa T cells that support enhanced mitochondrial function, ribosome biogenesis, and oxidative phosphorylation compared to CAR T cells that are primarily engaged in lymphocyte proliferation and differentiation. CAR/VIPRa T cells are metabolically quiescent yet display plasticity, supporting robust energetic profiles needed to endure frequent antigen stimulation within the tumor microenvironment (TME). Furthermore, CAR/VIPRa T cells showing elevated levels of FOXP1 (associated with T cell quiescence) and KLRB1 (a marker of CD8 memory), among other key genes.

Functionally, CAR/VIPRa are proliferative after multiple rounds of antigen stimulation. In xenograft cancer mouse models, CAR/VIPRa T cells exhibit superior expansion while maintaining a less exhausted memory phenotype and greater tumor infiltration. Additionally, in immunocompetent mouse models, CAR/VIPRa T cells increased endogenous T cell infiltration of endogenous T cells into the tumor. These findings suggest that the secreted antagonistic peptide acts both in an autocrine manner to support CAR T cells and in a paracrine manner to modulate the TME, thereby enhancing overall anti-tumor activity.

Lastly, the translational impact of CAR/VIPRa T cells was confirmed in patient-derived T cells and tumors. The differentiation state of CAR/VIPRa T cells prior to antigen-stimulation is shifted from effector to central memory phenotypes compared to CAR T cells. In aggressive patient-derived tumor mouse models, CAR/VIPRa T cells control tumor burden more effectively than standard CAR T cells.

We designed and engineered a novel antagonistic peptide drug-secreting CAR T cell that targets an emerging immune checkpoint pathway. Targeting the VIP/VIPR pathway is a promising strategy to preserve critical CAR T cell survival phenotypes and augment the intrinsic metabolic plasticity of CAR T cells that drives improved *in vivo* expansion and tumor infiltration to reduce disease burden. Ultimately, CAR/VIPRa T cells serve as micro-pharmacies that can deliver a drug both autocrinally to enhance CAR T cell phenotype and metabolism and in a paracrine manner to boost endogenous T cell infiltration, thereby strengthening anti-tumor responses.

111 Engineered CXCR3-A Expression Promotes Intracerebroventricularly Delivered B7-H3-specific CAR T Cell Trafficking and Efficacy against Diffuse Intrinsic Pontine Glioma in Orthotopic Mouse Models

Edward Song[1], Andrea Timpanaro[1], Michael Meechan[2], Leo Elena-Sanchez[2], Lucy Li[3], Sophie Jamet[2], Davina Lau[2], Lily Winter[2], Surojit Sarkar[2], Vandana Kalia[2], Michael Jensen[1], Matthew Biery[1], Nicholas Vitanza[4]*

[1]Seattle Children's Research Institute, Seattle, WA, [2]Seattle Children's Research Institute, Seattle, WA, [3]Benaroya Research Institute, Seattle, WA, [4]Seattle, WA

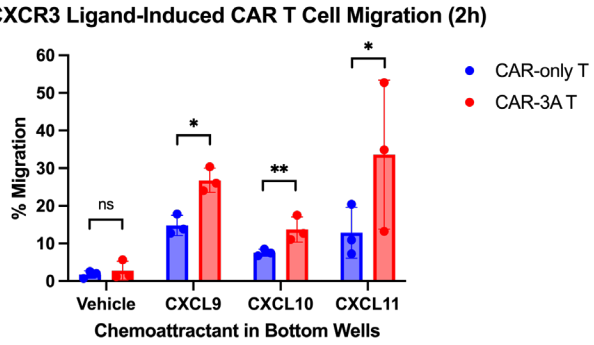
Diffuse intrinsic pontine glioma (DIPG) is an aggressive brainstem tumor that is the leading cause of death in children with brain cancer. DIPG is incurable with most patients passing away in a year, so more effective treatments are desperately needed. A promising approach is the use of chimeric antigen receptor (CAR) T cells, which has shown encouraging clinical evidence of feasibility, tolerability, and some activity against DIPG in early phase studies, including Seattle Children's BrainChild-03 trial conducted by our group. However, clinical benefit was not universal, and insufficient CAR T cell trafficking to the tumor is a known obstacle against solid tumors such as DIPG. Therefore, to improve CAR T cell trafficking and therapeutic efficacy, we engineered our clinically tested anti-B7-H3-CAR T cells to overexpress the chemokine receptor CXCR3-A, which detects the concentration gradient of its ligands, such as CXCL10, and directs cell migration.

Our BrainChild clinical trials have shown evidence that some CAR T cells would encounter tumor and produce CXCL10 following antigen-stimulation. Here, we hypothesize that these CXCL10 will attract substantially more CXCR3-A-modified anti-B7-H3-CAR T cells to the DIPG tumor site when compared to the standard CAR T cells. More CXCR3-A-modified CAR T cells engaging the tumor would lead to more CXCL10 production, which can further amplify CAR T cell recruitment through positive feedback, thus improving the trafficking and efficacy of CAR T cell therapy against DIPG.

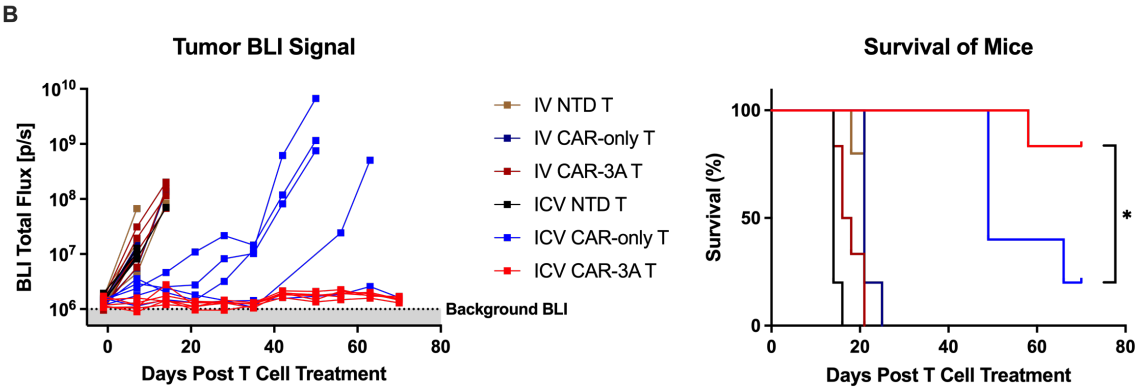
In this study, we demonstrate that compared to the standard anti-B7-H3-CAR T cells (CAR-only), the CAR T cells engineered to overexpress CXCR3-A (CAR-3A) migrate more efficiently towards the CXCR3 ligands, including CXCL9, CXCL10, and CXCL11, in chemotaxis assays (Figure A). These effects are statistically significant from three biological replicates using CAR T cells of different donors, with p values determined by ratio paired t tests. In vivo, intracerebroventricularly (ICV) delivered CAR-3A T cells show significantly improved efficacy in treating an orthotopic DIPG (SU-DIPG-13) xenograft mouse model (Figure B), based on both tumor bioluminescent imaging and mouse survival, with p value of the latter determined by Mantel-Cox log-rank test. Additionally, immunohistochemistry staining of human CD3, CD4, and CD8 confirms the increased presence of the CAR-3A T cells around the tumor sites 24-hour and 48-hour post ICV injections, compared to the CAR-only and non-transduced (NTD) T cells of the same donor. The enhanced therapeutic efficacy by the CAR-3A T cells via ICV delivery has been further validated in a second DIPG (PBT-27FH) mouse model with CAR T cells of another donor.

Overall, our data support the potential for engineering CXCR3-A expression in CAR T cells as a novel approach to enhancing CAR T cell trafficking and efficacy against DIPG. To our knowledge, we are the first to investigate the trafficking of chemokine receptor-modified CAR T cells via ICV delivery, which is clinically significant for CNS tumors.

A



(A) Percentage of CAR T cells that migrated from insert wells to bottom wells with vehicle, 300 ng/mL CXCL9, 100 ng/mL CXCL10, or 300 ng/mL CXCL11 after 2 hours. p values were determined by ratio paired t tests using data from three different T cell donors. Results are presented as means ± SD. ns, not significant; *p < 0.05; **p < 0.01.



(B) Luciferase-labeled SU-DIPG-13 tumor cells were intracranially implanted into NSG mice on day -7. Bioluminescent imaging (BLI) was performed on day -1 to quantify the signals of the engrafted SU-DIPG-13 tumor cells. On day 0, the mice were treated with 2 x 10^6 unmodified or CXCR3-A-modifed CAR T cells or the equivalent number of NTD T cells via either IV or ICV injection routes. On day 1 and day 2, three mice from each treatment group were euthanized to collect their brains for IHC staining to evaluate the migration of T cells towards the tumor site. BLI was performed weekly for the rest of the mice with routine health checks and recording of mouse weight and survival. (Left) Bioluminescent total flux from SU-DIPG-13 tumor cells at the indicated time points. (Right) Kaplan-Meier plot for mouse survival. p value was determined by log-rank (Mantel–Cox) test. *p < 0.05.

112 Modeling and Use of Engineering to Overcome On-Target/Off-Tumor Toxicity of Claudin 18.2-Targeted CAR-T cells in Gastric Cancer

Elizabeth Carstens[1], Kazuki Takahashi[1], Naoya Sakamoto[2], Martina De Vizio[1], Micaela Morgado[3], Shahryar Khoshtinat Nikkhoi[4], Abhishek Mangipudi[5], Izuma Nakayama[2], Qiang Lv[6], Jue Zeng[7], Cui Nie[7], Changjing Deng[7], Xiaoxiao Wang[7], Lile Liu[8], Samuel Klempner[9], Anusuya Ramasubramanian[10], Jonathan Nowak[11], Andrew Aguirre[10], Kohei Shitara[2], Eric Smith[12]

[1]Dana Farber Cancer Institute, Boston, MA, [2]National Cancer Center Hospital East, Kashiwa, Japan, [3]Dana-Farber Cancer Institute, Boston, MA, [4]Dana Farber Cancer Institute, Allston, MA, [5]Dana Farber Cancer Institute, Boston, NH, [6]Nona Biosciences, Natick, [7]Nona Biosciences, Suzhou, China, [8]Nona Biosciences, Suzhou, Jiangsu, China, [9]Massachusetts General Hospital, Boston, [10]Dana Farber Cancer Institute, Boston, [11]Brigham and Women's Hospital, Boston, [12]Dana Farber Cancer Institute, Boston, Massachusetts

Claudin 18.2 (CLDN18) targeted therapies, such as monoclonal antibody, zolbetuximab, and CAR-T cell, Satri-cel (CT041) are expanding access to immunotherapy in gastric cancer, however, high rates of nausea and vomiting were seen. Taking advantage of the high degree of homology of CLDN18.2 between mouse and human, we demonstrate this toxicity is likely driven by on-target/off-tumor (OT/OT) activity and inversely correlates with CAR binder affinity. We further develop novel, fully-human, nanobody-based CARs with superior therapeutic windows compared to CT041, decreasing OT/OT while preserving efficacy.

To evaluate the efficacy and OT/OT toxicity of targeting CLDN18.2, we engineered a CAR utilizing the scFv from CT041, with 4-1BB costimulatory domain and CD3ζ activation domain. NSG-DKO (MHC class I/II KO to avoid GvHD) mice were engrafted with human CLDN18.2-endogenously expressing esophageal adenocarcinoma cell line, OE19. Animals were treated with 1x10^6 CT041-scFv based CAR+ T cells and irrelevant BCMA-scFv CAR control. While tumor regressed rapidly in animals treated with the CT041-scFv based CAR-T, animals also rapidly lost weight, requiring euthanasia. Multiplex immunofluorescence from CT041-scFv based CAR-T treated animals show marked infiltrate of human CD3+ T cells into gastric tissue, coincident with CLDN18.2 expression (**Figure 1A-C**), and destruction of normal tissue architecture (**Figure 1D**). Control treated animals thrive and have no T cell infiltrate in the gastric epithelium. CT041-scFv based CAR-T mortality was even observed in tumor-free animals, suggesting tumor antigen driven expansion of CAR-T cell is not necessary to generate toxicity. To test the effect of dose on toxicity, OE19 tumor-bearing animals were treated with dose de-escalation of CT041-scFv CAR-T cells (1x10^6, 3x10^5, 1x10^5). Animals receiving lower doses had lower OT/OT but also less effective tumor control, making it difficult to identify an optimal therapeutic window. Following an antibody discovery campaign, novel fully-human heavy chain only antibodies (HCAb) specific to CLDN18.2; cross reactive to the human and mouse

protein, were cloned into the 4-1BB containing CAR. In vitro screening identified CARs with two highly active binders, "5795-VH" and "5797-VH". The binding kinetics of IgG reformatted versions of binders 5795, 5797 and CT041 were determined via SPR. CT041-IgG had highest affinity (K_D=3.64±0.2 nM) 5797-IgG had slightly lower affinity (K_D=4.5±3nM) while 5795-IgG had ~10-fold lower affinity (K_D=21.8±2nM; **Figure 1E**). Using the human xenograft in vivo model above, 5795-VH- and 5797-VH-based CAR-T were compared for tumor control and OT/OT toxicity with the CT041-scFv based CAR and irrelevant control at $1x10^6$ CAR T cell dose. Again, CT041-scFv based CAR-T treated animals all lost weight requiring euthanasia. 5797-VH CAR-T treated animals showed mixed results with some OT/OT toxicity requiring euthanasia and some survival with long term tumor control. No 5795-VH CAR-T treated animals lost weight from OT/OT tox, most animals demonstrating long term tumor control, until relapse at >100 days (**Figure 1F**).

A primary challenge to extending immunotherapies to solid tumors is selecting antigens with widespread tumor expression, but limited expression in normal tissues. We demonstrate that appropriate modeling of anticipated toxicity and careful examination of binding kinetics is critical to engineering a CAR with an optimal therapeutic window.

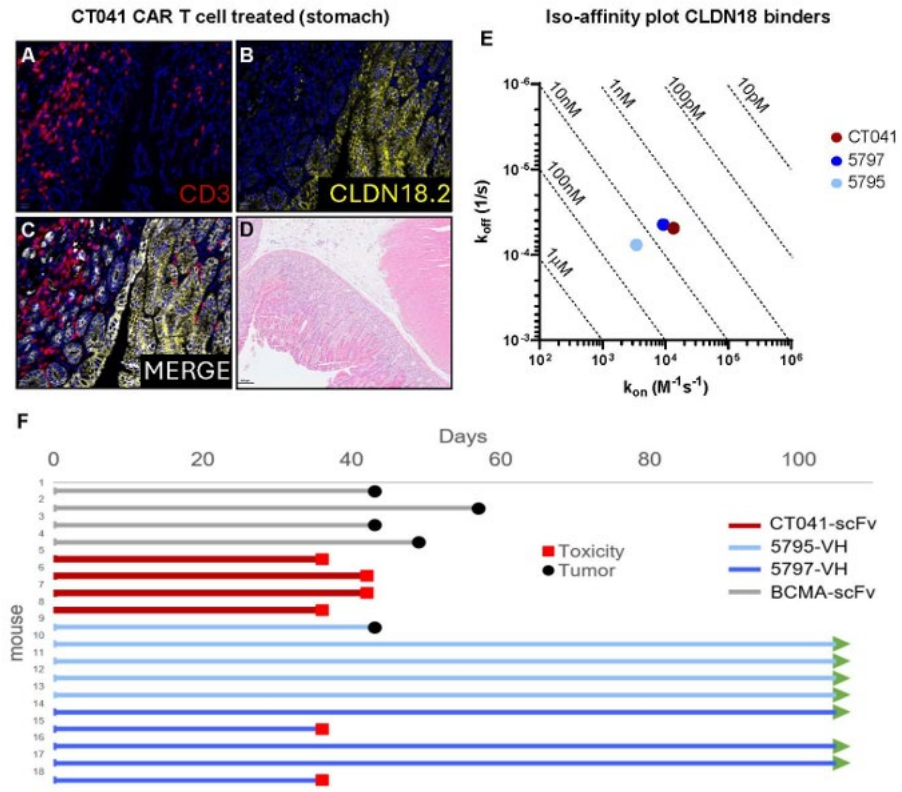


Figure 1: CLDN18-targeted CAR binder affinity determines on-target/off-tumor toxicity and therapeutic window. NSG-DKO mice bearing OE19 xenografts were treated on day 13 with $1x10^6$ CT041-scFv based CAR or BCMA-scFv based irrelevantly targeted CAR-T by tail vein injection. Introduction:
Solid tumors harboring actionable genomic alterations such as those frequently seen in non small cell lung cancer (NSCLC) have high response rates to tyrosine kinase inhibitors (TKI) and antibody drug conjugates (ADC) but most patients experience progression with few durable responses observed. Resistance to ADCs have been due to down-regulation or mutation of target antigen or resistance to the chemotherapy warhead target, and may explain the lack of durable responses. We utilized TROP2-targeted CAR T cells to treat TROP2+ solid tumors, including in the setting of resistance TKI targeted therapy (drug tolerant persister cells; DTPs), and ADC.

Methods/Results:
To study eradication of post-TKI resistant DTP cells, we treated a NSCLC PDX model with Osimertinib (Osi) for 6 weeks. In this model, bulky disease is eliminated but all tumors relapse. In the DTP setting we evaluated if repeat dosing of sacitizumab govitecan (SG), an anti-TROP2 ADC, could eradicate DTPs and prevent relapse, but saw only a small improvement in survival (mOS: Osi 94d vs Osi+SG 108d; n=10/arm). We then engineered a SG-scFv based TROP2-targeted CAR and evaluated how CAR T cells compared to the ADC in the post-Osi DTP model. We found that theTROP2 CAR induced significantly longer mOS compared to SG ADC (mOS: ADC 130d vs CAR 210d; n=10/arm, $p=0.005$, Fig. 1).

We also modeled known settings of resistance to TROP2 ADC due to low antigen expression, topoisomerase pathway mutations, and target epitope point mutations and demonstrated in NSCLC and Breast Cancer models that CAR T cells can be engineered to overcome them all. E.g., in an in vitro model of low TROP2 expression, cytotoxicity of ADC is decreased to 19%, while CAR T, at even low E:T, can eradicated 61% of tumor cells, $p<0.01$). To address emergence of point mutations we leveraged novel VH-only binders derived from a fully-human VH-only Tg mouse platform. This panel of VH-only binders was epitope mapped and engineered into novel VH-only TROP2 CARs that revealed their ability to target epitopes not accessible to clinically approved TROP2 ADCs. Leveraging this mapping, we rationally engineered structure-based biparatopic CARs with improved efficacy against point mutants. These biparatopic CARs showed significantly enhanced in vitro and in vivo efficacy compared to the benchmark SG-based CAR T in in vivo models of tumor heterogeneity (mOS: SG-based CAR 42d vs. biparatopic VH CAR not reached, $p<0.01$, Fig. 2).

Conclusion:
We demonstrate a high degree of in vivo activity of TROP2 CAR T against multiple models of TROP2+ solid tumors. We demonstrate that CARs have a unique advantage over ADCs, including in targeting TKI-resistant residual DTP cells, likely due to the senescence like state which is resistant to chemotherapy-based approaches, like ADCs, but sensitive to immune based therapies. We map the epitopes targeted by approved TROP2 ADCs as well as developed novel fully-human VH-only based TROP2 CARs that target novel epitopes. Biparatopic CARs demonstrated improved efficacy in vitro and in vivo, in models of emerging resistance, where single epitope targeted CAR failed. This work demonstrates that rational structure-based engineering of CAR can overcome mechanisms of resistance to ADC as well as improved targeting of post-TKI DTP cell reservoirs of relapse.

114 Chimeric RNA-Binding Proteins Enhance CAR T Cell Function

Courtney Kernick[1], Theodore Roth[2]
[1]*Stanford University, Palo Alto, CA,* [2]*Stanford University, Stanford, CA*

Genetically modified cell-based immunotherapy has been successful in multiple liquid tumors; however, the complex and immunosuppressive solid tumor microenvironment has limited the efficacy of cell-based therapies for solid tumors, which account for the majority of cancers. There is ongoing effort to achieve a more therapeutically effective T cell state by modulating the expression of endogenous genes to enhance chimeric antigen receptor (CAR) T cell activity against solid tumors and prevent T cell exhaustion. One promising strategy involves the use of RNA-binding proteins (RBPs), which regulate gene expression through mRNA splicing, export, stability, degradation, and translation. Previous research indicates that RBPs are crucial in T cell functions such as proliferation, cytokine production, inflammatory responses, and effector activities. However, genetic manipulation of endogenous RBPs have not been sufficient to produce improved effector phenotypes in CAR T cells for robust tumor clearance. To address this, we synthesized chimeric RBPs by combining effector and RNA binding domains from different natural RBPs involved in immune response pathways, each tagged with a unique DNA barcode. These chimeric RBPs were then integrated into a backbone with a CD19-28z CAR and a tNGFR selection marker. We edited primary human T cells using CRISPR-Cas12a to integrate a library of nearly 12,000 synthetic RBPs into the endogenous TRAC locus. In large scale pooled knockin screens, we repetitively co-cultured the library of edited CAR T cells with stress doses of Nalm6 target leukemia cells, and performed both acute and chronic antigen stimulation assays to assess CAR T cell survival and proliferation. Genomic DNA was collected from the T cell pool before and after the Nalm6 stimulations and was used for next-generation sequencing of the synthetic RBP library barcodes. The most effective chimeric RBPs were identified by comparing barcode readouts before vs after the acute or chronic stimulation assays, and linking the most abundant barcodes to enhanced CAR T cell proliferation. We identified multiple chimeric RBPs that outperformed both natural RBPs and CAR only cells. In particular, for the chronic stimulation assay, (N)HNRNPD–(RBP)PDCD4–(C)ELAVL1 emerged as a top hit with increased proliferation (fold change: 7.15). These enriched synthetic RBPs represent promising candidates for further study, potentially leading to improved CAR T cell therapies that can overcome the challenges posed by solid tumors. This approach represents a new method for the discovery and screening of new, synthetic genes for both CAR T cell therapies and in the future more broadly across cell types for gene and cell therapies.

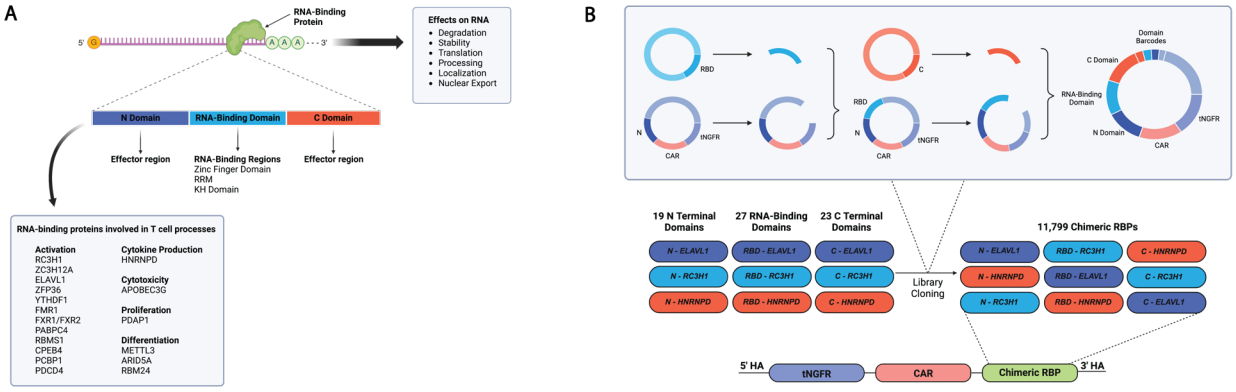

Figure 1. Design and cloning of 11,799 member chimeric RNA-binding protein library for CAR T cell engineering. (A) Three common types of RNA-binding regions were used to define the RNA-binding domain, with effector regions on either side to create interchangeable modules for combinatorial cloning. RBPs included in the screen impact cell fate of immune cells and/or are involved in many T cell response pathways. (B) Schematic of library construction using restriction enzyme digestion and ligation to iteratively add domains to a homology directed repair template backbone containing a tNGFR and a CAR (CD19-28Z).

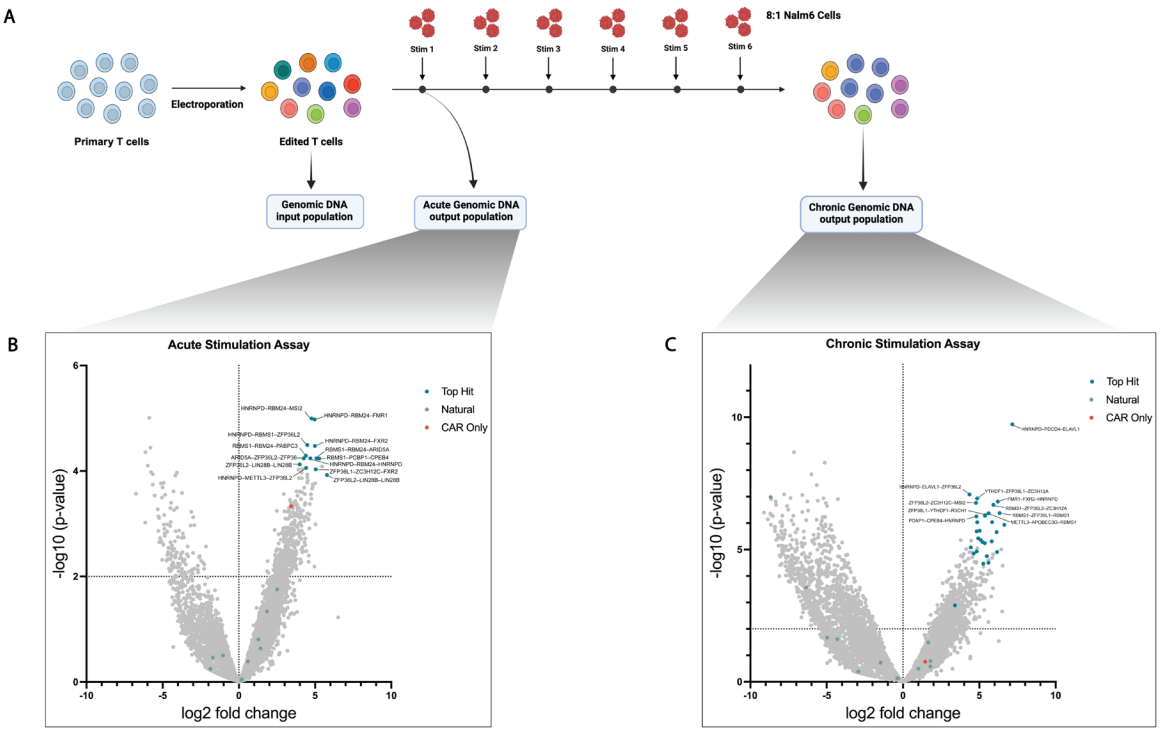

Figure 2. Chimeric RBPs can improve CAR T cell performance in a repetitive stimulation exhaustion assay. (A) Schematic of repetitive stimulation assay with target Nalm6 leukemia cells. (B/C) A comparison of barcodes from the edited CAR T cells pre- and post-stimulation found many top hits of highly proliferative chimeric RNA-binding proteins in both chronic and acute assays.

115 CRISPR-Based *In Vivo* Screen Identifies Key Gene Mediators of CAR-T Cell Dysfunction in Solid Tumors

**Corresponding Author*

Introduction:
Clinical efficacy of CAR-T therapy in patients with solid tumors has generally been limited. Primary mechanisms underlying treatment failure include limited proliferation, lack of persistence and restricted functionality of CAR-T cells. Here, we have characterized dysfunction of CAR-T cells driven by chronic antigen stimulation in an *in vivo* model of solid tumors. Using this model, we screened potential gene mediators of CAR-T cell dysfunction. We hypothesized that CAR-T cell dysfunction may be prevented or delayed by targeting specific genes, resulting in an enhanced CAR-T therapy for the treatment of solid tumors.

Methods:
We optimized an *in vivo* model of CAR-T cell dysfunction using CD28-based anti-HER2 CAR-T cells against

ovarian xenograft tumors in NSG mice. Tumor-infiltrating T cells (TILs) were isolated during two phases: 1) initial CAR-T activation leading to tumor regression ("effective CAR-TILs") and 2) progressive CAR-T functional decline and tumor escape ("dysfunctional CAR-TILs"). Bulk RNA-seq and single-cell RNA-seq analysis were performed on dysfunctional CAR-TILs compared to effective CAR-TILs and preinfusion product. We identified 300 upregulated candidate genes in dysfunctional TILs and designed a custom sgRNA library to genetically modify CAR-T cells using CRISPR/Cas9 technology. Knockouts providing a functional advantage to CAR-T cells were identified through *in vivo* screening in our model of CAR-T dysfunction by Amplicon-seq. Top candidate genes after the screen were individually evaluated in an *in vitro* model of CAR-T cell dysfunction based on a restimulation assay, as well as in different *in vivo* models of xenograft solid tumors with distinct CAR constructs.

Results:
Dysfunctional CAR-TILs from our model displayed key features of exhausted T cells, including elevated expression of inhibitory makers, reduced proliferation and cytotoxicity and impaired ability to produce cytokines upon stimulation with tumor cells. Using bulk RNA-seq and Ingenuity Pathway Analysis on dysfunctional compared to preinfusion CAR-TILs, we observed enrichment of T cell exhaustion and NK cell-like signatures in our model. Using an *in vivo* CRISPR knockout screen, we found that sgRNAs targeting 14 genes were positively enriched. Knock-out of four out of six validated gene candidates enhanced the antitumor effect of CAR-T cells against ovarian xenograft tumors. Single-cell RNA-seq analysis confirmed that these new gene candidates are expressed in clusters of early and late exhaustion. Among them, the top hit was ZC3H12C (Regnase-3). Targeted ZC3H12C deletion in CD28-based CAR-T cells enhanced cytotoxicity and cytokine production after repeated stimulations with tumor cells *in vitro*, compared to AAVS1-KO CAR-T cells. *In vivo*, ZC3H12C-KO CAR-T cells mediated superior antitumor responses and enhanced T cell persistence compared to AAVS1- or LAG3-KO CAR-T cells. Similar results were observed using different *in vivo* models of lung and pancreatic tumors with Mesothelin-CD28z and CD19-BBz CARs.

Conclusions: By using an *in vivo* model of CAR-T cell exhaustion in solid tumors, we provide new insights into the mechanisms underlying CAR-T cell dysfunction. These results link ZC3H12C with CAR-T cell loss of functions after chronic antigen exposure and demonstrate enhanced potency of ZC3H12C-deficient CAR-T cells in mediating antitumor effects.

Gene Editing: New Tools and Technology Advances

116 Systemic Delivery of a Mitochondria-Targeting ARCUS Gene Editing Nuclease by AAV Eliminates Mutant Mitochondrial DNA, Demonstrating Therapeutically Meaningful Heteroplasmy Shifts In Vivo

Wendy Shoop[1], Emma Sevigny, Emily Manzon, Joanna Dobson, Spencer McKinstry[1], Dominique Burgess[2], Traci Reddick[1], Cassie Gorsuch[1], Jeff Smith[3]
[1]Precision Biosciences, Durham, NC, [2]Precision Biosciences, Durham, [3]Precision BioSciences, Inc., Durham, NC

Pathogenic mutations in the multi-copy mitochondrial DNA (mtDNA) are commonly heteroplasmic, with both wild-type and mutant genomes co-existing in the same cell. Clinical symptoms manifest once the proportion of mutant mtDNA exceeds a particular disease threshold, resulting in multi-systemic disorders affecting high energy-demand tissues. The heteroplasmic m.3243A>G mutation is the most common pathogenic mtDNA point mutation and is responsible for approximately 1/3 of all mitochondrial diseases. Patients afflicted with m.3243-associated mitochondrial disease, for which there is currently no treatment, most commonly experience debilitating fatigue, muscle weakness, and exercise intolerance due to insufficient energy production within skeletal muscle. Taking advantage of the lack of double-strand DNA break repair within mitochondria and the unique ability of ARCUS nucleases to target DNA directly through protein contacts rather than guide RNAs, which cannot traffic across the mitochondrial membrane, we propose a therapeutic approach to correct m.3243-associated mitochondrial disease by utilizing an AAV-delivered mitochondrial-trafficked ARCUS nuclease (PBGENE-3243) to specifically cleave and eliminate mutant m.3423G mtDNA. This approach leaves the intact wild-type m.3243A mtDNA to repopulate the

cell, resulting in a shift in mtDNA heteroplasmy toward wild-type and restoration of normal energy production within skeletal muscle. While preclinical in vitro data for the PBGENE-3243 nuclease demonstrates a high degree of specificity and efficacy, there is no available animal model that contains m.3243A>G in which to evaluate PBGENE-3243 for in vivo efficacy. Therefore, we utilized the heteroplasmic m.5024C>T mouse to establish proof-of-concept for ARCUS-mediated heteroplasmy shift in skeletal muscle following systemic AAV delivery. We used a surrogate ARCUS nuclease targeting mutant m.5024T that demonstrates a similar level of potency to the PBGENE-3243 nuclease. Following delivery of 5.0 x 10^{13} vg/kg of surrogate AAV in adult mice, we observed transduction of key target tissues including the quadriceps, gastrocnemius, tibialis anterior, diaphragm, and heart, culminating in reductions in mutant m.5024T mtDNA ranging from 55% to 90% across the same organs at 12 weeks post-treatment. These reductions in mutant m.5024T mtDNA, along with concomitant increases in wild-type m.5024C mtDNA, were sustained at 24 weeks. While there is no phenotype associated with this mouse model, a reduction in mutant m.3243G mtDNA by 20-50% is cited to be sufficient to alleviate clinical symptoms of m.3243-associated mitochondrial disease in humans, and thus the efficacy observed with the surrogate in mice is more than sufficient. These data demonstrate the ability of ARCUS nucleases to shift heteroplasmy at levels beyond what is expected to be therapeutic and will further inform development of PBGENE-3243 in IND-enabling studies.

117 Programmable gene insertion in human cells using an evolved CRISPR-associated transposase

The mutational diversity of many genetic diseases complicates their treatment with precision genome editing methods, which are typically allele-specific. Genomic integration of a healthy gene copy at a target locus could enable one-time, allele-agnostic treatments for loss-of-function genetic diseases, but current strategies for targeted genomic integration of large DNA sequences in mammalian cells are limited by low efficiency, limited programmability, or excess byproduct formation. Here we use protein evolution and engineering to develop CRISPR-associated transposases (CASTs) that enable efficient, RNA-guided integration of large DNA sequences into genomic sites in human cells. Using phage-assisted continuous evolution (PACE), we performed hundreds of generations of mutation, selection, and replication to identify transposase variants with ~200-fold averaged improved integration activity. Combining evolved transposase variants with rational engineering yielded an optimized, evolved CAST (evoCAST) system that supports ~10–30% integration efficiencies of kilobase-size DNA cargoes across 14 tested human genomic sites. We used evoCAST to install human factor IX cDNA into *ALB* intron 1; to insert a CD19-targeted chimeric antigen receptor into *TRAC*; and to integrate wild-type cDNAs of four genes implicated in loss-of-function genetic diseases into intron 1 of their respective endogenous loci. Collectively, our findings overcome key bottlenecks for CAST integration activity in human cells, establish a platform for the evolution of mammalian cell-active CASTs, and advance a broadly applicable system for the targeted genomic integration of large DNA cargoes.

118 Site-Specific DNA Insertion into the Human Genome with Engineered Recombinases

Alison Fanton[1], Patrick Hsu[2]*, Liam Bartie[1]
[1]Arc Institute, Palo Alto, CA, [2]UC Berkeley & Arc Institute
**Corresponding Author*

Technologies for precisely inserting large DNA sequences into the genome are critical for diverse research and therapeutic applications. While large serine recombinases (LSRs) can mediate direct, site-specific genomic integration of multi-kilobase DNA sequences without a pre-installed landing pad, current approaches suffer from low insertion rates and high off-target activity. Here, we present a comprehensive engineering framework that

combines directed evolution, computational modeling, and DNA-binding protein fusions to dramatically enhance both the efficiency and specificity of LSR-mediated genomic integration.

Using the genome-targeting LSR Dn29 as a proof-of-concept, we performed deep scanning mutagenesis and substrate-linked directed evolution to identify mutations improving integration efficiency or specificity. Machine learning models trained on single mutation data accurately predicted higher-order combinatorial mutant activities (NDCG>0.97), enabling rapid optimization. Key variants included superDn29 with 10-fold improved efficiency, and goldDn29 with 5-fold enhanced specificity. Structural analysis of mutations using AlphaFold3 revealed distinct functional clusters - efficiency mutations in the coiled-coil hinge region likely modify tetramer stabilization, while specificity mutations near the DNA-binding interface modify target recognition.

To further enhance genomic targeting, we developed LSR-dCas9 fusions that facilitate recruitment to desired integration sites. Guide RNA optimization and multiplexing improved efficiency up to 6-fold, while incorporating guide binding sites on donor plasmids enhanced cargo recruitment. Additionally, we optimized the donor DNA sequence through comprehensive attachment site mutagenesis, identifying nucleotide preferences that improved integration rates.

Combining these orthogonal strategies generated highly efficient and specific recombinases. SuperDn29-dCas9 achieved 53% integration efficiency at an endogenous human locus, while hifiDn29-dCas9 demonstrated 97% genome-wide specificity. The optimized variants effectively integrated large DNA cargoes (5-12 kb tested) in challenging cell types - achieving 33% efficiency in non-dividing cells, 24% in human embryonic stem cells (hESCs), and 17% in primary human T cells. In hESCs, we demonstrated stable integration and expression of a 12 kb CRISPRi construct throughout differentiation into hematopoietic progenitor cells, enabling robust knockdown of endogenous genes.

Single cell analysis revealed that goldDn29-dCas9 produced predominantly single-copy, on-target integrations in hESCs. The system also demonstrates promise for cross-reactivity with various model organisms, including non-human primates and mice. This work provides a comprehensive blueprint for engineering site-specific recombinases and enables precise insertion of multi-kilobase DNA sequences into diverse cell types without exposed double-strand breaks. The developed tools have broad applications in gene therapy, particularly for replacing entire genes rather than correcting individual mutations, as well as in functional genomics studies requiring controlled transgene integration.

119 Monoallelic Knockout of Mutant *ELANE* in Congenital Neutropenia Patient HSPCs Rescues Neutrophil Development In Vivo

Aidan Laird[1], Quinn DeGottardi[2], Yidian Ye[3], Chris Thouvenel[3], Beth Loots[3], Tamar Auerbach-Nevo[4], Hadas Shoham-Nissan[4], Asael Herman[4], David Dale[5], Aleksandra Petrovic[6], Rafi Emmanuel[4], David Rawlings[5]*

**Corresponding Author*

Severe Congenital Neutropenia (SCN) and Cyclic Neutropenia (CycN) are primary hematopoietic lineage genetic disorders predominantly resulting from autosomal dominant mutations in *ELANE*, the gene encoding neutrophil elastase. Expression of the mutant allele leads to partial or near complete neutrophil lineage maturation arrest at the promyelocyte stage. This results in reduced neutrophil counts in the blood and frequent, recurrent infection. Therapeutic approaches that correct the *ELANE* mutation and restore neutrophil differentiation and function would provide significant benefit and/or a potential curative therapy. In the current study, we utilized a highly engineered, CRISPR-derived nuclease editing strategy to selectively knock-out the mutant allele in CycN and SCN $CD34^+$ HSPCs (PMID: 35795780). This approach eliminates only the dominant mutant allele thereby preserving neutrophil elastase function derived from the wild type allele. In this approach, the OMNI A1 V10 nuclease is co-delivered with two sgRNAs, one targeting a constant region creating a double stranded break in both alleles, and one targeting a heterozygous SNP on the mutant allele resulting in partial excision of the mutant allele leading to mRNA

destabilization and degradation after RNP delivery. Here, we describe our extensive pre-clinical studies of this approach for treatment of patient-derived HSPCs in a humanized mouse model. Patient cells were edited, and we were able to achieve input excision rates of 25.8% on average. For xenotransplantation studies, 1 million untreated patient (NT), edited patient, or healthy donor mPB $CD34^+$ cells were transplanted into immunodeficient NBSGW recipient mice and recipients were monitored for 16-22 weeks post-engraftment. At study endpoint, detailed immunophenotyping by flow cytometry was performed for bone marrow, spleen, and peripheral blood cells. The proportion of mature neutrophil precursors was defined as the percentage of $CD66b^+$ $CD15^+$ $CD11b^+$ $CD16^+$ within the engrafted human (h)$CD45^+$ hematopoietic population. Strikingly, gene editing resulted in a marked increase in the proportion of mature neutrophil precursors in the BM of mice that received edited cells in comparison to the untreated condition with 4.016% vs 0.372% in recipients of CycN HSPCs and 1.14% vs 0.017% in recipients of SCN HSPCs. The proportion of mature neutrophil precursors in the BM approached the level of the healthy donor in both settings. Excision rates in the BM averaged at 9.19% for CycN cells and 5.6% for SCN cells, indicating relatively low levels of editing are required to rescue the phenotype. In parallel, we performed ex vivo neutrophil differentiation using $CD34^+$ cells (or bulk BM cells) isolated from recipient mice at the time of sacrifice; demonstrating the retained the capacity to differentiate after editing and long-term engraftment. Additionally, HSPCs and myeloid cells were FACS-sorted from total BM of humanized mice for scRNAseq to analyze myeloid developmental trajectories and differential expression of neutrophil associated genes between the untreated, edited, and healthy donor groups; results showed a block in myeloid development in untreated mice which was rescued with editing. Taken together, these data demonstrate that monoallelic *ELANE* disruption rescues neutrophil development *in vivo* while also retaining the healthy *ELANE* allele and neutrophil elastase function; and support moving this approach forward for clinical application.

120 Highly efficient and seamless selection of long-range gene-edited HSPCs by targeting haploinsufficient genes

**Corresponding Author*

Random integration of strong promoters by viral vectors resulted genotoxic in patients treated with eli-cel for X-linked adrenoleukodystrophy (X-ALD), who developed myelodysplasia and acute leukemia, and in previous murine models. Still, not all patients incurred in serious adverse events, indicating that strong promoters may be tolerated upon targeted gene integration.

Gene editing (GE) by homology-direct repair (HDR) allows for target integration of a therapeutic cassette in hematopoietic stem and progenitor cells (HSPCs), enabling characterization of genomic and transcriptional perturbations. However HDR GE is constrained by low efficiency, and often yields heterogeneous genetic outcomes, raising genotoxic concerns.

Rationale
We developed an innovative selection strategy that greatly enriches for HDR-edited HSPCs, while removing genotoxic byproducts, called CLEAN (Clear-cut integration of Large payloads into Essential Alleles with spontaneous counterselection of NHEJ outcomes). CLEAN is based on nuclease-based disruption of haploinsufficient loci in HSPCs, and reconstitution of the same loci by an HDR template that also include the gene of interest (GOI). As a result, all cells whose target locus is disrupted by the nuclease either have the GOI at the target location or are purged out along with their burden of large deletions and translocations (Fig 1).

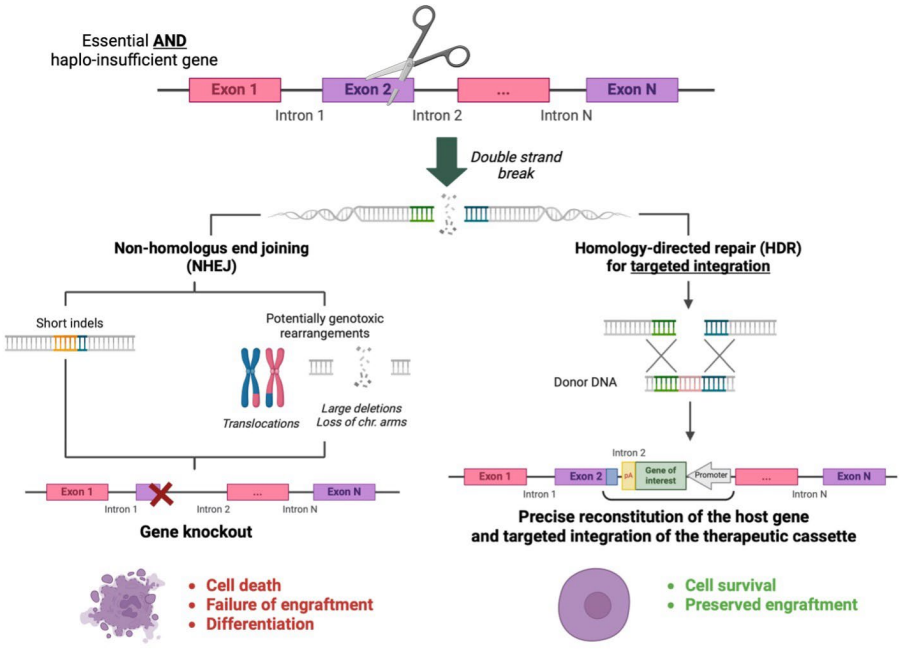
Results
After screening of putative haploinsufficient loci we identified 3 candidate genes (*UBA1, OGT, RPS19*) whose

knock-out impairs the clonogenic output of HSPCs in vitro. Conversely, rescue with a suitable HDR template, also including a GFP reporter, restored the clonogenic output to a significant degree, and 80-90% of the colonies were GFP+; precise bilateral HDR outcomes were then confirmed by long-read sequencing.

Using our optimized, GMP-ready GE protocol we achieved ≥60% HDR efficiency across tested loci. Upon xenotransplantation into immunodeficient mice, HSPCs bearing indels were spontaneously counter-selected over time. Bone marrow engraftment of human cells was lower (<10%) than the control group (40-60%), consisting of mice xenotransplanted with HSPCs bearing indels at the *AAVS1* site. HSPCs HDR-edited at all target genes resulted in engraftment of 40-60% and nearly 100% of human cells were GFP+. This compares favorably to cells HDR edited at the control *AAVS1*: at comparable levels of pre-transplant HDR efficiencies, only 40-50% of cells remained reporter positive at the experiment endpoint.

Depending on the target locus, GOI expression may be coupled to the target gene or placed under the transcriptional control of a strong promoter. Preliminary investigations into gene expression perturbations of the target and nearby genes upon integration of the model SFFV strong promoter did not raise concerns. Further comprehensive characterization of genomic and transcriptional perturbations is ongoing.

Conclusion
CLEAN tackles the limitations of HDR GE, i.e. efficiency and potentially genotoxic byproducts. It is a one-size-fits-all approach for HSPC gene therapy, well suited for targeted integration of corrective cassettes in a well characterized locus for the treatment of X-ALD, other inborn errors of metabolism requiring strong promoters and very high levels of correction, and gene therapies with a tight therapeutic interval. While selection constitutes an intrinsic bottleneck in clonal diversity, high GE efficiency reduces the magnitude of this effect.



121 Engineered Hematopoietic Stem Cells Give Rise to Therapeutic Antibody Secreting B Cells

Sofia Luna[1], William Feist[2], Ashley Utz[3], Hana Ghanim[4], MASASHI MIYAUCHI[5], Sridhar Selvaraj[6], Anais Amaya[6], Freja Ekman[7], Norman Russkamp[3], Ludwig Schmiderer[3], Matthew Porteus[8]*

The therapeutic antibody market dominates modern medicine, with monoclonal antibodies representing half of the top ten selling drugs with global sales of >$200B. Despite their proven efficacy across a wide variety of diseases (i.e. cancer, autoimmunity, metabolism, etc.) they still require repeated administration to remain effective. Conversely, cell-based medicines have entirely different pharmacokinetics and pharmacodynamics than traditional medicines, including the potential to have lifetime durability. To this end, we have developed a genetically engineered stem cell-based therapy that enables continuous antibody production from a single dose. Using CRISPR/Cas9 homology directed repair mediated editing, we engineered hematopoietic stem and progenitor cells (HSPCs) such that when they differentiate into B cells they will secrete therapeutic levels of antibodies. We insert the antibody expression cassette in the *CCR5* safe-harbor locus under the control of a synthetic B cell promoter, enabling antibody expression across B cell subtypes while preserving normal hematopoiesis and endogenous B cell function. We validated this platform using two clinically approved antibodies: anti-TNFα for autoimmune disease and anti-PCSK9 for hypercholesterolemia. We achieved 35-40% targeted integration of the gene-targeted antibodies (GT-Ab) in human HSPCs and demonstrated robust engraftment (up to 85% chimerism) of these cells in sub-lethally irradiated NSG mice with maintenance of edited alleles (average 35%) in the bone marrow 16 weeks post-transplant. Because immunodeficient mice lack an immune system and do not reconstitute with mature IgG-secreting B cells, we used two other models to demonstrate antibody secretion using our system. First, we engineered GT-Ab human B cells in vitro and demonstrated efficient expression of anti-TNFα or anti-PCSK9 antibodies into the culture supernatant. We then modeled autologous hematopoietic stem cell transplant (HSCT) by transplanting engineered GT-Ab murine HSPCs into lethally irradiated C57BL/6 immunocompetent mice. We detected therapeutic antibodies in the serum of mice by week 4 post-transplant, with week 16 concentrations reaching 4-9 µg/mL for anti-TNFα and 125-300 µg/mL for anti-PCSK9 – meeting or exceeding therapeutic requirements in humans. Notably, these levels were achieved with less than 10% gene-modified cells in the peripheral blood, suggesting compatibility of the system with reduced-intensity, non-toxic conditioning regimens. In terms of safety, we observed normal B cell development in the mice, including formation of IgM^+IgD^+ mature B cells, with stable maintenance of the engineered GT-Ab alleles in B cells sorted from the spleen. The high levels of antibodies in the mouse studies prompted us to develop a system in which the levels could be modulated. By fusing the antibody to a destabilization domain, we demonstrated that levels of antibody secretion could be controlled through small molecule regulation. This ability to regulate antibody level may be essential to achieve both safety and efficacy of sustained cell-based delivery of monoclonal antibodies. Overall, this platform represents a modular approach for treating chronic diseases currently reliant on repeated administration of therapeutic antibodies, offering the potential for a durable production of antibodies from a single treatment.

122 RNA Switch-Based Inducible AAV-CRISPR System for *In Vivo* Genome Editing

Chengzhi Du[1], Haimin Wang[1], Xiaojuan Tang[1], **Guocai Zhong[1]***

The adeno-associated virus (AAV) vector is so far the most efficient delivery platform for *in vivo* genome editing therapies targeting extrahepatic tissues, such as muscle and the central nervous system (CNS). However, a single administration of AAV can result in prolonged transgene expression lasting years to decades. This poses significant safety concerns, including (i) persistent off-target genome editing, (ii) immune clearance of nonself-editor-expressing (edited) cells, and (iii) double-strand break-induced integration of AAV DNA into host chromosomes. Synthetic RNA switches [refs 1-3], compact (~100 bp) RNA-based cis-regulatory elements that function independently of protein cofactors, hold great promise for addressing these challenges by enabling precise temporal control of genome editor expression. The key challenge is designing an RNA switch that provides both robust, inducible expression of genome editors and complete suppression of leaky expression in the dormant state.

Here, we first present our unpublished *in vitro* and *in vivo* data detailing the development of a multilayer-RNA-switch-regulated CRISPR-Cas12a system. This system is characterized by its leak-free behavior, efficient inducibility, and compact design suitable for packaging within a single AAV vector. In the optimized construct, Cas protein expression, crRNA expression, crRNA folding, and crRNA maturation are simultaneously suppressed by

two integrated cis-acting RNA elements. A single steric-blocking antisense oligonucleotide (ASO) targeting both cis-acting RNAs can deactivate all four regulatory layers, enabling precise temporal control. In mouse models, this multilayer-regulated system demonstrated negligible basal editing activity prior to induction and was effectively switched "ON" with a single dose of ASO. Furthermore, we will describe our latest efforts in developing a tightly regulated Cas9-ABE8e system toward leak-free and highly inducible *in vivo* base editing, leveraging an unpublished ultra-efficient RNA ON-switch systems (Z^{on}). These RNA switch-based inducible AAV-CRISPR system enables precise temporal control of *in vivo* genome editing, which may have broad potential for *in vivo* therapeutic editing applications.

Viral Vectors in Large Animal Models

123 Systemic Gene Therapy CAP-002 Demonstrates Potential for Disease-Modifying Treatment of Seizures and Motor and Cognitive Deficits of STXBP1-DEE Using an Engineered, CNS-Targeted AAV

Allison Knoll[1], Alberto Lopez[1], Brandon Wheeler[1], Kenna Whitley[1], Lubov Grigoryeva[1], David Goertsen[1], Evan Walsh[1], Pavel Tchourilov[1], Hari Acharya[1], Paul Denis[1], Wu Chen[2], Joo Hyun Kim[2], Alysee Michaels[2], Armando Rivera[2], Yusuf Sham[2], Catalina Elwonger[2], Jose Paulo Carneiro[2], Shawn Nguyen[2], Zain Moin[2], Sheldon Zou[2], Kevin Jin[2], Kelly Nguyen[2], Amy Wang[2], Nikita Dhar[2], Peter Park[3], Jaimie Vega[2], Alice Chen[2], Kendall Culpepper[2], Brooke Horist[2], Hongmei Chen[2], Mingshan Xue[2], Swati Tole[1], Nicholas Goeden[1], **Nicholas Flytzanis**[1]*, Melanie Brandabur[1]

Syntaxin-binding protein 1 (STXBP1) developmental and epileptic encephalopathy is a rare and severe genetic epilepsy and neurodevelopmental disorder that impacts approximately 3.3 to 3.8/100,000 live births globally. De novo heterozygous mutations in the STXBP1 gene lead to impairments in synaptic vesicle release, neuronal communication, and network activity across the brain, resulting in numerous disease manifestations. STXBP1 encephalopathy is characterized by treatment-resistant epilepsy, profound intellectual disabilities, speech and motor impairments, behavioral issues, and increased risk of early mortality due to sudden unexpected death in epilepsy (SUDEP). To date, there are no approved disease-modifying therapies for this debilitating disorder.

Using an Stxbp1 haploinsufficient mouse model that recapitulates the major features of the human disease, including motor, cognitive and seizure phenotypes, we assessed the phenotypic efficacy of 3 doses of an intravenous (IV) administered adeno-associated virus (AAV) vector delivering the CAP-002 therapeutic cargo (human STXBP1 gene, or hSTXBP1). Study results demonstrate STXBP1 supplementation that achieves brain-wide biodistribution can reverse disease phenotypes across all three disease domains (motor, cognitive, and seizure) in a dose-dependent manner, with long-lasting correction out to a year post-intervention. We also utilized human iPSC-derived Stxbp1 knockout neurons to demonstrate that CAP-002 not only robustly transduces human neurons but also restores synaptic firing and network activity in vitro. These results demonstrate that AAV gene therapy, if able to achieve wide-spread biodistribution and supplementation of STXBP1 protein in neurons across the brain, has the potential to be disease-modifying and provide a long-lasting treatment for STXBP1 encephalopathy.

Using our high-throughput, non-human primate (NHP)-based AAV engineering platform, novel AAVs have been engineered to cross the blood-brain barrier and efficiently deliver therapeutic cargos at breakthrough levels throughout the brain after intravenous delivery. The CAP-002 candidate consists of one such engineered capsid, that achieves brain-wide distribution in up to 70% of neurons in the NHP, at low to moderate doses. We have identified a novel human receptor that binds to CAP-002; this receptor has complete homology between humans and macaques in the predicted CAP-002 binding pocket, increasing confidence in the translatability of CAP-002 performance from NHP to humans. When packaging hSTXBP1, CAP-002 achieves expression across the CNS at levels comparable to those that reversed disease phenotype in the mouse model. This breakthrough profile of brain transduction, coupled

with significant de-targeting of the liver compared to AAV9, allows CAP-002 to be delivered at lower doses than historically used with systemically delivered gene therapies, offering the potential for a greater therapeutic window. Based on these data and the well-tolerated efficacy profile of CAP-002, Capsida's STXBP1 program is targeting a 1H 2025 IND filing with the goal of achieving a disease-modifying treatment for patients suffering from STXBP1 encephalopathy.

124 Enhancer AAV Toolbox for Accessing and Perturbing Striatal Cell Types and Circuits

The striatum, a key component of the basal ganglia, plays a critical role in motor control, habitual behaviors, and cognitive functions, and its dysfunction is central to a variety of movement disorders and substance use disorders. Effective targeting and manipulation of distinct cell types in the striatum is crucial for unraveling specific cellular contributions to functional circuits and for developing effective therapeutic interventions to treat basal ganglia disorders. Here we developed and validated an enhancer AAV toolbox for targeting several major striatal neuron populations, including pan-medium spiny neurons (MSNs), direct and indirect pathway MSNs, and Sst-Chodl, Pvalb-Pthlh, and cholinergic interneurons. Using enhancer elements derived from bulk and single-cell ATAC-seq data, we engineered AAV vectors that demonstrate high specificity in labeling these neuronal populations in the mouse brain. We evaluated these enhancer AAVs for their strength and specificity through various routes of administration and functional assays, including the use of Cre recombinase and opsins. Moreover, we investigated suitability of these enhancer AAV vectors for cross-species applications by comparing *in vivo* chromatin accessibility for select MSN enhancers across mouse, rat, and human, and conducting *in vivo* characterization of enhancer AAV activity in rat and macaque brain. The high conservation of enhancer activity across species underscores the immense potential of these tools for new directions in comparative cellular neuroscience and translational research. Finally, enhancer AAV screening and validation data from this collection can be viewed in the Allen Institute's Genetic Tools Atlas (GTA) at https://portal.brain-map.org/genetic-tools/genetic-tools-atlas, an open access community resource created with the support of the NIH BRAIN Armamentarium consortium.

125 Therapeutic efficacy of AAV-delivered HIV-1 bNAbs to prevent SHIV rebound in rhesus macaques

Priya Dhole[1], Michael Kuipa[2], Isai Leguizamo[3], Natalie Correa[4], Abubakarr Koroma[2], Matthew Gardner[2]
[1]Emory University, Atlanta, GA, Decatur, GA, [2]Emory University, Atlanta, GA, [3]Emory University School of Medicine, Atlanta, GA, [4]Emory University School of Medicine, Decatur, GA

Background:
In the past decades, antiretroviral therapy (ART) has become the gold standard for HIV-1 therapy for people living with HIV-1. However, ART does not eliminate the viral reservoir highlighting the need for alternative therapies. New approaches including the incorporation of broadly neutralizing antibodies (bNAbs) for HIV treatment have been explored. Our lab has been evaluating the use of adeno-associated virus (AAV) vectors to express HIV-1 bNAbs in rhesus macaques for prevention and therapy approaches against HIV. However, the host immune response routinely limits the achievable concentrations of AAV-expressed bNAbs. In an ongoing study, we have demonstrated that co-administration of PD-L1 with HIV-1 bNAbs limits the host immune response and results in sustained bNAb expression in rhesus macaques. In the present study, we aimed to demonstrate that when co-delivered with PD-L1, AAV-delivered bNAbs could maintain suppression of SHIV viremia in rhesus macaques after lifting ART.

Methods:
Two groups of eight rhesus macaques were infected with a dose of 10,000 IU/ml/animal of barcoded SHIV-AD8(EOM). All macaques were treated with ART after 17 days post-infection to suppress infection. Viral loads were monitored by plasma qPCR. Macaques in the treatment group received AAV9 vectors encoding 10-1074 and 3BNC117 co-delivered with AAV9 vectors encoding PD-L1 administered intramuscularly at 36 weeks post-infection. ART was at 46 weeks post-infection, viral loads were monitored by qPCR of the plasma, and bNAb concentrations were determined by ELISA. We will further quantify the unique barcodes of rebounding virus by deep sequencing and quantify the viral reservoir by IPDA. ELISA and ELIspot will determine anti-drug host responses.

Results:
All 16 rhesus macaques were successfully infected after one challenge with SHIV-AD8(EOM). Peak plasma viral loads between the treatment and control groups averaged from 2.0 to 2.7E+7viral RNA copies/ml, respectively. All macaques became suppressed by eight weeks after starting ART. On week 36, all macaques received AAV9 vectors to determine whether expressed bNAbs can maintain viral suppression without ART. Macaques receiving only AAV9.PD-L1 had viremia rebound within 2-4 weeks following the removal of ART. In contrast, six out of 8 macaques that received AAV9.PD-L1 with AAV9.101074 and AAV9.3BNC117 cocktails maintained viral suppression for at least 8 weeks after ART was discontinued. This observation was supported by measurable concentrations of both 3BNC117 and 10-1074 in the serum of the infected macaques.

Conclusions:
Our ongoing study reveals that the co-expression of PD-L1 is sufficient to achieve therapeutic concentrations of bNAb expression in rhesus macaques that can suppress a SHIV infection without ART. Additionally, these results suggest AAV-delivered bNAbs are a possible alternative to ART therapy in SHIV-infected macaques.

126 Focused Ultrasound Enhances Deep Brain Gene Delivery via Intra-CSF AAV Administration in Rodents and Non-Human Primates

Bradford Elmer[1], Rikke Kofoed[2], Kate Noseworthy[3], Jeffrey Ardinger[4], Kathleen Wu[3], Erik Wischhof, Laura Vecchio[5], Shih-Ching Chou[6], Shuruthisai Sivadas[5], Aishwarya Mahendran, Chinaza Dibio[7], Jie Bu, Sheng-Kai Wu, Dallan McMahon[7], Kristina Mikloska[7], Malik White[8], Shyam Ramachandran[8], Kullervo Hynynen[3], Christian Mueller[9], Isabelle Aubert[10]
[1]Sanofi, Waltham, Massachusetts, [2]Sunnybrook Research Institute, Toronto, Ontario, [3]Sunnybrook Research Institute, [4]Sanofi, waltham, MA, [5]Sunnybrook Research Institute, Toronto, ON, [6]Genzyme, a Sanofi Company, Waltham, MA, [7]Sunnybrook Research Institute, Toronto, [8]University of Toronto, Toronto, ON, [9]Sanofi Genzyme, Waltham, MA, [10]Toronto, ON

Gene delivery via recombinant adeno-associated viral (AAV) vectors offers the potential for durable therapeutic effects following a single treatment, yet effective distribution throughout the brain remains a critical challenge for addressing neurological disorders with widespread pathology. While intravenous AAV delivery provides broad systemic access, poor biodistribution in brain tissue necessitates high doses, raising safety concerns. Low-intensity focused ultrasound (FUS), in combination with intravenously injected gas-filled microbubbles, has been shown to safely and transiently modulate the permeability of the blood brain barrier (BBB) at targeted locations to enhance AAV brain delivery in non-human primates (NHPs), but only in the context of intravenous administration.

Infusion of AAV directly into the cerebrospinal fluid (CSF) is a clinically relevant route of administration that enables higher levels of transduction in superficial brain regions at relatively low doses. However, achieving widespread transduction of deep brain structures remains a major limitation. Here, we hypothesized that combining intra-CSF AAV administration with FUS-mediated BBB modulation could resolve this limitation by expanding AAV delivery into targeted deep brain regions.

In this study, we demonstrate that FUS-mediated BBB modulation combined with intra-cisterna magna AAV administration increases vector delivery to the rat striatum by 5-fold, with substantial enhancement in transduction of non-targeted brain regions, compared to intravenous AAV+FUS treated animals at equivalent doses. Building on

this success, we scaled this delivery strategy to NHPs. Following intra-cisterna magna infusion of AAV, FUS was applied unilaterally, targeting the caudate and putamen. BBB opening was confirmed throughout both targeted structures using T1-weighted scans with intravenous gadolinium contrast administration. Remarkably, three weeks post-administration, AAV vector genome delivery to the caudate and putamen was increased by up to 100-fold, and transgene expression was enhanced by up to 1000-fold, compared to the contralateral side. Robust transgene expression in the putamen, confirmed by *in situ* hybridization, was exclusive to the sonicated regions, with no detectable transduction in non-sonicated areas. Histopathological analysis of the anterior region of the sonicated structures revealed unresolved microscopic findings only in the caudate. These findings establish a compelling case for the use of FUS to extend the therapeutic reach of intra-CSF AAV delivery to deep brain structures with precision and scalability.

This approach represents a significant advancement in AAV-based gene delivery, offering a transformative platform for treating neurodegenerative diseases with widespread pathology. By enabling targeted and efficient transduction of deep brain regions through non-invasive FUS, these studies expand the transduction footprint of intra-CSF delivery, paving the way for the clinical translation of this technology to revolutionize the management of devastating neurological disorders.

127 Non-Human Primate (NHP) Safety Study of High-Dose EPI-321: A Novel AAV-Delivered Epigenetic Editing Gene Therapy for the Treatment of FSHD

Siddaraju Boregowda[1], Vishi Agarwal[1], Nalinda Wasala[2], Weston Miller[3], Alexandra Collin de L'Hortet[4]

S Boregowda, PhD, DABT[1], V Agrawal[1], N Wasala, PhD[1], W Miller, MD[1], A Collin de l'Hortet, PhD[1]

[1]Epic-Bio, Inc., South San Francisco, CA, USA

At Epicrispr Biotechnologies, we are advancing an innovative therapy for Facioscapulohumeral Muscular Dystrophy (FSHD) using our proprietary Gene Expression Modulation System (GEMS) platform. EPI-321, our investigational product, is a single-vector adeno-associated virus (AAV) serotype rh74 gene therapy designed to target the D4Z4 epigenome and permanently suppress DUX4 expression. EPI-321 incorporates an ultracompact, catalytically inactive, non-bacterially derived Cas protein fused to gene-suppressing modulators, under the control of the muscle-specific promoter, along with a guide RNA targeting the chromosome 4 D4Z4 locus.

Myotropic recombinant AAV vectors are widely used for systemic gene therapies for muscle disorders due to their unique ability to achieve clinically relevant levels of gene delivery to skeletal muscle. However, effective, global muscle delivery requires high-dose intravenous administration, which is associated with AAV class-effect toxicities. These toxicities commonly include systemic inflammatory responses characterized by complement activation, and coagulopathy. To address these challenges, we conducted a comprehensive safety study of high-dose EPI-321 in AAVrh74 seronegative cynomolgus macaques, both with and without immunosuppressive regimens aimed at mitigating AAV-related toxicities.

All animals survived until scheduled termination following high-dose - intravenous administration of EPI-321. Animals that received EPI-321 without immunosuppression (n=4) exhibited transient and stochastic complement activation, mild and transient thrombocytopenia, mild and transient elevation of hepato-biliary parameters, and mild and transient increases in prothrombin time (PT) and activated partial thromboplastin time (aPTT). These findings are hallmark features of AAV class-effect previously described in NHPs. Immunosuppressive regimens, including methylprednisolone sodium succinate (MPSS) alone (n=4) or a combination of MPSS, sirolimus, and rituximab (Triple IS; n=4), successfully mitigated these effects. Both regimens delayed and suppressed complement activation, ameliorated thrombocytopenia, and stabilized coagulation parameters, effectively reducing the severity of PT and aPTT changes.

These findings establish the safety profile of high-dose EPI-321 and highlight the benefits of immunosuppression, including methylprednisolone alone, in minimizing these AAV-related class effects in NHPs. We plan to initiate first-in-human trials in 2025, bringing us closer to delivering a novel therapeutic option for patients with FSHD.

128 Cardiovascular Investigation of SRP-9005 (AAVrh74.MHCK7.hSGCG) in Non-Human Primates: A Gene Therapy for Limb-Girdle Muscular Dystrophy 2C/R5

Stephen Baine[1], Luke Lemmerman[2], Robert Schulingkamp[3], Wenjing Xu[4], Mariana Guerrero[3], Kaiyu Greve[3], Ahmed Abokor[3], Louise Rodino-Klapac[3], Rachael Potter[1]
[1]Sarepta Therapeutics, Cambridge, MA, [2]Sarepta Therapeutics, Inc., Columbus, OH, [3]Sarepta Therapeutics, Inc., Cambridge, MA, [4]Sarepta Therapeutics, Columbus, OH

Introduction: Limb-girdle muscular dystrophy 2C/R5 (LGMD2C/R5) is a rare and progressive neuromuscular disorder caused by mutations in the γ-sarcoglycan (SGCG) gene that leads to SGCG deficiency with consequent muscle weakness and atrophy. Additionally, LGMD2C/R5 is often associated with cardiac impairment or cardiomyopathy that may present in childhood. SRP-9005 (rAAVrh74.MHCK7.hSGCG), an investigational gene therapy, utilizes a self-complementary recombinant adeno-associated virus serotype rh74 (AAVrh74) vector to deliver a codon-optimized full-length human SGCG transgene to restore functional SGCG expression and reduce LGMD2C/R5 disease burden. The safety profile of SRP-9005 in large animals following systemic delivery has not been established. We therefore evaluated the safety of SRP-9005 in non-human primates with an emphasis on cardiac safety.

Methods: Cynomolgus monkeys (N=16; n=2 male and n=2 female per dosing group; age ~3 years) received a single intravenous (IV) bolus of SRP-9005 (7.00×10^{12}, 2.00×10^{13}, or 7.41×10^{13} vector genomes per kilogram [vg/kg]) or saline (control) and were observed for 12 weeks. Prednisolone 1 mg/kg was also administered orally to all animals on Days –1 to 60. Study endpoints included echocardiography (at baseline, Week 6, and Week 12), electrocardiography (at baseline and Day 81), quantification of SGCG protein expression in skeletal and cardiac muscle by western blot (at baseline [skeletal muscle only] and Week 12), and clinical pathology evaluation including hematology, coagulation, serum chemistry, and urinalysis (blood and urine samples were collected at Weeks –2, ~4, and 12). In addition, the effect of SRP-9005 on cardiac biomarkers (cardiac troponin I) was assessed. Organ weight assessment and macroscopic and histopathological examinations of the heart were performed at scheduled necropsy (Day 85).

Results: At all timepoints, no abnormalities in cardiac function (systolic/diastolic function, left ventricular dimensions, heart rate, rhythm, or waveform morphology) were detected following administration of SRP-9005 compared to the saline-treated animals. Histopathology analysis revealed no evidence of cardiac remodeling or degeneration with SRP-9005 at all doses tested. Of note, as expected from wild-type animals, no cardiac improvement was observed. Furthermore, no SRP-9005–related effects were observed on organ weight, gross pathology, or histopathologic findings. There were no SRP-9005–related effects on hematology, coagulation, clinical chemistry, urinalysis, or cardiac troponin I levels. There was no cellular immune response to the AAVrh74 capsid or human SGCG transgene. However, a humoral response to both AAVrh74 capsid and human SGCG transgene was seen by Week 12 in all dose groups. Molecular evaluation determined a dose-dependent increase in SRP-9005 vector biodistribution and SGCG protein expression in skeletal and cardiac muscle of non-human primates administered SRP-9005.

Conclusions: A single IV dose of SRP-9005 in non-human primates did not elicit any adverse effects or cardiotoxicity at $\leq 7.41 \times 10^{13}$ vg/kg, which may guide dose selection in clinical trials for LGMD2C/R5. In addition, these data indicate SRP-9005–induced hSGCG expression in heart and muscle following systemic administration in non-human primates.

Sponsorship: The study was funded by Sarepta Therapeutics, Inc.

129 Evaluating a Bicistronic AAV9 Vector for Tay-Sachs and Sandhoff Disease: Impact of Promoter-Driven Genome Truncations on RNA Expression

Nathan Yingling[1], Samuel Lerner[2], Mitchell Yip[2], Hector Ribeiro Benatti[2], Sophia Esteves, Pamela St.Louis[2], Erin Hall[2], Jillian Gallagher[3], Abigail McElroy[4], Yvette LOPEZ[2], Sarah Nath[4], Deborah Fernau[2], Toloo Taghian[2], Robert King[5], Miguel Sena-Esteves[2], Phillip Tai[3]*, Heather Gray-Edwards[3]*
[1]UMass Chan, Worcester, MA, [2]UMass Chan Medical School, Worcester, MA, [3]UMass Chan Medical School, Worcester, Massachusetts, [4]University of Massachusetts Chan Medical School, Worcester, MA, [5]University of Massachusetts Chan Medical School
**Corresponding Author*

Tay-Sachs disease (TSD) and Sandhoff disease (SD) are neurodegenerative disorders that result from mutations in the genes that encode the α (HEXA) and β subunits (HEXB) of the hexosaminidase A heterodimeric enzyme. TSD and SD are clinically similar and manifest in infantile, juvenile, and late-onset forms. While patients with the infantile and juvenile forms face early mortality, late-onset patients can have a normal lifespan but become wheelchair-bound. A completed clinical trial for infantile TSD and SD, using two monocistronic AAVrh8 vectors encoding HEXA and HEXB, showed positive effects on disease progression and increases in cerebrospinal fluid HEXA. However, to circumvent the need for dual vectors and bi-thalamic injections, a bicistronic AAV9 vector encoding both *HEXA* and *HEXB* cDNA (AAV9Bicis_*HEXA*/*HEXB*), driven by a bidirectional CMV/chicken β-actin promoter (*BiCBA*) was developed. In a TSD sheep model, treated animals survived up to 5 years whereas untreated sheep typically die at ~nine months of age. The efficacy of AAV9Bicis_*HEXA*/*HEXB* was further supported via clinical examination and with correction of CNS histopathology 4-5 years after treatment. This data led to the submission of a pre-IND to the FDA outlining a toxicology study in rats, normal sheep, and non-human primates (NHPs).

To better understand the effectiveness of AAV9Bicis_*HEXA*/*HEXB*, we performed single molecule, real-time (SMRT) sequencing and AAV-genome population sequencing (AAV-GPseq) of packaged vectors, encoding for rat, sheep, and human cDNAs of the *HEXA* and *HEXB* transgenes. Unexpectedly and across all vector datasets, fully functional self-complementary *HEXA*- or *HEXB-only* genomes were also packaged, with these species being more prevalent than full-length genomes (Fig. 1a). The full-length species exhibited the lowest proportion of genomes in the sheep vector (11.5%), rat vector (22%), and human vector (20%) (Fig. 1b). Truncated genomes were also evident on both native and alkaline, agarose gel electrophoresis (Fig. 1c). These stark vector truncation patterns suggest that the *BiCBA* promoter is a hotspot for template-switching events during replication, likely as a result of the promoter being an inverted repeat and GC-rich.

To assess these effects on expression, wildtype NHPs, and sheep were randomly assigned to either an AAV9Bicis_*HEXA*/*HEXB* vector-treated (NHP: n=2; sheep: n=2) or a PBS control cohort (NHP: n=1; sheep: n=1). Vector or PBS was administered via combined bilateral intracerebroventricular, cisterna magna, and lumbar intrathecal injections, with treated animals receiving a total of 2.38E14 vg. At the endpoint, animals were terminated, and tissues were collected for vector genome biodistribution (Fig. 2), HexA enzymatic activity, and RT-PCR for HexA and HexB expression by qRT-PCR.

This study clarifies the efficacy of the AAV9Bicis_*HEXA*/*HEXB* vector utilizing the *BiCBA* promoter for TSD gene therapy. Truncation patterns demonstrate that *BiCBA* influences the packaging of AAV, leading to varying proportions of full-length genomes and *HEXA*- or *HEXB*-only self-complementary genomes. We hypothesize that the packaging of these unique vector constructs may have positively contributed to the efficacy of the AAV gene therapy. Forthcoming RNA expression profiles of AAV9Bicis_HexA/HexB transfected NHPs and sheep will underscore the impact of these truncation patterns on *HexA* and *HexB* RNA expression.

Novel Neurological Disease Models and Therapeutic Approaches

130 Mouse Models of Jordan's Syndrome Provide New Insights Into Disease Pathophysiology and Therapeutic Development

Isaac Villegas[1], Rency Dahduk[2], David Cameron[3], Jody Findley,[4], Julian Halmai[1], Jill Silverman[5], Stefan Strack[6], Kyle Fink[7]

[1]UC Davis, Sacramento, California, [2]University of California Davis Health Systems, Sacramento, CA, [3]University of California Davis Department of Neurology, Sacramento, CA, [4]University of California, Davis, Sacramento, CA, [5]University of California Davis SOM, Sacramento, CA, [6]University of Iowa, Iowa City, IA, [7]UC Davis, Sacramento, CA

Mutations in Protein Phosphatase 2, Regulatory Subunit B' Delta (*PPP2R5D*, OMIM 601646) lead to a rare intellectual disability disorder known as PPP2 syndrome type R5D, or Jordan's syndrome (JS). Whole exome sequencing of JS patients has identified 16 unique pathogenic variants in *PPP2R5D*, with clusters of mutations found in exons 5, 7, and 12. The two most prevalent variants, p.E198K and p.E200K, represent approximately 50% of known cases and arise from G>A transition mutations. The underlying pathophysiology of JS remains unclear; however, recent clinical case studies offer some insights with reports of patients harboring E198K and E200K variants presenting with levodopa-responsive early-onset Parkinsonism. Disease modeling using human iPSC-derived midbrain neurons has also associated JS with altered dopamine signaling. Novel mouse models of JS containing human equivalent mutations in *Ppp2r5d* have been developed. Preliminary behavioral assessments in these mice have revealed hyperlocomotive phenotypes. In our study, we investigated the role of *Ppp2r5d* variants and their pathophysiological effects in mouse brain tissues. We also explored prime editing mediated gene correction as a novel therapeutic intervention for JS. Utilizing 12- to 16-week-old E198K and E200K variant mice, protein analysis showed that *Ppp2r5d* variants do not affect overall *Ppp2r5d* expression in the brain. Immunohistochemical analysis demonstrated no structural alterations to nigrostriatal dopaminergic circuits with no loss of tyrosine hydroxylase stained (TH^+) neurons in the substantia nigra or reduction in TH^+ neuronal projections innervating the striatum. Unbiased transcriptomic analysis of tissues from the prefrontal cortex, striatum, hippocampus, and cerebellum uncovered significantly upregulated genes across genotypes and tissues that affect protein folding, translation, and RNA processing; and upregulate key pathways associated with endoplasmic reticulum stress. Furthermore, we observe altered genes in striatal tissues with known or suspected roles in Parkinson's Disease pathogenesis. To evaluate site-specific gene correction of pathogenic *Ppp2r5d* mutations, we utilized Neuro2a cells and designed enhanced prime editing guide RNAs (epegRNAs) targeting *Ppp2r5d*. The initial epegRNAs yielded <0.1% editing. By optimizing epegRNAs and assessing alternative PBS and RTT sequences, we improved editing efficiencies by more than 100-fold and can achieve up to 18% editing *in vitro* with minimal insertions and deletions detected. In summary, this data provides new insights into potential cellular and molecular mechanisms underlying JS and, more importantly, generates novel targets for therapeutic development.

131 Comparison of Angelman Syndrome Candidate Therapeutics Using a Novel Humanized Ube3a-ATS Mouse Model Highlights Major Differences in Efficacy, Tolerability, and Biodistribution

Lucas James[1], Benjamin Philpot[1]*
[1]*UNC Chapel Hill, Chapel Hill, NC*
**Corresponding Author*

Angelman syndrome (AS) is a severe neurodevelopmental disorder caused by mutations of the maternally-inherited *UBE3A* allele (*matUBE3A*). In neurons, the paternally-inherited *UBE3A* allele (*patUBE3A*) lies dormant due to silencing by a long-noncoding RNA commonly referred to as *UBE3A-ATS*. Disruption of *UBE3A-ATS* can unsilence *patUBE3A*, including by small molecules, CRISPR/Cas9, or antisense oligonucleotides (ASOs) which are currently in clinical trials. Thus, targeting *UBE3A-ATS* is a major therapeutic strategy for the treatment of AS. While the function of *UBE3A-ATS* to silence *patUBE3A* is well conserved between rodents and primates, the sequence is highly divergent. Therefore, preclinical proof-of-concept studies targeting *UBE3A-ATS* must currently use a non-clinical surrogate rather than a test article which could be used in non-human primate or clinical studies.

To overcome this limitation, we generated and characterized a novel, humanized *Ube3a-ATS* mouse model harboring 170 kb of human *UBE3A-ATS* knocked into the syntenic mouse 7q locus by CRISPR/Cas9. Notably, the humanized region encompasses *SNORD115* and the target sequence for each ASO currently in clinical trials. We confirmed that the humanized *Ube3a-ATS allele* (*hsATS*) silences mouse *patUbe3a* as efficiently as the wild-type mouse *Ube3a-ATS* (*mmATS*). Accordingly, we also confirmed the full penetrance of several reliable AS mouse model behavioral phenotypes in *hsATS* mice bred on the AS mouse background: open field hypoactivity, reduced marble burying, poor rotarod performance, deficient nest building, increased hind-limb clasping, and markedly increased immobility in the forced swim assay. *hsATS*/AS mice further exhibited increased body weight and reduced brain weight, two morphological hallmarks of AS model mice.

Collectively, our studies validate this model for the testing of human sequence-specific strategies to downregulate *hsATS* and unsilence *patUbe3a*. gRNAs targeting Cas9 to the *hsATS* allele significantly upregulated *patUbe3a* in primary cortical neurons prepared from *hsATS* mice but not wild-type littermates. Similarly, ASOs in clinical trial including RO7248824 (Roche), 1273062 (Ionis), and 4.4.PS.L (Ultragenyx) significantly upregulated *patUbe3a* in primary cortical neurons prepared from *hsATS* mice but not wild-type littermates. Further, dose response experiments revealed differences in maximal efficacy and EC50 among these ASOs. Finally, we assessed in vivo *patUbe3a* unsilencing mediated by these ASOs following neonatal ICV injection, capturing differences in ASO efficacy that mirrored our in vitro findings, and identifying major differences in their tolerability and brain biodistribution. Overall, these studies highlight the power of the humanized *Ube3a-ATS* model for preclinical studies of potential Angelman syndrome therapeutics.

132 Investigating Blood-Brain Barrier Functionality in ACTA2 Multisystemic Smooth Muscle Dysfunction Syndrome: A Murine Model Study

Aarushi Gandhi[1], Vijai Krishnan[1], Sunayana Mitra[1], Sabyasachi Das[1], Nancy Uribe Ruiz[2], Pazhanichamy Kalailingam[3], Rachel Bennett[2], Patricia Musolino[4]*

Objective:
Multisystemic Smooth Muscle Dysfunction Syndrome (MSMDS) is an ultrarare monogenic disorder caused by a missense mutation in the ACTA2 gene, where arginine at position 179 is replaced by histidine (R179H). This mutation disrupts actin polymerization, leading to shear stress on large vessels and microvascular dysfunction. The objective of this study is to characterize the effects of this vasculopathy on the blood-brain barrier (BBB) and determine whether CRISPR base editing of the ACTA2 mutation can restore BBB integrity and prevent neurodegeneration in MSMDS.

Background:
MSMDS is characterized by smooth muscle myopathy and major dysfunction in the vascular, respiratory, enteric, and genitourinary systems. In particular, cerebrovascular involvement results in strokes and white matter injury in childhood. Ischemic strokes are commonly triggered during episodes of hypotension or anesthesia, suggesting impaired cerebral autoregulation and neurovascular coupling. Previous studies in the MSMDS mouse model have shown evidence of BBB dysfunction, which contributes to the neurovascular abnormalities observed in the disorder. Additionally, CRISPR base editing has demonstrated success in restoring smooth muscle contractility and alleviating white matter disease in these same mice. This study aims to further explore the potential of CRISPR base editing to correct BBB dysfunction and mitigate neurodegeneration in MSMDS.

Design/Methods:
We developed a conditional knock-in ACTA2 R179H mouse model where the mutation is restricted to smooth muscle cells (SMCs) throughout the body. To study the effects on the blood-brain barrier (BBB), we isolated pericytes and primary endothelial cells to create an in vitro BBB model. We used dextrans of various sizes to assess the integrity of the barrier. Two-photon (2P) microscopy was employed to visualize BBB leakage using fluorescent dextran and to quantify blood flow velocity, baseline pulsatility, and functional hyperemia. Histological analysis was performed to assess BBB integrity, looking for signs of leakage, vessel damage, and neurovascular remodeling. To correlate our findings with human data, perfusion maps and MRIs were analyzed to identify vessel stenosis and straightening.

Results:
We observed accelerated neurodegeneration in the MSMDS model, displaying histopathological features similar to those seen in neuronal proteinopathies (Laur, 2021). Using CRISPR-Cas9 adenine base editing delivered by two adeno-associated virus (AAV) constructs, we corrected the ACTA2 R179H mutation in SMCs. This intervention successfully restored smooth muscle contractility and reduced BBB permeability. The in vitro BBB model showed differences in integrity, with consistent trans-endothelial electrical resistance (TEER) measurements indicating BBB

dysfunction in mutant cells. Two-photon microscopy confirmed BBB leakage in mutant mice, which correlated with accelerated neurodegeneration seen in histological analysis. Histological examination of the BBB in mutant mice revealed structural abnormalities in the blood vessels, confirming the presence of barrier dysfunction.

Conclusion:
Histological analysis revealed demyelination and neuronal loss in cortical and hippocampal regions, supporting the role of BBB dysfunction in neurodegeneration. Targeted correction of the ACTA2 mutation improved myelination and reduced pathological microglial and astrocytic activation. Future work will focus on optimizing AAV delivery.

133 AAV Delivery of Full-Length SYNGAP1 Rescues Epileptic and Behavioral Phenotypes in a Mouse Model of SYNGAP1-Related Disorders

Syngap1-related disorders (SRDs) are rare but profound neurodevelopmental disorders that manifest in a spectrum of symptoms, ranging from epilepsy to motor deficits to autism spectrum disorder (ASD). Treatment options for patients with SRD are limited with many patients relying on a cocktail of medications to manage the diverse symptoms rather than addressing the underlying pathology. Around 80% of SRDs are caused by haploinsufficiency of the SYNGAP1 gene, which encodes a critical synaptic protein, SynGAP1. We developed a gene replacement strategy to deliver SYNGAP1 driven by a pan-neuronal promoter human synapsin1 (hSyn1) via adeno-associated virus (AAV). We were able to confirm packaging of full-length transgene and successfully produce full-length protein in vivo. Cultured neurons and brain sections from vector-treated mice further suggested appropriate trafficking and synaptic enrichment of SynGAP1, consistent with expected physiological localization. To assess the potential of our transgene as a therapeutic, we administered it to a Syngap1 heterozygous (Het) mouse model and measured the effects on epileptiform activity and behavioral phenotypes. Our results revealed a developmental and dosage-dependent effect. When delivered on postnatal day 2 (P2), we observed a partial reduction of interictal spikes (IIS) and a reduction in risk-taking behavior, but no rescue of the hyperlocomotor activity. However, when we delivered the transgene at P21, we observed rescue of IISs, reduced risk-taking behavior, and normalized locomotor activity. These results demonstrate the feasibility of rescuing multiple disease phenotypes by using a gene supplementation strategy. Importantly, efficacy was observed both early and later in development, showcasing the potential of an AAV-based gene therapy approach for SRDs.

134 Developing an AAV-based gene replacement therapy for leukodystrophy caused by mitochondrial alanyl-tRNA synthetase 2 (*AARS2*) deficiency

Ailing Du[1], Ruxiao Xing[2], Lingzhi Ren[3], Nan Liu[4], Chen Zhou[1], Jialing Liang[5], Xiupeng Chen[5], Jiaming Wang[6], Guangping Gao[5], Dan Wang[5]*

The nuclear *AARS2* gene encodes mitochondrial alanyl-tRNA synthetase 2, an enzyme responsible for attaching alanine onto the cognate tRNA in mitochondria, a process known as tRNA charging. The resulting alanyl-tRNA plays a crucial role in mitochondrial translation, which produces essential proteins constituting the mitochondrial respiratory complexes. Mutations in *AARS2* have been implicated in two recessive diseases: infantile cardiomyopathy and late-onset leukodystrophy. Currently, no treatment is available for *AARS2* related diseases. To

develop a potential gene replacement therapy, we designed AAV9 vectors expressing human *AARS2* under a ubiquitous promoter (rAAV9.hAARS2). Systemic delivery to neonatal wildtype (WT) mice via facial vein injection resulted in rapid lethality due to liver toxicity, evidenced by apoptotic hepatocytes in TUNEL assays. Incorporating miR122 binding sites to enable liver-specific silencing (rAAV9.hAARS2. miR122BS) mitigated hepatotoxicity and prevented lethality. Developing animal models that accurately mimic human disease is critical for AAV gene therapy development. However, homozygous *Aars2* knockout mice are embryonically lethal. Therefore, we created a compound heterozygous mouse model that mimics the two mutations found in a patient. This mouse model harbors an exon 3 deletion and the M146T point mutation (*Aars2*$^{dEx3/M146T}$). The *Aars2*$^{dEx3/M146T}$ mice showed a 60–80% reduction in AARS2 protein levels across multiple tissues, and approximately a 50% reduction in mt-tRNA^{Ala} charging efficiency in the heart. Systemic treatment with rAAV9.hAARS2.miR122BS in adult *Aars2*$^{dEx3/M146T}$ mice partially corrected the mt-tRNA^{Ala} charging defect in these mice. In another approach to overcome embryonic lethality associated with constitutive *Aars2* knockout and to further test gene therapy, we generated a conditional knockout (cKO) mouse model by depleting AARS2 specifically in neurons. Compared to littermate controls, cKO mice exhibited significant body weight loss, severe motor deficits, and a maximum life span of 19 days. Intracerebroventricular (ICV) delivery of rAAV9.hAARS2.miR122BS to neonatal cKO pups extended their survival up to 150 days. These findings demonstrate the safety and therapeutic potential of *AARS2* gene replacement therapy. (AD and RX: Co-first authors, GG and DW: Co-corresponding authors)

135 Isoform-specific re-expression of human FMRP in mice rescues Fragile X syndrome-related translation and behavior phenotypes

Kathryn Reynolds[1], Maria Majid[1], Kyoeun Keum[1], Jun Xie[2], Xuan Chen[1], Sophia Chung[1], Robert McDermott[1], Guangping Gao[2], Yongjie Yang[1]
[1]Tufts University, Boston, MA, [2]UMass Chan Medical School, Worcester, MA

Fragile X syndrome (FXS) is the most common monogenic form of intellectual disability and frequently co-occurs with autism spectrum disorder. Patients with FXS exhibit symptoms of cognitive and social deficits, hyperactivity, sensory hypersensitivity, and sensory stimulation-induced seizure. Currently, there are no effective treatments for FXS. FXS is caused by CGG repeat expansion and hypermethylation within the 5' untranslated (UTR) region of the Fragile X messenger ribonucleoprotein 1 (FMR1) gene, resulting in transcriptional silencing and lack of FMRP protein. FMRP is an RNA-binding protein that regulates translation of a large number (~ 800) of mRNAs. Its absence often leads to excess protein synthesis, cortical neuronal hyperexcitability, and synaptic deficits. Because of the monogenic nature of FXS and the many mRNA targets of FMRP, gene therapy has been considered an attractive strategy for FXS treatment. However, it remains unclear which FMRP isoform should be re-expressed, as FMR1 undergoes alternative splicing to produce >20 unique isoforms that may have distinct functions. In this current study, we focus on two predominant FMR1 mRNA isoforms that either include or exclude exon 12 (FMR1+E12 or FMR1-E12). Sequence alignment has shown that exon 12 encodes the KH2 variable loop region, thought to be important for maintaining mRNA binding stability, on the KH2 RNA-binding domain. To examine relative abundance of FMR1+E12 or FMR1-E12 in total FMR1 during postnatal development, we performed RT-PCR with specific primers and RNA isolated from mouse and human cortex. Our results showed that the ratio of E12+ FMR1 to total FMR1 was highest at early postnatal stages and decreased with maturation in both mouse and human. By developing a novel FMRP+E12-recognizing antibody, we also found that the proportion of FMRP+E12 isoforms relative to total FMRP was highest during childhood (≤10 years) in human cortex. To determine which isoform best rescues FXS phenotypes, we then generated isoform-specific, inducible, and humanized FMR1+E12 and FMR1-E12 mice in which endogenous transcription of mouse Fmr1 mRNA is completely abolished but human FMR1+E12 and FMR1-E12 can be separately induced following breeding with the germline B-actin-Cre (ACTB-Cre). Isoform-specific FMRP was observed in the brain as early as embryonic day 15. Both FMRP+E12 and FMRP-E12 isoforms normalized excess protein synthesis relative to Cre$^-$ controls (Fmr1 KO equivalent) in BONCAT and puromycin assays, and also rescued hyperactivity in male Cre$^-$ control (Fmr1 KO equivalent) mice. However, only FMRP+E12 was able to fully correct learning deficits in fear-conditioned memory acquisition in Cre$^-$ controls (Fmr1 KO equivalent), indicating distinct roles for these isoforms during brain development and learning behaviors. We further designed an AAVPHP.eB-FMR1+E12 virus to selectively re-express FMRP+E12 in the Fmr1 KO mouse model through retro-orbital injection (at P1). FMRP+E12 re-expression was clearly observed in the Fmr1 KO mouse brain 2 weeks after injection. Consistently, AAVPHP.eB-mediated re-expression of FMRP+E12 also rescued fear-conditioned learning deficits. Together, our results suggest that FMRP+E12 is uniquely abundant in early postnatal

development and important for learning behaviors. Re-expression of FMRP+E12 therefore has the potential to become an innovative gene therapy strategy for treating FXS.

136 How Knocking Out Galectin-3 In Canavan Disease Model Mice Affects Disease Progression

Morgan Mooney[1], Anoushka Lotun[1], Peiyi Guo[1], Jie Wang[1], Nhat-Anh Nguyen[1], Guangping Gao[1]*, Dominic Gessler[1]*
[1]*UMass Chan Medical School, Worcester, MA*
**Corresponding Author*

Canavan disease (CD) is a lethal neurodegenerative disease caused by mutations in the Aspartoacylase (ASPA) gene, leading to accumulation of N-acetylaspartate (NAA) in the brain. Due to the severity of neurodegeneration, most CD patients will only live to early childhood. Some common symptoms are inability to walk, lack of head control, macrocephaly, and failure to meet developmental milestones. Histopathologically, spongiform degeneration, astrogliosis and microglia activation are prominent findings. However, the underlying pathomechanism is unclear but crucial to develop and optimize gene therapy.

A hallmark of neurodegeneration is neuroinflammation, caused by microglial reactivity, which is widely studied as a therapeutic target. However, microglia are a diverse population. To understand the microglial role in CD, single cell sequencing was performed, comparing WT, KO, and AAV treated KO mice. A significant multi-fold increase in galectin-3 (gal-3) in KO mice compared to WT was observed. We hypothesized that gal-3 contributes to CD pathomechanism and can function as a biomarker to monitor response to gene therapy. Gal-3 is a protein released by activated microglia as a neuroinflammatory response and is associated with neurodegeneration in the central nervous system (CNS).

Given its association with neuroinflammatory response, gal-3 levels and colocalization with microglia was explored before and after treatment in Nur7 mice and WT. The Nur7 mouse model has a single point mutation in the ASPA gene but has near normal life expectancy while still showing neurologic phenotypes of other CD mouse models. Gal-3 positive microglia increased significantly in Nur7 mice, particularly in brain regions of pronounced brain pathology, and decreased after treatment. The gal-3 positive microglia were also shown to be ameboid shaped and returned to a resting state post-treatment. The ameboid shape is associated with microglia activation and release of gal-3. Interestingly, we found a similar pattern when mice were treated at different time points, suggesting that gal-3 might allow monitoring to therapeutic response as it can easily be detected in cerebrospinal fluid and blood.

To determine if gal-3 positive ameboid microglia have protective or damaging function, Gal-3/ASPA double knockout (DKO) mice were created. Using brain vacuolization as an initial readout, P21 DKO and Nur7 brains showed similar vacuolization in a brain region specific manner. A similar trend was seen at P70, however, DKO seem to show worsening vacuolization.

Overall, the findings in DKO mice suggest that gal-3 might have a protective effect in untreated CD. However, gal-3 also shows a strong response to gene therapy at different treatment time points and might therefore be a viable biomarker to monitor gene therapy.

Pharmacology/Toxicology Studies and Analytics/Assay Development Session I

137 A Comprehensive and Robust Analytical Platform for Clinical Grade CAR-T Cells

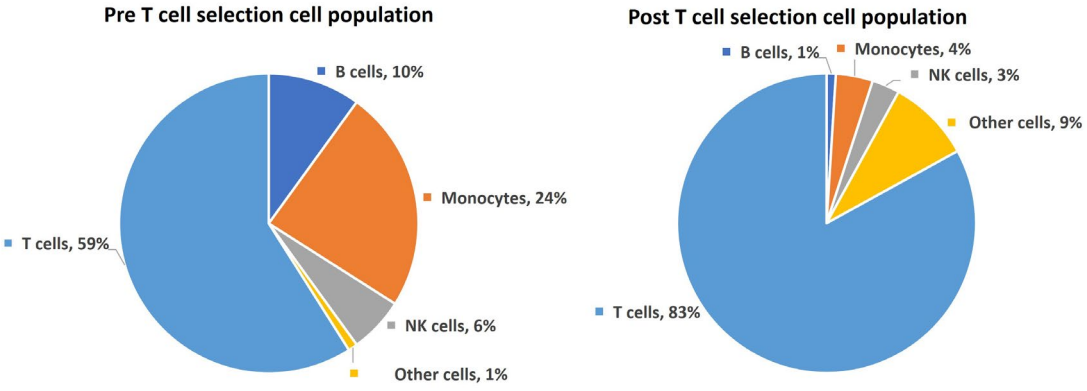
Tejashree Redij[1], Xuan Guo[2], Junxia Wang[3]
[1]Catalent Pharma Solutions, Princeton, NJ, [2]Catalent Cell and Gene Therapy, Princeton, USA, Princeton, NJ, [3]Premier Biosciences, Princeton, NJ

Background & Aim
A comprehensive and robust analytical platform has been developed using the Analytical Quality by Design (AQbD) approach to support clinical-grade Chimeric Antigen Receptor (CAR)-T cell therapy. This platform incorporates and optimizes both existing and new analytical methods to ensure robustness, reliability, and suitability for CAR-T cell manufacturing. By defining and monitoring Critical Quality Attributes (CQAs), the platform ensures consistent product quality, optimizes manufacturing processes, improves product yields, reduces variability, and identifies potential risks associated with cell therapy manufacturing.

Method
Studies were conducted to evaluate a panel of CQAs using various T cell development lots. T cells were isolated from leukopak using conventional and new cell isolation methods. A flow cytometry-based panel was developed to characterize different cell populations, including T, NK, B cells, and monocytes. Thereafter, Lentiviral Vector (LVV)-CAR was transduced to T cells, and analysis of transduction efficiency was optimized per product type by using anti-linker monoclonal antibodies-based flow cytometry. Potency was assessed through proliferation and cytokine release assays. Additionally, different characteristics of CAR-T cells were analyzed by various flow cytometry panels: A) memory, B) activation, C) cytokine, D) exhaustion, E) degranulation, and F) apoptotic panel.

Results
The analytical platform has successfully evaluated: 1) T cell purity and other cell populations (Figure 1: Flow cytometry-based analysis to evaluate the cell phenotype in pre and post T cell selection) when comparing various T cell isolation methods; 2) characterization of activation of T cells; 3) optimal transduction efficiency; 4) stemness of CAR-T cells; and 5) viability and presence of apoptotic CAR-T cells. Cytokine release analysis confirmed proper effector function and potency to kill specific target cells.

Conclusion
This integrative T cell therapy analytical platform accelerates the development of CAR-T cell therapies by reducing method development timelines for new CAR constructs. This platform is flexible and customizable to enhance the speed and quality of T cell therapy development. The platform systematically evaluates and mitigates risks associated with analytical methods and manufacturing processes, ensuring consistent product quality and advancing CAR-T cell manufacturing for clinical applications.



138 Development of Orthogonal Potency Assays for Multi-Characteristic Opsin Gene Therapy: Gene Expression and Light-Stimulated Activity

SUBRATA BATABYAL[1]*, AMIR SINGH[2], Brett Kiedaisch[3], Michael Carlson[3], Sabrina Macias[3], Sanghoon Kim[4], Najam Sharif[5], Samarendra Mohanty[6]
[1]Nanoscope Technologies LLC, Bedford, TX, [2]Nanoscope Therapeutics, Arlington, TX, [3]Nanoscope Therapeutics Inc, Dallas, [4]Nanoscope Instruments, Inc., Bedford, TX, [5]Nanoscope Therapeutics, Dallas, TX, [6]Nanoscope Therapeutics Inc, Bedford, TX
**Corresponding Author*

Multi-characteristic Opsin (MCO-010) is an AAV2-based optogenetic gene therapy product, which, upon intravitreal delivery, photosensitizes retinal neurons in the photoreceptor-degenerated retina of patients. Quality assurance of such gene therapy products requires robust potency assays that mimic biological activity relevant to the mechanism of action. This requirement presents unique challenges for optogenetic therapies like MCO-010, which must demonstrate both successful gene expression and light-activated functioning. The development and validation of appropriate potency assays for such products must navigate multiple challenges due to the non-availability of standardized assays and the complexity of developing such assays while meeting ICH requirements. The development steps include standardization of cell-based systems, optimization of viral transduction parameters for reproducible measurement of transgene expression, selection of molecular probes, establishment of reference standard, and integration of light-stimulation device with device for activity measurement. We developed a potency assay matrix that comprehensively evaluates MCO-010's critical quality attributes.

The primary assay quantifies relative potency through flow cytometric measurement of MCO-010 expressing cells, utilizing an intrinsic fluorescence reporter. This assay employed a dose-response curve to evaluate relative potency with respect to a well-characterized reference standard. The method development and validation encompassed the study of various system suitability and assay criteria such as goodness of curve fit, precision (intra-assay, inter-assay), and specificity across multiple doses meeting ICH validation requirements for product release testing.

The secondary assay measures light-stimulated calcium activity, directly evaluating the functional aspect of the MCO-010 protein. This assay quantifies calcium influx following white light stimulation using calcium-fluorescence indicators, enabling evaluation of the biological activity of MCO-expressing cells in response to light as compared to control cells. The development of this functional assay includes the optimization of multiple parameters, including the selection of cell line, light stimulation protocol, calcium indicator (concentration, incubation period), and gating for cellular response measurement.

We will present data from both expression-based and functional potency assays for MCO-010. Our results include method development findings, robustness studies across critical parameters, and validation data demonstrating assay reliability and reproducibility. We will show how these assays effectively measure product quality through a comprehensive evaluation of viral transduction, transgene expression, and light-activated functioning. This potency matrix offered enhanced confidence in product quality while providing insights into different aspects of MCO-010’s biological activity, effectively balancing manufacturing requirements with biological relevance and regulatory compliance. The successful implementation of these potency assays supports product release and stability testing and establishes standards for optogenetic gene therapy products.

139 Preclinical safety evaluation of AAV5-hNR2E3 (OCU400), a mutation agnostic gene therapy candidate for retinitis pigmentosa and leber congenital amarousis

Pushpendra Singh[1], Selina Drag[1], Rasappa Arumugham[1], Arun Upadhyay[2]
[1]Ocugen, Malvern, PA, [2]Ocugen, Inc., Malvern, PA

Background:
Retinitis pigmentosa is a debilitating ocular disease that affects 1/4000 people worldwide. In the early stages, patients develop night blindness and lose their peripheral vision, which often leads to complete vision loss at advanced stages. Nuclear receptor subfamily 2 group E member 3 (NR2E3) is a nuclear hormone receptor that regulates multiple transcriptional networks that are known to modulate retinal cell homeostasis. In preclinical studies, subretinal delivery of mouse NR2E3 rescued the RP and LCA phenotype by resetting the molecular

pathways to restore the normal ocular structure and function in all the RP and LCA disease models. In this study we evaluated safety and biodistribution of OCU400 after its subretinal administration in Gottingen minipigs.

Methodology:
AAV5-NR2E3 was administered subretinally in Göttingen minipigs at dose levels of 1.0×10^{10}, 5.0×10^{10}, and 1.25×10^{11} vg/eye. The safety and toxicity of AAV5-h*NR2E3* were evaluated in the ocular and non-ocular tissues of the animals upon administration of a single dose. All positive tissues in which vector transgene was detected were analyzed for protein expression and sustenance. Additional parameters of the study included clinical observations, body weights, food evaluation, ophthalmology, tonometry (intraocular pressure; IOP), electroretinography (ERG), multimodal cSLO fundus imaging and spectral domain optical coherence tomography (SD-OCT). Clinical pathology was evaluated using hematology, coagulation, and clinical chemistry parameters. Anti-drug antibody (ADA) analyses were performed in serum and aqueous humor for viral capsid (AAV5) and transgene (NR2E3). Cellular immune response was evaluated by ELISpot in peripheral blood mononuclear cells (PBMC), spleen, and mandibular lymph nodes, organ weights, and macroscopic and microscopic examinations.

Results:
OCU400 was specifically expressed ocular tissues with transient, low expression in some non-ocular tissues. Expression of NR2E3 was sustained in retina through 6 months post-dosing, suggesting that OCU400 targets the appropriate tissue, and is present for longer duration. Ophthalmological findings were generally mild and related to the dosing procedure, as they were present in both treated and untreated animals and were resolved over time. OCU400 treatment resulted in the development of anti-viral capsid and anti-NR2E3 ADA responses. NR2E3 demonstrated a weak antibody response, while higher antibody titers, were detected against AAV5 capsid, particularly in aqueous humor, but there were no corresponding systemic clinical signs or ophthalmic changes. There was no immunogenic response in PBMCs or lymphocytes at any time during the study. Histology data showed changes in the bleb area of all the study animals related to surgical procedure, and no OCU400-related mortality, macroscopic changes, or organ weight changes were observed.

Conclusions:
We observed that OCU400 is specifically delivered to the target tissues and efficiently transduces retinal cells where it is translated to produce NR2E3 protein. Administration of OCU400 at all dose levels was well tolerated and resulted in ocular changes that were minor and mostly related to the dosing procedure with no significant signs of toxicity.

140 Development and Evaluation of AAV9.anti-IGF1R (Insulin-like Growth Factor-1 Receptor) Vector Potency Methods for KRIYA-586, a One-time Gene Therapy for Thyroid Eye Disease (TED).

Lakmini Wasala[1], Christopher Knuckles[2], Victoria Dowling[1], Wayne Yount[1]
[1]Kriya Therapeutics, Redwood City, CA, [2]Kriya Therapeutics Inc., Durham, NC

Introduction:
TED is a debilitating chronic autoimmune disease that causes inflammation and enlargement of muscle and fat tissues in the extraocular space, leading to symptoms including proptosis and diplopia which significantly impacts quality of life. A key pathological implication of TED is the overexpression of insulin-like growth factor-1 receptor (IGF1R) in several cell types. KRIYA-586 is a gene therapy designed to inhibit IGF1R activity using AAV9.anti-IGF1R to attenuate the downstream signaling pathways to mitigate disease pathology. Assessment of vector potency is critical prior to vector release in preclinical and clinical development.

Our vector potency strategy is based on three key aspects; 1. Assessment of vector cellular entry by capsid immunostaining for specific serotype, 2. Quantitation of expressed protein to evaluate the vector-delivered transgene expression, 3. Testing for biological activity reflecting the disease specific mechanism of action.

Methods:
Vector transduction was evaluated in HEK293 cells using different transduction enhancers-at several multiplicities

of infection (MOIs). Protein expression levels were evaluated to determine the most effective transduction method using an in-house developed Gyrolab™ sandwich-immunoassay. Quantification was based on a standard curve, established through the analysis of on-column fluorescence binding profiles using the Gyrolab™ Evaluator software. Following transduction, the cells were harvested at different time points, immunostained to identify the AAV9 capsid and analyzed via flow cytometry to determine the optimal cell harvest time to detect capsid cellular entry.

Biological activity was assessed using an in-house developed chemiluminescence assay based on an IGF1R overexpression cell line. Using the vector derived anti-IGF1R protein, inhibitor-dose response curves were generated to determine the IC50 value. Potency methods were also assessed using a biologically relevant cell line along with the HEK293 cells to determine the suitability of HEK293 cells to represent the vector potency.

Results:
Addition of a transduction enhancer during AAV9.Anti-IGF1R vector transduction demonstrated a significant increase in protein expression ≥3-folds at all tested MOI's (Figure 1). Harvesting the cells at 3.5 hours post transduction was selected as a feasible time point to assess vector cellular entry. The resulting anti-IGF1R protein was quantified using Gyrolab™ immunoassay with a dynamic range of 7.8 – 500 ng/ml of target protein (Figure 2). Comparison of potency methods between a more biologically relevant cell line and the HEK293 cell line resulted in comparable protein expression levels at 233 ng/mL and 493 ng/mL, and biological activity with similar IC50 values of 61ng/mL and 67 ng/mL, respectively.

Conclusions:
The KRIYA-586 potency assessment successfully demonstrated a robust evaluation of AAV vector transduction and therapeutic protein activity. The approach of using a simplified Quality-Control feasible cell line yielded comparable biological activity measurements to those obtained from a more biologically relevant cell line, validating a more efficient approach to vector potency testing. This analytical framework allows characterization of vector functionality prior to release, while maintaining feasibility for routine testing in a GMP environment.

141 Automated and Miniaturized Sonication Linker-Mediated PCR (SLiM-PCR) for High-Throughput Integration Site Analysis in Gene Therapy Applications

Fabrizio Benedicenti[1], Sergio Arevalo[2], Giulio Spinozzi[3], Barbara Gega[4], Maria Luisa Dalessandro[4], Stefano Zancan[5], Andrea Calabria[6], Daniela Cesana[7], Alessandro Aiuti[6], Eugenio Montini[8]
[1]SR-TIGET, MILAN, Italy, Italy, [2]San Raffaele Hospital, ITALY, [3]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy, Milan, MI, Italy, [4]SR-Tiget, Milan, Milano, Italy, [5]Fondazione Telethon ETS, Milan, Italy, [6]San Raffaele Telethon Institute for Gene Therapy, ITALY, [7]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Milano, Italy, [8]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy, Milan, Milano, Italy

Vector Integration Site (IS) analysis is crucial for assessing the safety and efficacy of preclinical and clinical gene therapy (GT) applications based on integrating vectors.We developedSonication Linker mediated-PCR (SLiM-PCR), a methodthat enables retrieval and quantification of IS through specific PCR amplification of vector/genome junctions from sheared genomic DNA, combined with next-generation sequencing (NGS) and bioinformatic analysisby dedicated software. SLiM-PCR allowed for accurate identification, quantification and long-term tracking of vector marked clones, in whole blood or bone marrow samples, and in several isolated hematopoietic lineages in clinical trials based on hematopoietic stem cell (HSC) GT. It is compatible with multiple vector systems, including lentiviral(LV), gammaretroviral, and Sleeping Beauty transposon-based vectors. Over the past 10years we analyzed >7000 samples from 156 patients enrolled in 7 clinicaltrialsand >8000 samples from several preclinical studies. Given the increasing number of samples, we fully automated our laboratory procedures with liquid handling robotscapable of processinghundreds of DNA samples per week in 96/384-well plates, and enabling barcoding for multiplexed NGS. To further optimize efficiency,we are miniaturizing reaction volumes by leveragingAcoustic Droplet Ejection (ADE) technology usingthe Beckman Labcyte Echo 525, which allows precise nanoliter-scale liquid transfers via acoustic waves.So far, working on LV transduced cell lines,we have successfully reducedreaction volumes 10-fold, down to5microliters, consequently achieving increased throughput, reduced reagent consumption, and enhanced reproducibility. Our results show that we can obtain comparable results to those obtained with standard volumes in terms of IS number retrieved fromthe same amount of genomic DNA, maintaining the precision in IS relative abundance estimation (down to 0.1%) and detection limit. To further refine SLiM-PCR, we are investigating PCR-induced artifacts and chimeric sequences, which can lead to false-positive IS detection and affect overall data accuracy. By applying SLiM-PCR to genomic DNA from monoclonal cell lines harboring IS at known genomic positions, we aim to systematically assess the frequency and nature of PCR artifacts. We are optimizing PCR conditions by testing different polymerases, reducing input DNA amounts, and minimizing the number of amplification cycles to strike the best balance between sensitivity and specificity. In parallel, we are developing bioinformatics pipelines incorporating clustering algorithms and artificial intelligence (AI)-driven

approaches to detect and filter putative chimeric sequences, enhancing the accuracy of IS analysis.These advancements in automation, miniaturization, and artifact detection significantly improve the scalability, precisionand reliability of SLiM-PCR, enabling high-throughputIS tracking and strengtheneningthe robustness of longitudinal safety assessments in vector-based gene therapy applications.

142 Evaluation and Modeling of TransAct Addition for synNotch--CAR Induction Assay in E-SYNC T Cells

Background and aim:
Amplification and rearrangements of the epidermal growth factor receptor (EGFR) gene are frequently found in glioblastoma multiforme (GBM). The most common variant is EGFR variant III (EGFRvIII). At UCSF, we manufactured autologous E-SYNC T cell product to treat patients with EGFRvIII+ GBM. The percentage of induced Anti-EphA2/IL-13R alpha2 CAR is used to prepare the final dose formulation. During prior manufacturing runs, we noted that (1) the percentage of transduced cells measured by the CAR induction assay was lower than the expected percentage from the digital PCR (dPCR)-based genomic measurement of integrated copy numbers, and (2) the level of detectable CAR expression demonstrated a positive correlation with the activation state of cells. Here, we evaluated whether treating T cells with the Miltenyi TransAct, T cell activator, prior to measurement of the induced-CAR expression, would improve the sensitivity of this assay to more accurately determine the percentage of transduced cells.

Methodology:
To assess TransAct activation influence, three post-thawed cell samples from previous runs and one in-process cell sample were co-cultured with EGFRvIII-coupled beads, in the presence and absence of TransAct, to induce CAR expression from synNotch activation. Flow cytometry was utilized to assess CAR induction at the phenotypic level, while dPCR readouts were deployed as a complementary assay to evaluate transduction efficiency at the genomic level. Mathematical modeling based on the Poisson distribution principle was applied to correlate data from both genomic and phenotypic readouts.

Results:
Our data demonstrated that activating E-SYNC T cells with TransAct in CAR-induction assay improves assay sensitivity to determine transduction efficiency and calculations more accurately for vector copy number. This change improves the measurement of drug product identity, purity, and safety and ensures more accurate dose formulation. Comparison data supporting this change using in-process clinical manufacturing drug substance from patient PBMC and three additional healthy donor drug products demonstrate that the addition of TransAct more accurately aligns the flow cytometric measurements with genomic data as measured by dPCR.

Conclusion:
The addition of TransAct improves the CAR induction assay based on more reasonable associations with dPCR-based VCN analyses. We have updated assay qualification to incorporate these changes and plan to use the modified assay for future E-SYNC T Cells product releases.

143 Highly Sensitive Detection and Characterization of Intended and Unintended Gene Editing Events by TES.

Joanna Szumska-Aubermann[1], Muhammad Jamil[2], Manuel Palacios Pérez[3], Jorge Peral-Redruejo[4], Francisco Diaz Pascual[5], Rafaelle Fronza[6], Saira Afzal[7], Juan Bueren[8], Susana Navarro[9], Richard Gabriel[7]
[1]ProtaGene CGT GmbH, Heidelberg, Germany/ Baden-Württemberg, Germany, [2]ProtaGene CGT GmbH, Heidelberg, Baden-Wuerttemberg, Germany, [3]CIEMAT, Madrid, Madrid, Spain, [4]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT), Madrid, Spain, [5]Heidelberg, BW, Germany, [6]ProtaGene GmbH, GERMANY, [7]ProtaGene CGT, Heidelberg, Baden-Wuerttemberg, Germany, [8]CIEMAT, Madrid, Spain, [9]CIEMAT/CIBERER/IIS-FJD, Madrid, Spain

Gene editing (GE) is a revolutionary technology that offers the potential to treat genetic disorders and improve human health. Techniques like CRISPR-Cas9 have made GE more accessible and efficient, opening promising avenues for medicine and biotechnology. However, one of the significant safety concern is off-target effects, where unintended alternations occur in the genome. These **off-target editing events** can potentially lead to harmful consequences, such as the disruption of essential genes or deregulation of cancer-associated genes. As GE technologies continue to evolve, ensuring accuracy and minimizing these unintended alterations is essential to mitigate risks and ensure the safety of these powerful tools.

Commonly used off-target GE detection and characterization methods in cells and tissues, such as GUIDE-seq, Bless and Discover-seq are mainly suitable for developmental phase of GE tools. Due to reliance on exogenous tags, requirement for live and dividing cells or cells fixed upon double strand break induction, real time active repair-based detection, low sensitivity and complex workflows these methods might be impractical for routine, scalable monitoring of patient samples after treatment.

Thus, it is essential to develop methods that not only assess off-target activity during development but also enable the quantification of **genomic integrity in the cell-based product**. Additionally, these methods should allow for the **monitoring of gene-edited patient cells and tissues**. Applying our **advanced target enrichment sequencing (TES)** method we developed a novel approach for GE off-target detection and characterization, which can be applied for non-clinical as well as clinical setting. The method uses a set of RNA baits designed for enrichment of known on-target site as well as **>1600 predicted CRISPR-Cas off-target cut sites** on DNA samples obtained from CRISPR-Cas9 gene edited cells.

We optimized our experimental workflow on a novel knock in HDR developed strategy to edit RPL5 locus to apply it to several pipelines of interest, achieving very high sensitivity of our method for **DNA input as low as 50ng**. In particular we were able to characterize all predicted off-target sites. Using low DNA input is highly beneficial when testing for off-target effects in GE therapy, allowing analysis of more precious samples, which is particularly important when working with patient-derived or limited DNA sources.

Moreover, we were capable to detect internal control DNA sequences with known ratio of **small insertion-deletion mutation with a high precision and accuracy**. High level of accuracy and precision was also confirmed for the detection of more infrequent genetic alterations, such as **chromosomal translocations**. The ability to identify mutations at rare frequency ensures that even subtle genomic alternations, which could have significant biological implications, are reliably detected and analyzed.

Our method can be adapted and qualified for **any type of GE approach** by applying sequence-specific probes. Hence it will be a valuable tool in determination and characterization of potential off-target sites for GE- based gene therapy sample analysis. While assessing the precision and efficiency of developing GE therapies as well as providing precise monitoring of genomic stability in patients, it will become an essential tool for safety assessment in GE development.

144 Bioinformatic analysis of the genetic basis of differential AAV production capability of 293 variants

Junping Zhang[1], Christopher Herzog[2], Xiaomin Feng[3], Thao Dang[4], Xiangping Yu, Jie Huang[2], Fang Fang[2], Hongyu Gao[1], Xuhong Yu[2], Yue Wang[2], Yulong Liu[2], Kenneth Cornetta[1], Weidong Xiao[1], Weihong Xu[5]
[1]Indiana University, Indianapolis, IN, [2]Indiana University School of Medicine, Indianapolis, IN, [3]Fudan University, Guangzhou, China, [4]Department of Medical and Molecular Genetics, School of Medicine, Indiana University, Indianapolis, IN, [5]Greater Bay Area Institute of Precision Medicine (Guangzhou), Fudan University&Stanford Genome Technology Center, Palo Alto, CA

A major application of 293 cells is the production of adeno-associated virus (AAV) vectors. Stable integration of adenoviral genes E1a and E1b, which are required for AAV production, in the 293 cell genome, makes 293 cell lines the predominant choice for AAV production in mammalian systems. During the process of AAV vector development, 293 cell lines have been evolved in parallel for maximum vector yield. Despite the excellent performance of these new variants in AAV manufacturing, the molecular basis of these new variants has yet to be investigated. In this study, we sought to study the genomes of two high AAV production cell lines, 293A, an adherent variant derived from a clone commonly used in our laboratory, and 293S, derived from a commercially available suspension cells (VPC2, Thermo Fisher Scientific.). Genomic DNA from these two HEK293 derivatives was sequenced by Nanopore long-read sequencing technology. Sequencing yielded an average depth of coverage exceeding 10×. For comparison, we retrieved Illumina short-read sequencing data from the SRA database for the original HEK293 cell line and three derivatives-HEK293F, HEK293Freestyle, and HEK293H-under the accession numbers SRR10129632, SRR10129614, SRR10129620, and SRR10129613, respectively. The origins of these cell

lines are summarized in **Figure 1**. For simplicity, these cell lines are referred to as 293, 293F, fs293F, and 293H, respectively.

Our study revealed that the two high rAAV-yielding cell lines, 293A and 293S, exhibit greater genomic similarity compared to other 293 variants, despite their markedly different origins. While 293A is an adherent cell line maintained in our lab for over 20 years, 293S is a recently developed suspension cell line from Thermo Fisher Scientific. This unexpected finding suggests that both cell lines may share underlying genetic mechanisms that confer efficient rAAV production. We for the first time identify a genomic duplication of adenovirus integration regions (~328kb region). The high AAV yield variants, 293A and 293S, both showed a duplication pattern in this region that is distinct from that of other 293 cell variants (**Figure 2**). In addition, the viral E1A and E1B genes are brought into close proximity to strong regulatory elements, such as enhancers GH19J043180 and GH19J043200. These enhancers, which are associated with the (PSG) family, are enriched with H3K27Ac marks and transcription factor binding sites, indicative of high enhancer activity. Following adenoviral gene integration, GH19J043180 and GH19J043200 may predominantly interact with the integrated viral genes, effectively "hijacking" the local regulatory environment and redirecting their activity to drive robust expression of E1A and E1B. These findings showed that the molecular states of the adenovirus integration region may be one of the key factors leading to high yield production of AAV vectors.

A limitation of this study is that HEK293 derivatives were sequenced using two different sequencing technologies, with different sequencing depths and read lengths. This difference may introduce systematic bias when comparing genomic features between two sequencing technologies, especially in the absence of internal controls at critical genomic loci. Future studies incorporating unified sequencing platforms and orthogonal method validation will be important to further confirm these findings.

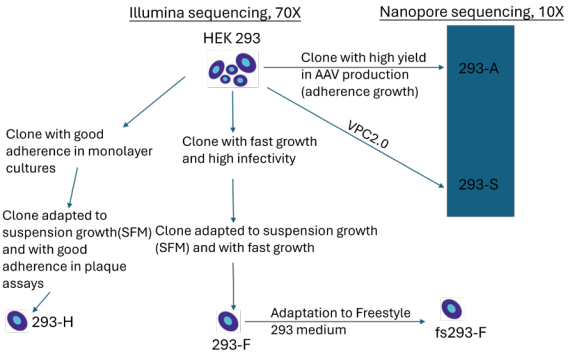

Figure 1. 293 genome sequencing and acquisition. The origins of these cell lines and sequencing methods utilized are summarized.

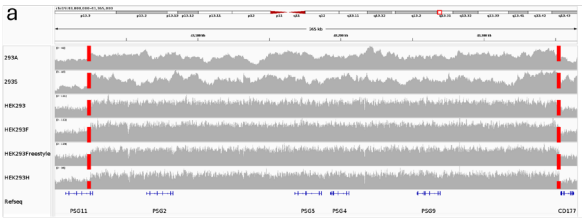

b

	# of reads supporting reference:alternative SV alleles

Ensuring the molecular quality and authenticity of biomaterials is critical for the reproducibility and reliability of scientific research. ATCC® supports these efforts by maintaining a vast collection of highly authenticated and characterized biomaterials widely used across the biological sciences. However, as genetic and molecular data become increasingly complex, more rigorous quality assurance processes become essential.

To address these challenges, ATCC® is building a comprehensive reference omics database to warehouse genomic and transcriptomic sequencing data, detailed gene expression analyses and genetic status information for all ATCC® human and animal cell models. By integrating next-generation sequencing technologies, bioinformatics, and expertly curated reference data, we are creating a robust framework to ensure the validity and molecular integrity of ATCC® cell model collections. Access to the entire database is currently available through the ATCC® Cell Line Land from QIAGEN Digital Insights® and will be made available through the ATCC Genome Portal later in 2025.

Our work involves mapping transcriptomic landscapes, performing variant analyses, and standardizing data to deliver a reliable platform for researchers to verify the identity and quality of their biomaterials. We have completed whole-transcriptome and exome sequencing for over 600 human and mouse cell lines and expect to continue adding new data for at least 250 additional cell models per year. These datasets lay the foundation for improved quality control, the elimination of molecular ambiguity, the reduction of contamination risks, and enhanced reproducibility in biomedical research.

In this presentation, we will share our progress in sequencing cell models, discuss the challenges we've encountered, and outline long-term strategies to maintain these databases as indispensable global resources for the scientific community.

146 Comparison of Linker mediated PCR (LM-PCR) and Target enrichment mediated (TES) methods for genome wide retrieval of rare AAV integration events in preclinical models

The retrieval of rare AAV integration events from preclinical and clinical specimens is important for understanding the safety and efficacy of gene therapies involving AAV and other DNA-based vectors. Given that AAV integration is considered a rare event and AAV genomes are frequently rearranged due to concatemerization in transduced tissues, it is vital to assess the sensitivity and quality of assays commonly used to detect AAV integration for the development of more standardized analytical assays supporting preclinical safety assessments. To address this, we generated a reference sample which consisted of mixing genomic DNA isolated from AAV transduced livers with synthetic dsDNA standards which were spiked in limiting dilutions. This reference sample set was used for evaluating and comparing two widely used methods—LM-PCR and TES—for their sensitivity, reproducibility, and efficiency in retrieving AAV integration sites with NGS platforms.

Results from mouse tissues injected with two doses of AAV vectors revealed integration frequencies ranging from 1 x 10^{-3} to 3 x 10^{-2} integration events per haploid genome depending on the method applied and dose analyzed. The synthetic standards were detected at a frequency of 1.5 x 10^{-5} using LM-PCR and 1.5 x 10^{-4} copy numbers per haploid genomes with TES, with LM-PCR showing higher sensitivity compared to TES. Generally, NGS-based relative clonal abundances were more easily resolvable with LM-PCR-based methods compared to TES. However, LM-PCR also yielded more PCR artifacts, as evidenced by the retrieval of false positive reads specific to the spiked in standards, suggesting that TES methods are less prone to such artifacts. A comprehensive genome wide distribution of AAV integration site patterns in the mouse genome and their association to cancer-related genes was evaluated based on over 20,000 integration sites detected in the liver of AAV dosed mice. A significant advantage of TES is its ability to capture integration events involving fusion of non-ITR regions to the host genome, which are challenging to detect with tiled primers in LM-PCR. This ability allowed for the generation of a map of fragile regions of the AAV genome involved in AAV integration and concatamerization events, indicating that the 3' end of the AAV vector may have a higher probability of being involved in integration and concatamerization events.

This comparative study highlights the strengths and limitations of the most commonly used NGS methods for detecting rare AAV integration events, providing the research community with valuable insights to guide the selection of appropriate methods for analyzing rare AAV/DNA integration events for preclinical safety studies.

147 Evaluation of Target Enrichment Sequencing to Assess AAV Integration Patterns for the Safety Assessment of Gene Therapies

Myriam Lemmens[1], Erica Coratella[2], Martin Beibel[2], Rebecca Bohnert[2], Lara Bontadelli[3], Ulrike Naumann[2], Mevion Oertli[2], Eloise Hudry[1], Silvana Libertini*

**Corresponding Author*

Recombinant adeno-associated viruses (rAAVs) are frequently used as vector for gene therapy due to their ability to transduce various cell types and their favorable safety profile. RAAV viral genomes primarily persist as episomes within the nucleus, but a small percentage of integration into the host genome has been reported in both nonclinical and clinical studies. In murine models, rAAV integration has been linked to the development of hepatocellular carcinoma, though this finding has not been observed in other species or clinical trials. To further investigate this risk across nonclinical and clinical samples, the development of a reliable pipeline to identify rAAV integration sites is paramount. While various methods have been successfully developed for lentiviruses, assessing the integration profile for rAAVs presents unique challenges due to their low integration frequency and the occurrence of viral genome rearrangements. Additionally, the absence of well-characterized controls impedes the assessment of different techniques.

In this study, we used stable cell clones as tools to evaluate Target Enrichment Sequencing (TES) for AAV integration site analysis. These clones were generated by leveraging the tendency of rAAVs to integrate in genomic double-stranded DNA (dsDNA) breaks. DsDNA breaks were induced in the *PTPN12* and *Meg8* genes via CRISPR/Cas9-mediated cleavage in the human MCF10A cell line, followed by transduction with a rAAV-GFP tool vector. Subsequently, single-cell cloning was performed. The clones were thoroughly characterized by Vector Copy Number (VCN) quantification via ddPCR, and long-range PCRs, which demonstrated homozygous and heterozygous integrations in the intended target site of varying sizes. Discrepancies between VCN and long-range PCR also suggested additional integrations at unknown sites. Further characterization using TES with PacBio long-read sequencing revealed that most integrations indeed occurred at the CRISPR/Cas9 target site, but approx. 40% of the clones exhibited integrations at random loci, including repetitive regions that were difficult to map. Integrated viral genomes were truncated, with sizes ranging from 70 bp to concatenated integrations of multiple AAV genome copies. Rearrangements of the vector sequence and integrations containing parts of the plasmid backbone used to generate the rAAV were also identified. Additionally, deletions were detected in the human genome around the AAV integration site. Whole genome sequencing confirmed the TES results. Finally, the limit of detection of TES was evaluated.

In conclusion, this study characterizes TES' performances for AAV integration site analysis, aiming to support the safe development of gene therapies. Additionally, our findings provide valuable insights into the patterns of CRISPR/Cas9-targeted AAV integration, demonstrating that integrations do not always occur at the intended target and can be accompanied by genomic deletions, vector rearrangements, and truncations.

148 Highly Sensitive Detection of Integration Sites by S-EPTS/LM-PCR and TES for Various Types of Therapeutic Vectors

Tim Rath[1], Ivan Labik[2], Matteo Franco[3], Loubna Youssar[1], Rene Heimke[4], Saira Afzal[1], Richard Gabriel[1]
[1]ProtaGene CGT, Heidelberg, Baden-Wuerttemberg, Germany, [2]ProtaGene GmbH, Heidelberg, Baden-Wuerttemberg, GERMANY, [3]ProtaGene US Inc., Burlington, MA, [4]ProtaGene, Heidelberg, Baden-Wuerttemberg, Germany

Safety is critical for development and application of every therapeutic vector in cell and gene therapy. Cases of insertional mutagenesis in previous clinical trials have demonstrated importance of detection, tracking and further characterization of **vector integration sites (IS)** from preclinical development to longitudinal monitoring of patients. Originally developed for integrating vectors, such as gamma-retroviral (gRV) and lentiviral vectors (LV), highly sensitive and specific detection methods have been further refined allowing detection of rare integration events of non- or low-integrating vectors, such as recombinant adeno-associated viral (rAAV) vectors or non-viral vectors.

We have developed **shearing extension primer tag selection ligation-mediated PCR (S-EPTS/LM-PCR)** to achieve high sensitivity, fast turnover and high specificity in IS detection. S-EPTS/LM-PCR was validated for LV based on common long terminal repeat (LTR) sequences. Via analysis of cell clones representing single, specific IS in polyclonal background, the assay's dynamic range was confirmed to cover accurate quantification for clinically relevant clonal contributions. S-EPTS/LM-PCR detects IS using a set of nested primers specific for the vector of interest. As other PCR based methods, S-EPTS/LM-PCR allows detection of vector IS containing the primer binding sites. S-EPTS/LM-PCR therefore is particularly well-suited for integrating vectors that are characterized by stable LTR regions present in a multitude of different vectors.

We have further developed an approach utilizing **target enrichment sequencing (TES)** to capture the entire vector sequence. Thereby, TES enables detection of vector fragments integrated into the host cell genome. This method is particularly advantageous for AAV vectors, which are known for rearrangements and partial vector integration (Batty et al., 2024). Both methods, S-EPTS/LM-PCR and TES, can be adapted and qualified for any type of vector by applying sequence-specific primers or probes.

Sequencing data generated from these experimental methods is analyzed using tailored, comprehensive bioinformatics framework, designed to facilitate IS analysis through the core tool, **GENE-IS** (Afzal et al., 2017). Beyond the representation and quantification of IS by GENE-IS, the framework extends to advanced downstream assessment, allowing, e.g., IS distribution profiling, identification of common IS and IS in proximity of cancer-associated genes, or assessment of sample diversity, enhancing insights into clonal dynamics. The key component of our framework is safety assessment and understanding the risk of insertional mutagenesis posed by vector integration into the host genome.

Complementing the two methods, we have developed a **whole-genome sequencing (WGS)** analysis framework. Combination of WGS with either S-EPTS/LM-PCR or TES delivers a comprehensive, whole genome perspective on IS as well as structural genetic variants, thus enabling thorough evaluation across preclinical and clinical studies and of particular interest in cases of serious adverse events in gene therapy.

To date, our methods for IS analysis have been applied in more than 60 clinical studies as well as many pre-clinical studies and generated data were part of safety assessment enabling approval of multiple gene therapies using gRV, LV and rAAV.

149 Redefining rAAV Vector Analysis and Quality Control with Orthogonal Long-read Sequencing Technologies.

Luca Nanni[1], Marc Antoine Perrenoud[2], Rachel Buchs[2], Jens Stolte[2], Romain Daveau[3], Pelin Kolcak Yasli[3], Ann-Kristin Hov[1], Thierry Schuepbach[4], Igor Fisch[2], Efrain Guzman[1], Nicolas Mermod[3]
[1]NewBiologix, Epalinges, Vaud, Switzerland, [2]NewBiologix SA, Epalinges, Vaud, Switzerland, [3]NewBiologix SA, Epalinges, Switzerland, [4]NewBiologix SA, Epalinges, VD, Switzerland

A major challenge in recombinant adeno-associated virus vectors (rAAV) production arises from the difficulty for traditional identity analytical methods such as PCR amplification and DNA sequencing of the encapsulated vector genomes to accurately assess the quality of the material produced. Massive parallel sequencing can be used to provide identity and quality information on rAAV drug products as well as the effect of upstream and downstream processes on the resulting rAAV. However, technical and bioinformatic processes greatly influence the quality and reliability of the produced information.

To overcome these challenges, we have developed an integrated platform for the analysis and quality control of rAAV based on high-throughput, long-read sequencing technologies and a standardized bioinformatic pipeline. Viral genomic DNA is extracted and processed to generate DNA library preparations using a set of high-quality quality standards to control potential extraction and sequencing biases. Viral DNA sequencing is implemented using both SMRT-seq (PacBio) and Oxford Nanopore (ONT) technologies.

Both platforms were compared in terms of their sequencing output, read quality, mappability on the vector sequences, percentage of partial and intact vector genomes, as well as the ability to detect contaminating host cell and plasmid DNA sequences. As an orthogonal method, duplex digital-PCR was used as a baseline for vector integrity quantification. We also dissected potential biases in the SMRT-seq and ONT library preparation processes, quantifying their impact on the downstream analysis. We quantified a bias towards long DNA fragments generated during SMRT-seq library preparation, which is not present in ONT libraries. SMRT-seq outcomes depend also on the second-strand generation strategy used, while ONT sequencing is instead able to sequence single-stranded DNA directly, though with less accuracy. We have developed and implemented internal process controls to correct for these technical challenges.

A novel bioinformatic pipeline quantifies ITR-to-ITR sequences as well as the potential presence of rep-cap, host cell and plasmid sequences. The pipeline performs first a raw quantification of the detected sequences, followed by a corrected estimation based on the inferred biases, allowing for a realistic assessment of the rAAV products.

This novel process relying on strong internal and process controls can be used to provide Critical Quality Attributes (CQA) of rAAV preparations for use in pre-clinical and non-clinical studies.

Innovations in in vivo Targeting of HSPCs and Immune Cells

150 *In Vivo* HSC Gene Editing for Correction of the Sickle Cell Mutation Using RNA Gene Writers

Tessera Therapeutics is pioneering a new approach to genome engineering through the development of Gene Writing and delivery platforms. Our RNA Gene Writers leverage all-RNA components and harness the mechanism of target-primed reverse transcription, to edit genetic information without the need to introduce DNA double stranded breaks. RNA Gene Writers can introduce a broad range of genomic alterations, from writing in a transgene to introducing single nucleotide changes, providing a versatile toolkit for addressing monogenic diseases. Here, we applied RNA Gene Writers to correct the sickle cell disease (SCD) causing mutation HBB E6V, in hematopoietic stem cells (HSCs), with the aim of achieving therapeutically relevant levels of gene correction *in vivo*.

We first modeled the efficiency of HBB editing by introducing HBB Makassar variant (E6A) in WT CD34+ human HSCs. We observed an average of 74% editing *in vitro* after optimization of the RNA template and RNA Gene Writer expression. We measured high engraftment levels and maintenance of ~70% HBB editing in long-term repopulating HSCs and their multi-lineage progeny at 16 weeks post-transplant in mice. Comparable editing levels were also maintained after secondary transplant. We then demonstrated efficient editing of HSCs from multiple SCD patients, showing ~70% correction of sickle alleles to WT. Erythroid differentiation from edited cells showed 98% restoration of normal adult hemoglobin levels by HPLC and abrogation of cell sickling.

RNA Gene Writers are designed to be delivered as all-RNA compositions, facilitating *in vivo* delivery by lipid nanoparticles (LNPs) and eliminating the need for viral vectors and DNA template-based editing. We previously demonstrated that our HSC-targeting LNPs achieved ~95% delivery of GFP reporter cargo to HSCs in humanized mice and non-human primates (NHP) through intravenous administration.

We have now demonstrated 62% HBB Makassar install *in vivo* in LT-HSCs (Lin-CD34+CD38-CD90+ cells) in humanized NBSGW mice, after a single dose of RNA Gene Writer formulated in HSC-targeting LNP. Comparable editing levels were maintained in HSCs and multi-lineage progeny after transplanting *in vivo* edited CD34+ into secondary mice, demonstrating absence of functional impairment after *in vivo* editing and successful targeting of bona-fide LT-HSCs. We have also shown in repeat dosing studies that a second administration of LNPs enabled a near linear increase in the percentage of HBB editing in LT-HSCs.

Importantly, in cynomologous NHP we showed an average of 24% HBB Makassar install *in vivo* in LT-HSCs (day 14 post treatment). Editing levels were stable up to 4 months and edited cells were present in multiple hematopoietic lineages. Longitudinal analysis of edited cells in NHP provided insights on the kinetics of output after editing, showing stable myeloid output as early as 2 months after treatment.

Finally, we validated the robustness of our *in vivo* HSC editing system by using RNA Gene Writers targeting an independent genomic locus (B2M). We achieved high (>70%) and stable levels of *in vivo* editing of B2M in NHP LT-HSCs that was maintained for over 6 months post treatment, further demonstrating the applicability of our findings to other targets.

All together, we demonstrated that RNA Gene Writers can efficiently edit long-term HSCs *in vivo* in mouse and NHP, across multiple targets, and have the potential to provide therapeutic benefit to patients with SCD.

151 In Vivo Generation of TRAC-Targeted CAR T Cells via Site-Specific Integration Enables Cell-Specific Engineering and Potent Antitumor Activity

William Nyberg[1], Pierre-Louis Bernard[1], Jonathan Ark[2], Wayne Ngo[3], Jennifer Hamilton[4], Robert Stickels[5], Jennifer Doudna[6], Aravind Asokan[7], **Justin Eyquem[1]***

Engineered T cells, reprogrammed to express chimeric antigen receptors (CAR) or T cell receptors (TCR), have transformed cancer treatment and are being explored as therapeutics for autoimmune disorders and infectious

diseases. Enhancing T cell function through genome editing—either by disrupting endogenous genes or precisely inserting DNA payloads—has shown significant promise. However, ex vivo manufacturing of these therapies is costly, complex, and logistically challenging, limiting their scalability and accessibility. In addition, adoptive T cell therapies require lymphodepletion, which can lead to severe side effects such as cytopenias and subsequent infections.

In vivo generation of engineered T cells represents a promising advance in cancer immunotherapy because it bypasses ex vivo manufacturing and lymphodepletion preconditioning, thereby offering the potential for more accessible and effective treatments for cancer patients. However, current methods for in vivo delivery rely on transient or random integration of DNA payloads, which may limit their persistence and safety.

We hypothesized that integrating a promoter-less CAR transgene at the TRAC locus in vivo would combine T cell-specific and physiological CAR expression. To achieve this, we developed the first method for in vivo site-specific integration of large DNA payloads in human immune cells. We used a two-vector system in which an enveloped delivery vehicle (EDV) delivers a Cas9 ribonucleoprotein (RNP) and an adeno-associated virus (AAV) carrying a homology-directed repair (HDR) template ensures precise integration at the TRAC locus. We optimized both vectors for delivery specificity and gene targeting efficiency. First, we pseudotyped the EDV envelope with a mutated VSVG to prevent interaction with the LDL receptor and then targeted it to T cells using an anti-CD3 antibody, thereby ensuring both specificity and T cell activation. Second, we evolved a novel AAV capsid, named Ark312, which is resistant to neutralizing antibodies and exhibits T cell-biased tropism.

To assess our system, we performed a single injection of the two vectors encoding a TRAC-targeted CD19 CAR-2A-EGFRt into a humanized mouse model (MHC I/II DKO NSG engrafted with human PBMCs). Notably, our in vivo approach achieved TRAC-CAR engineering in up to 20% of T cells in the spleen—an efficiency unprecedented for in vivo genome editing techniques—and resulted in deep B cell aplasia. To demonstrate the exquisite specificity of our approach, we performed an ex vivo experiment in which we knocked in a GFP transgene at the clathrin A (CLTA) locus, a gene ubiquitously expressed in T cells, B cells, NK cells, macrophages, hematopoietic stem cells, and multiple malignant B cell lines. We showed that only T cells were engineered using our two-vector system, confirming that the combination of our delivery method and TRAC-restricted expression results in a highly T-cell–specific therapy. To validate the therapeutic potential of in vivo–generated TRAC-CAR T cells, we tested the vectors in an aggressive humanized B-cell leukemia tumor model (Nalm6) and observed complete tumor resolution. The edited T cells were functionally persistent, as demonstrated by their ability to control tumor growth upon rechallenge. Thus, in vivo–generated TRAC-CAR T cells combine cell-specific and physiological CAR expression while bypassing ex vivo manufacturing and patient preconditioning.

152 Efficient and Liver-Detargeted *In Vivo* Multiplex Gene Editing of Human Hematopoietic Stem and Progenitor Cells

Pauline Schmit, Ethan Waple, Matteo Gentili, Dylan Dautel, Chen Wang, Geoffrey Burns, Karol Budzik, Mahmudul Hasan, Lauren Ferreira, Claudia Pereira, Angela Dao, Anne Richard, Yi Yu, Cosmin Mihai, Melissa Bonne[3], Luca Biasco*

In vivo genetic engineering of hematopoietic stem and progenitor cells (HSPCs) has the potential to transform the treatment of numerous diseases with significant unmet needs. An ideal delivery system for gene-modifying cargos should a) deliver transient species, such as ribonucleoproteins (RNPs), to reduce immunogenicity and off-target gene editing, b) efficiently target human HSPCs in their quiescent state, c) access HSPCs in the bone marrow niche, and d) minimize off-tissue delivery, particularly to the liver.

To this aim, we developed targeted virus-like particles (DLVR) carrying RNP gene-editing cargoes fused to a retroviral capsid and equipped with an envelope with targeting moieties designed to confer high tropism for human HSPCs. Our first design incorporated a Baboon endogenous retrovirus glycoprotein (BaEVTR) and an MMLV capsid fused to an RNP Adenine Base Editor (ABE) targeting the human Beta-2-Microglobulin (B2M) gene. These particles achieved high editing efficiency (up to 80%) *in vitro* in human HSPCs without cytokine stimulation. Systemic intravenous delivery in a short-term humanized NBSGW mouse model resulted in double-digit editing levels in BM-resident HSPCs (20%). Our BaEVTR DLVR also displayed a high tropism for B cells. To evaluate HSPC targeting under more challenging conditions, we dosed BaEVTR DLVR particles in long-term humanized mice with fully engrafted human BM (92%) and high proportions of human B cells in the peripheral blood (PB) and spleen (23% and 19%, respectively). In this scenario, BaEVTR DLVR achieved high editing levels in PB and spleen (26% and 35%, respectively) while maintaining robust BM HSPC editing (5%). Notably, transduction enhancers such as vectofusin-1 (VF1) are dispensable *in vivo*. Most importantly, and differently from other delivery systems aimed at HSPCs, our BaEVTR DLVR particles essentially avoid human hepatocytes *in vitro* and *in vivo* in the FRG mouse model (0.9% vs. 18% editing achieved with a VSV-G DLVR at equivalent dose).

To enable multiplex editing, we developed BaEVTR DLVR particles carrying ABE complexed with two gRNAs targeting B2M and BCL11A, achieving efficient editing at both loci *in vitro* in resting HSPCs (up to 85% and 64%, respectively) and *in vivo* in NBSGW mice (average of 22% and 12%, respectively). Further enhancing potency and specificity, we next designed a new class of engineered envelopes (BaEVX) swapping the cytoplasmic domain of BaEVTR with that of different retroviruses to improve compatibility with the DLVR platform. Two BaEVX constructs demonstrated equal multiplex editing capability, but superior editing potency compared to BaEVTR *in vitro* in absence of VF1 (up to 59% vs. up to 22%) and, when further engineered with a CD133-specific binder, achieved unprecedented levels of in vitro editing of resting HSPCs without transduction enhancers (up to 92%). *In vivo* dosing of BaEVX particles in humanized mice is ongoing. Importantly, BaEVX particles produce in high titers in suspension cell lines, and manufacturing scale-up is underway to enable studies in cynomolgus macaques. Overall, we demonstrated that our HSPC-tropic BaEVX particles efficiently achieve RNP-mediated editing in human HSPCs under resting conditions *in vitro* and *in vivo*, accessing HSPCs within their natural BM niche. BaEVX DLVR enables multiplex *in vivo* editing of HSPC while avoiding liver transduction, making it a promising candidate for clinical translation.

153 Targeted LNP Delivery of an RNA Gene Writer *In Vivo* Enables Generation of functional CAR-T Cells in a Humanized Mouse Model

Alberto De Iaco[1], Jason Rodriguez[2], James Rottman[3], Donghui Li[4], Kartika Venugopal[1], Xin Qiao[5], Yu Cao[5], Jessica Desmond[5], Rebecca Levy[5], Mohit Gupta, Rahul Palchaudhuri[6], Jane Wang[1], Bill Querbes[1], Hari Pujar[7], Cecilia Cotta-Ramusino[3], Michael Holmes
[1]Tessera Therapeutics, Somerville, MA, [2]tessera therapeutics, Cambridge, [3]Tessera Therapeutics, Inc., [4]Tessera Therapeutics, [5]tessera therapeutics, Cambridge, MA, [6]Tessera Therapeutics - Somerville, MA, Somerville, MA, [7]Flagship Pioneering, Philadelphia, PA

Autologous *ex vivo* Chimeric Antigen Receptor (CAR) T-cell therapies are a powerful treatment option for relapsed and refractory leukemias and lymphomas. However, significant challenges limit access to these therapies, including long vein-to-vein times for drug delivery, viral vector supply chain constraints, complex manufacturing processes, and high costs. While allogeneic CAR-T therapies offer an alternative, they have not yet matched the therapeutic efficacy of conventional autologous T-cell therapies, emphasizing the urgent need for same-day *in vivo* treatment solutions.

RNA Gene Writers are designed to edit cellular genomes using RNA templates by harnessing the mechanism of target-primed reverse transcription (TPRT). These Gene Writers can be engineered to perform various editing reactions, from introducing gene-length DNA sequences, to rewriting genomic regions by making single nucleotide substitutions, to small insertions or deletions. These edits can be achieved by delivering all-RNA compositions to primary cells *in vitro* or *in vivo*, eliminating the need for viral vectors and DNA template-based genome editing methods.

Initial testing of T cell specific lipid nanoparticles (LNPs) containing a Gene Writer with a B-cell maturation antigen (BCMA) CAR template *in vitro* led to an observed average of 16% BCMA CAR+ T cells, in primary human T cells that were pre-activated with TransACT. Moreover, these CAR+ T cells generated *ex vivo* could clear antigen specific tumors *in vivo* in human xenograft mice, mediating robust cytotoxic response and CAR-T cell expansion.

For *in vivo* applications, targeting and editing of resting T cells is a critical milestone to overcome. Utilizing a CD19 CAR template, we delivered T cell specific LNPs to freshly isolated human primary T cells *in vitro*, without pre-activation, generating an average of ~40% CD19 CAR^+ cells. These CAR+ cells were observed to be potent in their ability to drive cytotoxicity, cytokine production and CAR-T cell expansion in response to multiple tumor types. Additionally, we demonstrated Gene Writers delivered with T cell specific LNPs integrated CAR transgenes targeting CD20 into resting non-human primate (NHP) T cells *in vitro*, achieving approximately 60% CAR writing and enabling a path towards writing in NHPs *in vivo*.

For *in vivo* proof-of-concept studies, we tested two humanized xenograft mouse models for CAR specific activity. A single intravenous infusion in a tumor bearing xenograft mouse model of Gene Writer with a CD19 CAR template formulated in targeted LNPs generated an average of 24% CAR-T cells *in vivo* that were able to expand and eradicate tumor burden compared to control. Additionally, LNP delivery of Gene Writer with a CD20 CAR template in a CD34+ engrafted humanized mouse model resulted in an average of 30% CAR-T cells *in vivo* and consequent elimination of human B cells, highlighting its therapeutic potential in autoimmune diseases.

The ability to generate *in vivo* CAR-T cells using Gene Writers and our proprietary LNP delivery platform provides a unique opportunity to potentially eliminate the challenges associated with conventional *ex vivo* CAR-T cell therapies and viral based *in vivo* CAR-T gene therapies.

154 Targeted Multiplexed Virus-like Particles (MVPs) enable robust in vivo Hematopoietic Stem Cell (HSC) engineering

Justin Thomas[1], Stefan Radtke[2], Greta Kanestrom[1], Malia Callier[3], Kyle Swing[1], Heather Mack[1], Carl Wolf[1], Mitchell Egan[1], Alvin Tong[1], Hans-Peter Kiem[2]*

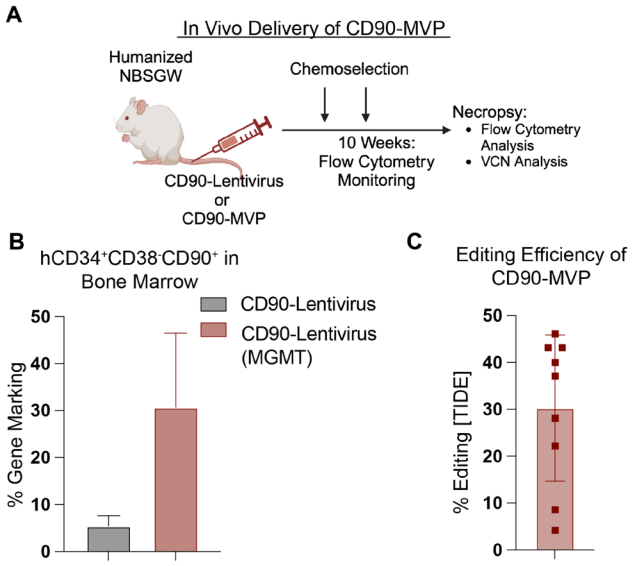
Background:
Ex vivo Hematopoietic Stem Cell (HSC) gene therapy has significantly changed the treatment landscape of many chronic disorders, including sickle cell disease (SCD). However, barriers persist regarding the accessibility of these treatments, as these platforms require significant medical infrastructure. The advent of in vivo delivery strategies in the clinic will substantially broaden the accessibility of gene therapy. However, current putative delivery platforms lack iterative capacity, requiring binary choices to be made on gene modification strategies and cell population

targets. Here, we report the development of HSC-targeted Multiplexed Viral-Like Particles (MVPs), enabling concomitant *in vivo* transduction and gene-editing in HSCs.

Approach/Results:
HSC targeting was enabled by studding MVPs with an anti-CD90 single-chain variable fragment (CD90-MVPs). Intravenous administration of these particles in humanized NBSGW mice without the use of mobilization regimens displayed high specificity, with an average of 83% of all gene marked cells in the bone marrow (BM) expressing CD90 (n=9). In primary injected mice, average gene marking in the HSC compartment ($CD34^+CD38^-CD90^+$) was 2.6%. Transplantation of CD34+ hematopoietic stem and progenitor cells (HSPCs) from injected mice into secondary recipient mice showed an increased average gene marking of 14.8% (n=5), suggesting CD90-MVPs preferentially transduced long-term self-renewing HSCs. Depending on disease pathology, some disorders require a minimal threshold of gene modification chimerism for pathophysiological relief. This includes a 20% gene modification threshold found in clinical trials for SCD gene therapy. To enable the enrichment of gene-modified cells, we concomitantly expressed the MGMT(P140K) transgene which protects modified cells from carmustine chemoselection. After two round of selection, gene marking reached up to ~65% in HSCs. Additionally, CD90-MVPs administration and chemoselection did not perturb differentiation capacity as gene marking was found in all hematopoietic lineages (i.e. B-cell, T-cells, Monocytes, etc.). We next sought to apply the CD90-MVP platform to the delivery of therapeutic payloads for SCD gene therapy. CD90-MVPs loaded with Cas9 protein and co-transfected with HBG-directed gRNA and MGMT(P140K) transgene were administered on $CD34^+$ HSPCs *ex vivo*. We observed an 8-fold higher gene transduction rate on $CD34^+CD90^+$ HSCs than 90^- HSPCs. Additionally, 66.33% of HBG promoter alleles in $CD34^+CD90^+$ HSCs contained indels. This was concomitant with a 50% increase in fetal hemoglobin expression in erythrocytes derived from edited $CD34^+CD90^+$ HSCs. *In vivo* administration of CD90-MVPs in humanized NBSGW mice confirmed successful gene modification of $CD34^+$ HSPCs with an average vector copy number (VCN) of 0.18 and HBG allele editing frequency of 30.3%.

Conclusions:
In summary, CD90-MVPs is a novel in vivo HSC gene delivery platform, allowing for the multiplexing of HSC engineering strategies and enabling the broad use of gene therapy. The multiplexing of both integration gene modification as well as gene editing strategies enables a more iterative platform, which could increase the efficiency of gene therapy broadly. Furthermore, the high specificity of CD90-MVPs without the use of mobilization, surpasses a high safety benchmark as gene therapy moves toward in vivo administration and enables a wider application of HSC gene therapy.



(A) Experimental design for in vivo transduction of human HSCs in xenograft NBSGW murine model. **(B)** Transduction efficiency of CD90-targeted lentiviral particles on HSC population with or without MGMT chemoselection . **(C)** Allele editing efficiency at the HBG -1113 locus of human $CD34^+$ (hCD34+) HSPCs isolated from xenograft NBSGW mice injected with CD90-MVP.

155 In Vivo Hematopoietic Stem Cell Gene Therapy for HIV by Base Editing of CCR5 Alone and in Combination with HIV Decoy Receptor Expression

Anna Anderson[1], Aphrodite Georgakopoulou[2], Anne-Sophie Kuhlmann[3], Andrew Riker[3], Karthik Karuppusamy[2], John Bui[3], Stefan Radtke[4], Hans-Peter Kiem[4], Andre Lieber[2], Chang Li[5]*

Our approach utilizes helper-dependent adenovirus (HDAd) vectors that target therapeutic gene delivery to HCSs in vivo. Here, we employed this approach for HIV therapy. We screened a panel of single guide RNAs paired with base editors in TZM-bl cells to achieve CCR5 knockout and found that a sgRNA targeting the CCR5 start codon (referred to as SILENCE2) combined with an ABE (ABE8e) and a sgRNA that creates a premature stop codon (referred to as STOP1) combined with a CBE (BE4max) or a laboratory-evolved CBE (TadCBE) exhibited the highest on-target editing rates as well as CCR5 down-regulation. We then produced all-in-one base editor HDAd vectors containing the sgSTOP1 and sgSILENCE2 alone or in combination with a Dual editor (TadDE). In addition to the editing machinery, the vectors contained an expression cassette for $mgmt^{P140K}$, which allows for enrichment of edited cells by selection with low doses of O^6BG/BCNU. Downregulation of CCR5 and inhibition of HIV infection was demonstrated in TZM-bl cells. CCR5 base editing by the HDAd-STOP1-TadCBE and HDAd-STOP1-SILENCE2-TadDE vectors conferred 98% inhibition of HIV-BaL infection. Next, we transduced human $CD34^+$ cells from the cord blood of three healthy donors and subjected them to O^6BG/BCNU selection and in vitro differentiation over 42 days resulting in $CD4^+CCR5^+$ T-cells. At the end of differentiation, cells were exposed to HIV. HIV genome titers in supernatants of T-cells derived from HDAd-STOP1-TadCBE and HDAd-STOP1-SILENCE2-TadDE-transduced $CD34^+$ cells were 21-fold and 4-fold lower, respectively, compared to T-cells derived from untransduced $CD34^+$ cells. Based on HIV-Gag flow cytometry of T-cells, inhibition of HIV replication was 84% and 70%, respectively. For in vivo studies, we have generated humanized mice by transplanting human $CD34^+$ cells that can differentiate into $CD4^+/CCR5^+$ T-cells, into NSG neonate mice. After the engraftment, mice were mobilized with G-CSF/AMD3100 and intravenously injected with HDAd-STOP1-TadCBE or HDAd.control followed by O^6BG/BCNU selection. Eight weeks after selection, mice were challenged by intraperitoneal injection of HIV. Viral load in plasma and tissues was measured 7 weeks later. CCR5 editing rates in bone marrow mononuclear cells were on average 50% at the end of the study without significant off-target editing at any of the top 20 sites identified. HDAd-STOP1-TadCBE treated animals had 8-fold lower HIV plasma titers than control animals. Significantly lower HIV loads were also found in the lower GI tract and the liver. A major problem in HIV therapy is the development of virus mutants that escape therapy, especially if the therapy targets only R5-tropic HIV strains. To reduce the chance of escape mutants, we combined the CCR5 knockout module with an eCD4-Ig decoy receptor expression cassette and compared it to single-module HDAd vectors in the inhibition of HIV infection of TZM cells. On average, HDAd-STOP1-TadCBE (CCR5KO), HDAd-eCD4Ig, and HDAd-combo inhibited HIV infection 93, 77, and 98%, respectively The combo vector exerted a significant additive inhibitory effect of the CCR5-KO and eCD4Ig expression modules and provided inhibition of both CCR5 and CXCR4 tropic HIV strains. We have started *in vivo* HSC transduction studies in non-human primates using an HDAd-combo vector and a chemotherapy-free approach to expand HDAd-combo transduced HSCs.

156 Analysis of safety, selectivity, and efficacy of in vivo hematopoietic stem cell transduction after intravenous administration of AVID adenovirus vector in Rhesus macaques

Jia Yao[1], Svetlana Atasheva[2], Rama Amara[3], Dmitry Shayakhmetov[3]*
[1]Emory University, Atlanta, Georgia, [2]Emory University, [3]Emory University, Atlanta, GA

Viral vectors represent a clinically validated platform for therapy of numerous genetic diseases with demonstrated potential of transforming patients' lives. Although several FDA-approved therapies are based on adeno-associated vectors (AAV), their relatively small therapeutic cargo capacity limits their utility for therapy of genetic diseases via gene editing approach. Viral vectors based on adenovirus (Ad), on the other hand, can deliver much larger

therapeutic genes compared to AAV and represent an attractive platform for therapeutic gene editing in vivo after intravenous vector administration. We recently engineered a novel AVID-388 Ad vector platform, which efficiently delivered reporter genes to human hematopoietic stem cells (HSCs) after intravenous administration without triggering cytokine storm, hepatotoxicity, nephrotoxicity, or thrombocytopenia. We envision that the AVID vector platform can deliver gene editing enzymes to HSC in vivo for correcting sickle cell disease (SCD) and other genetic diseases of the blood and immune system. In this study, we conducted the first-in-primate analysis of safety, selectivity, and efficacy of *in vivo* HSC transduction following intravenous administration of AVID-388-based vector, E7-GFP, in rhesus macaques. To better mimic the potentiated inflammatory state exhibited by SCD patients, we recruited rhesus macaques with a potentiated inflammatory state due to SIV infection. In our pilot experiment, rhesus macaques were conditioned with G-CSF, and bone marrow HSCs were mobilized into peripheral blood using plerixafor. The E7-GFP vector was administered intravenously at a single dose of 0.4×10^{12} v.p./kg, and bone marrow aspirates were collected 3- and 7-days after vector administration. $CD34^+$ cells were enriched to 80% purity using a primate-specific CD34 antibody and magnetic columns, then stained with an antibody panel to quantify GFP^+ cells in different bone marrow populations by flow cytometry. Our experiments showed that *in vivo* transduction of total $CD34^+$ cells was 0.3%. However, in the most primitive LT-HSC population (cells of $CD34^+CD45RA^-CD117^{high}CD90^+$ phenotype), the percent GFP^+ cells reached 15.1%, representing a ~50-fold increase in selectivity, consistent with the data from our study in humanized huCD34+ NSG mice. Importantly, the intravenous E7-GFP vector administration did not trigger thrombocytopenia, a hallmark of acute systemic inflammation and coagulopathy observed after intravenous administration of Ad vectors at high doses, thus demonstrating a significantly improved safety profile of the AVID platform compared to earlier generation Ad vectors. Taken together, the data from this first-in-primate study demonstrated improved safety, high selectivity, and near therapeutic level efficacy (~20% of HSC correction is required for ameliorating SCD) of in vivo LT-HSC transduction following i.v. administration of our novel engineered E7-GFP vector to NHPs. These data strongly support the rationale for developing clinically useful AVID platform-based vectors for in vivo HSC-targeted gene therapy of SCD and other genetic diseases of blood and immune system.

To give more specific and efficacious treatments, Neurofibromatosis Type 1 (NF1) patients need new targeted therapeutics that can be used alone or in combination with the currently approved MEK inhibitor, selumetinib. Antisense oligonucleotides (ASOs), chemistries of which are already clinically approved for other rare pediatric diseases due to their tolerability, could provide mutation-specific therapies. Certain NF1 pathogenic variants (PVs) can be rescued by modifying splicing using ASOs to induce skipping of exons containing PVs to restore expression of functional neurofibromin. Our research has published *in vitro* evidence highlighting the therapeutic potential of antisense oligonucleotides (ASOs) for numerous NF1 pathogenic variants through targeted exon skipping, including exon 17. To provide pre-clinical validation of ASOs *in vivo* and to facilitate translational development, various

mouse models have been developed. The first is a conditional tamoxifen-inducible systemic knockout *Nf1* mouse model with floxed NF1 alleles. Following tamoxifen inactivation of floxed *Nf1* alleles, adult CAGGCre-ER^{TM};*Nf*$^{Flox/Flox}$ mice lose expression/function of *Nf1* systemically; we refer to this as the "acute" model as mice die 12 days post tamoxifen induction. We have bred the acute model to the humanized exon 17 allele with patient-specific pathogenic variant G629R to obtain CAGGCre; NF$^{Flox/hG629R}$ mice. We have used these mice to evaluate two ASO delivery platforms: conjugation of ASOs with morpholino chemistry (PMO) to cell penetrating peptides (PPMO) and recombinant Adeno-Associated Viral (AAV) vectors carrying U7-SnRNA expression cassettes to give proof-of-concept of *in vivo* exon skipping efficacy of our optimized ASOs. We treated five CAGGCre; NF$^{Flox/hG629R}$ mice with a single ICV dose of 1.34 mg/kg exon 17 PMO conjugated to a CPP (PPMO) designed for cell membrane penetration and endosomal escape (5 mice with PBS injection were used as control). One week post PPMO/Ctrl injection tamoxifen induction was performed. We see PPMO-driven skipping of the humanized allele in RNA from brain and optic nerve (both NF1 relevant tissues). We also see restoration of neurofibromin protein expression and partial functionality (as measured by reduced pERK/ERK) in brain. PPMO has been limiting to date. We are working on improving PPMO solubility, purity, and production scale to allow multiple dosing schedules. We were also able to treat small cohorts of CAGGs-Cre$^{Flox/hG629R}$ mice with AAV-U7-SnRNA vectors delivered by ICV. We have been able to show evidence of *in vivo* exon skipping of the humanized allele in the brains and whole blood of AAV-U7-SnRNA treated mice using q-RT-PCR. This provides evidence of *in vivo* efficacy and gives rationale for dose and route that may be effective in future studies with improved vectors.

Conclusions: This preliminary data is the first to show *in vivo* splice modulation and restoration of neurofibromin protein expression in NF1-relevant tissues including the brain and optic nerve. Detection of skipping in blood provides an important clinical biomarker of on-target activity.

158 Silencing of *Inhbe* mRNA Using GalNAc-siRNAs Induces Durable Weight Loss in a Mouse Model of Diet-Induced Obesity

Naoki Iwamoto[1], Wei Liu[2], Stearne Briem[1], Michael Byrne[1], Cynthia Caracta[1], Arindom Chatterjee[1], Jigar Desai[3], Frank Favaloro[1], Pachamuthu Kandasamy[2], Tomomi Kawamoto[4], Anthony Lamattina[5], Fangjun Liu[5], Ken Longo[5], Richard Looby[5], Khoa Luu[1], Subramanian Marappan[1], Jake Metterville[5], Padma Narayanan[1], Lola Owen[1], Qianli Pan[5], Erin Merrill[1], Priyanka Shiva Prakasha[5], Himali Shah[1], Stephany Standley[5], Kristin Taborn[5], Snehlata Tripathi[1], Hailin Yang[5], Hsiu-Chiung Yang[1], Yuan Yin[5], Erik Ingelsson[1], Chandra Vargeese[1]
[1]Wave Life Sciences, Cambridge, MA, [2]Wave Life Sciences, Waltham, MA, [3]Wave Life Sciences, Cambridge, [4]Wave Life Sciences, Worcester, [5]Wave Life Sciences

We aimed to develop small interfering RNAs (siRNAs) to suppress expression of the liver gene inhibin βE (Inhbe). Human heterozygous INHBE loss-of-function (LoF) carriers have reduced abdominal fat, and reduced risk for type 2 diabetes (T2D) and coronary artery disease, suggesting that lowering INHBE expression by 50% may restore a healthy metabolic profile in obesity. We investigated the impact of reducing Inhbe expression, via N-acetylgalactosamine (GalNAc)-conjugated stereopure siRNA targeting Inhbe mRNA (Inhbe GalNAc-siRNA), on body weight and composition in a diet induced obesity (DIO) mouse model, alone or added to semaglutide, a GLP-1 receptor agonist (GLP-1RA). To develop siRNAs that suppress expression of Inhbe, we have optimized siRNA chemistry for desired pharmacological properties. In previously published work, we showed that incorporating phosphoryl guanidine backbone linkages in siRNAs, and controlling siRNA backbone stereochemistry, can improve the potency, tissue exposure, and durability of knockdown in mouse liver in vivo. These benefits corresponded with both an increase in thermal instability at the 5′-end of the antisense strand and improved Argonaute 2 (Ago2) loading. Since reporting this design, we have performed additional screening and optimization of our siRNA chemistry, further improving silencing durability. Using an updated design, siRNAs targeting mouse Transthyretin (Ttr) as a benchmark supported >50% knockdown of Ttr protein for ~50 days after a single 0.5 mg/kg dose, compared to a stereorandom reference siRNA based on a clinically proven format, which sustained >50% knockdown for only ~27-days post-dose. Using our advanced siRNA chemistry, we generated INHBE-00002 and INHBE-00003, stereopure GalNAc-siRNAs targeting mouse Inhbe. In DIO mice, INHBE-00002 supported >50% Inhbe mRNA knockdown compared to PBS, up to 28 days after a single 3 mg/kg subcutaneous dose, with significant weight loss compared to PBS-treated mice. The impact of the siRNA on weight loss was durable, as INHBE-00002-treated DIO mice remained significantly lighter than PBS-treated mice for the duration of the study (84 days). Using a different Inhbe siRNA (INHBE-00003), we explored the impact of adding Inhbe siRNA to

semaglutide treatment, as Inhbe regulates body weight through a peripheral mechanism distinct from GLP-1RAs. After 28 days of daily semaglutide, mice weighed ~9% less than PBS treated mice, which was similar to weight loss observed 28 days after a single dose of INHBE-00003. In INHBE-00003-treated mice, epididymal visceral fat mass was reduced by 40% relative to PBS, while quadricep muscle mass was not impacted. Adding a dose of siRNA at the start of the semaglutide dosing regimen (day 0) increased weight loss to 18% by day 28, compared to PBS-treated mice. By 28 days after last dose, mice treated with semaglutide had regained all lost weight whereas those treated with semaglutide and two doses of siRNA maintained their weight loss relative to PBS-treated controls. Taken together, these data show that we have developed an siRNA design that supports potent and durable knockdown. The impact of Inhbe siRNA on mouse body weight supports a strategy to achieve healthy weight loss in people with obesity by reducing INHBE expression. Our results indicate several potential uses for INHBE GalNAc-siRNA treatment as a therapeutic approach for people with obesity, including as a monotherapy, as an add-on to GLP-1RAs to potentiate weight los

159 Splice-Switching Antisense Oligonucleotide Drug Discovery for CLN3 Batten Disease

Jessica Centa[1], Matthew Stratton[2], Vicki Swier[3], Wanda Pfeifer[4], Clarissa Booth[5], Karlee Albert[3], Mitchell Rechtzigel[3], Fox Duelli[6], Hannah Leppert[3], Trisha Smit[7], Jill Weimer[8], Arlene Drack[4], Michelle Hastings[1]*

**Corresponding Author*

Splice switching antisense oligonucleotides (SSOs) are short sequences of modified nucleic acids that can be designed to selectively base-pair to an RNA target and modulate pre-mRNA splicing. SSOs are a powerful drug platform with clinical success, including therapeutics designed specifically for individuals carrying unique pathogenic variants (n-of-1). CLN3 Batten disease is a fatal, pediatric lysosomal storage disease caused by mutations in the gene encoding CLN3, a lysosomal protein of unknown function. Symptoms, which begin in young children, include blindness, seizures, loss of motor function, and death in early adulthood. CLN3 Batten disease-causing variants can disrupt the open reading frame by creating a premature termination codon and produce a truncated, non-functional protein. We have devised a therapeutic strategy for treating CLN3 Batten disease caused by particular frame shift variants using SSOs to induce skipping of a targeted exon to re-frame the mutated transcript. Building off our previous work in successfully developing an SSO to reduce neurological disease burden in Cln3 Batten disease mouse models when delivered to the central nervous system, we next tested the SSOs in a pig model of the disease to target visual deficits associated with the disease. A single intravitreal treatment with an SSO induced robust exon skipping in the retina for up to 12 months and improved retinal function. We next leveraged our experience to target to a rare pathogenic variant, c.569dupG in exon 8 of CLN3. We devised an approach to induce skipping of the mutation-containing exon 8 by redirecting RNA splicing using SSOs. We designed and tested SSOs in patient-derived cell models of the disease and identified an SSO, Zebronkysen, that is potent and effective at inducing exon 8 skipping from CLN3 mRNA to correct the open reading frame. Zebronkysen has received FDA approval and is being used to treat twins with this rare pathogenic variant. To date, three doses have been delivered to the patients. Together our results suggest that SSO-mediated exon skipping is a promising therapeutic approach for multiple CLN3 Batten disease-causing variants.

160 Thiopurine-Based Oligonucleotide for Targeted Telomere Damage in Leukemia and Lymphoma Cell in Vivo

Marcin Kortylewski[1], Chunsong Yu[2], Elaine Kang[3], Yong Liang[4], Piotr Swiderski[4], Haiqing Li[5], Stephen Forman[3], Larry Kwak[6]
[1]City of Hope Comprehensive Cancer Center, Duarte, CA, [2]Beckman Research Institute of City of Hope, Duarte, CA, [3]City of Hope, Duarte, CA, [4]City of Hope Beckman Research Institute, [5]Beckman Research Institute City of Hope, [6]City of Hope Inc

Telomerase (TERT) is an enzyme activated in the majority of human cancers and critical for maintaining telomere length and cell survival. Telomere shortening is accelerated especially in hematologic malignancies with high

proliferative rate such as acute myeloid leukemia (AML) or diffuse large B-cell lymphoma (DLBCL). Previous attempts to target TERT^{+} cancers faced challenges, including the delayed clinical responses and on-target/off-tumor toxicities. Here, we present a cancer cell-targeted oligonucleotide designed to deliver a synthetic TERT substrate, 6-thio-2'-deoxy-guanosine (6tdG), damaging telomeres and triggering apoptosis. In vitro, 6tdG-oligonucleotides (6tdGOs) were selectively cytotoxic to human TERT^{+} AML and DLBCL cells without affecting activated T-cells or non-malignant TERT^{-} cells. Repeated intravenous administration of 6tdGO, but not 6tdG nucleoside, had significant and directly cytotoxic antitumor effects against xenotransplanted human AML and DLBCL models in immunodeficient NSG mice. 6tdGO showed enhanced antitumor activity when tested in syngeneic mouse inv(16) AML and in Em-myc/15A lymphoma models in mice. In immunocompetent mice, treatment with 6tdGO induced systemic, cancer cell-specific and CD8 T-cell-mediated antitumor immune responses. The abscopal effects of 6tdGO were abolished in mice lacking expression of *Sting1* or *Ifnar1* but not *Trl9*. These findings suggest that STING-mediated type-I IFN signaling was triggered in response to 6tdGO-induced cancer cell death, thereby promoting recruitment/activation of CD8 T-cells. Importantly, the repeated 6tdGO treatments were well-tolerated in humanized hCD34/NOG mice. Except for the reduced percentage of human B-cells, 6tdGO did not decrease the numbers of hematopoietic stem cells, myeloid cells, or T-cells. Overall, 6tdGO offers an effective and safer strategy against aggressive TERT^{+} hematologic malignancies with potential to activate T-cell based antitumor immunity.

161 Advancing HTT-lowering divalent siRNA therapy for enhanced safety and efficacy in the central nervous system

Hector Ribeiro Benatti[1], Rachael Miller[2], Ken Yamada[1], Joseph Paquette[3], Rachel Prestigiacomo[3], Toloo Taghian[1], Grace Kadler[4], Ellen Sapp[5], Alexandra Barker[3], Nazomi Yamada[3], Jillian Caiazzi[3], Kathryn Chase[1], Vicky Benoit[1], Lori Kennington[1], Mark Salib[1], Ashley Summers[3], Nathan Yingling[6], Matt Gounis[3], Stephanie Bertrand[7], Susan Tuominen, Lindsey Bierfeldt[8], Jillian Gallagher[9], Erin Hall[1], Elizabeth Parsley[10], Julia Alterman[1], Dimas Echeverria[3], Marian DiFiglia[5], Heather Gray-Edwards[9], Anastasia Khvorova[1], Neil Aronin[9]
[1]UMass Chan Medical School, Worcester, MA, [2]UMass Medical School, Worcester, MA, [3]University of Massachusetts Chan Medical School, [4]University of Guelph, Ontario, [5]Massachusetts General Hospital, [6]UMass Chan, Worcester, MA, [7]Cummings School of Veterinary Medicine at Tufts University, [8]University of Massachusetts Chan Medical School, Worcester, MA, [9]UMass Chan Medical School, Worcester, Massachusetts, [10]Cummings School of Veterinary Medicine at Tufts University, North Grafton, MA

Oligonucleotide therapeutics, including antisense oligonucleotides (ASOs) and small-interfering RNAs (siRNAs), are under clinical evaluation for neurodegenerative diseases such as Huntington's disease (HD). However, their efficacy and safety profiles have varied. Non-selective lowering of both wild-type and mutant huntingtin (HTT) mRNA and protein has demonstrated safety across species and shown the potential to reduce disease progression in HD mouse models and effective biodistribution through the brain of a large animal model. The specific thresholds of RNA and protein lowering required to alter disease progression remain undefined. The advent of divalent small-interfering RNA (di-siRNA) has provided a platform with enhanced efficacy and prolonged durability throughout the central nervous system (CNS) following a single administration. Here, we report an optimized HTT-lowering di-siRNA compound (di-siRNA^{HTT}) with superior efficacy and safety in small and large animal models. This advancement incorporates the novel extended nucleic acid (exNA) modification, which enhances stability by protecting the di-siRNA scaffold from endonuclease degradation. Additionally, the formulation includes artificial cerebrospinal fluid (aCSF) supplemented with calcium and magnesium to mitigate acute neurotoxicity during intracerebroventricular (ICV) delivery. This innovation enabled the safe evaluation of increased dosing regimens across species.

In YAC128 HD transgenic mice, a single ICV injection of the lead di-siRNA^{HTT} compound achieved significant silencing of both wild-type and mutant HTT protein throughout the brain. At a low dose, silencing was sustained for two months, and at a high dose, silencing was maintained for up to six months. Six months post-injection, we observed 85–95% HTT protein reduction in key brain regions, including the caudate, putamen, cortex, thalamus, and hippocampus. In lambs, the lowest dose achieved 74% HTT protein silencing in the caudate and 28% in the putamen, a 20% improvement compared to the previous di-siRNA architecture (no exNA). Using di-siRNA^{exNA}, dose-response experiments revealed maximum efficacy and safety at twice the initial minimum dose, silencing HTT protein >75% in the caudate and approximately 50% in the putamen. Higher doses, although more effective, were not well tolerated. Electroencephalogram (EEG) recordings conducted in lightly sedated lambs confirmed the

absence of seizures at lower doses, while higher doses showed focal seizures evolving to bilateral ictal activity, with initial spike-and-wave patterns in the left hemisphere progressing to generalized polyspikes followed by spike-and-wave discharges. Intrathecal delivery did not achieve comparable efficacy in brain regions relative to equivalent doses delivered ICV.

These findings highlight a novel di-siRNA^{HTT} therapeutic platform capable of robust, sustained HTT mRNA and protein silencing across species. The compound's safety profile and efficacy expand the opportunity to advance this modality into pre-IND enabling studies, offering a promising therapeutic avenue for Huntington's disease.

162 Computationally Designed Miniproteins Enable Tissue-Specific Oligonucleotide Delivery Through Cell Surface Receptor-Targeting

Geoffrey Berguig[1], Benjamin Spangler[2], Cody Krivacic[3], Beeke Wienert[4], I-Li Tan[1], Stephanie Maiocco[5], Brian Vash[3], Cody Jackson[3], Josh Park[3], Erin Hsiao[1], Edurne Gonzalez[3], Felicia Ng[3], Ajeeth Adhikari[3], Hui Yin Tan[3], Colleen Matzie[3], Pengcheng Zhang[3], Oghene Efagene[3], Lizet Reyes Rodas[3], Clapton Hernandez[3], Meenu Karson[1]
[1]Evercrisp Biosciences, South San Francisco, CA, [2]Evercrisp Biosciences, Richmond, CA, [3]Evercrisp Biosciences, South San Francisco, [4]Evercrisp Biosciences, San Francisco, CA, [5]ATP, Boston

Oligonucleotide-based therapeutics hold transformative potential for treating a wide range of genetic diseases, yet their full realization has been limited by the constraints of current delivery technologies. Untargeted oligonucleotides suffer from poor cellular uptake and rapid clearance, requiring high-doses which are often prohibitive due to dose-limiting, class-based toxicities. In muscular and hepatic diseases, receptor-mediated delivery of oligos (via TfR1 and ASGPR respectively) has enabled therapeutic dosing paradigms, but similar approaches have remained elusive in other compartments.

To overcome these challenges, we have developed a targeted delivery approach that uses computationally designed miniproteins to route oligonucleotide-based therapeutics to target tissues *in vivo*. By building upon recent breakthroughs in machine learning for *de novo* protein design, we can rapidly develop stable proteins with tunable affinity profiles for a broad array of target receptors, including those without known crystal structures.

Using TfR1 as a benchmark, we highlight the unique features of these miniproteins, including their robust stability, low immunogenicity, and high receptor affinity. Our data reveal that TfR1-targeted oligonucleotide payloads drive efficient uptake into muscle cells in mice, resulting in significant target gene modulation sustained for 7 to 11 weeks.

Building on this success, we expanded the platform to target novel receptors, unlocking delivery potential to kidney and CNS. Intravenous administration of miniprotein-oligonucleotide conjugates for kidney delivery and ICV injections for CNS applications resulted in robust knockdown of gene targets within the respective tissues, demonstrating enhanced efficacy compared to untargeted payloads. These findings affirm the potential of computationally designed miniproteins to precisely deliver therapeutics to tissues previously inaccessible to larger modalities like antibodies.

Collectively, our platform drives therapeutic delivery by efficiently directing oligonucleotide payloads to the intended tissue improving on-target activity and mitigating off-target effects. Our flexible and efficacious miniprotein platform represents a transformative solution to the longstanding challenges of precision delivery, enabling new frontiers in the treatment of diseases once deemed inaccessible to oligonucleotide therapeutics.

163 NEAT1 lncRNA Structure-Mediated Functional Modulation as a Novel Therapeutic Approach for MYC-Driven Cancers.

Hagoon Jang[1], Mark Kay[2]*, Bo Kyoung Suh[3], Feijie Zhang[4]

MYC is a well-characterized oncogene implicated in the dysregulation of over 70% of human cancers. Despite its significance, MYC is widely regarded as an undruggable target due to its lack of structural pockets suitable for small molecule binding. Emerging evidence suggests that MYC physically interacts not only with DNAs but also with RNAs, raising the possibility that nucleic acid-based therapeutics could target MYC.

In this study, we identified MYC-interacting RNAs through MYC pull-down RNA sequencing and validated that NEAT1 lncRNA is a direct interactor of MYC. Intriguingly, suppression of NEAT1 using CRISPR interference (CRISPRi) or gapmer antisense oligonucleotides (ASOs) resulted in increased MYC protein levels, while MYC transcript levels remained unchanged. This finding indicates that NEAT1 regulates MYC protein stability.

To explore the potential of NEAT1 as an anti-cancer therapeutic target, we hypothesized that NEAT1 structure is critical for MYC stability regulation. We designed 88 tiled mixmer ASOs that do not degrade their target but instead bind to and modulate the secondary structure of the full transcript of NEAT1 and performed functional screens assessing both cell proliferation and MYC protein stability. Among these, ASO14 and ASO24 were identified as MYC destabilizers, whereas ASO43 and ASO85 were MYC stabilizers.

To elucidate the mechanism underlying NEAT1-mediated regulation of MYC protein stability, we conducted CRISPR-based screening using a proteasome-focused library (Bison library) in conjunction with ASO14 and ASO24 treatment. This revealed UBR5 as an E3 ubiquitin ligase important for NEAT1-mediated MYC degradation. Mechanistically, ASO14 and ASO24 enhanced the interaction between NEAT1, MYC and UBR5, thereby promoting ubiquitin-mediated proteasomal degradation of MYC.

Unlike traditional RNA-targeting strategies that focus on degrading the target RNA, our findings highlight a novel concept in which the structure of a target RNA can be modulated without degradation to either enhance or suppress a specific biologic activity. This study establishes the concept of RNA structure-mediated loss- and gain-of-function effects and proposes ASO14 and ASO24 as promising anti-cancer therapeutic agents targeting NEAT1 for MYC-dependent tumorigenesis.

HSC Transplantation and Gene Therapy

164 Attack and Defend Against HIV-1 Infection Using HSPC-based Gene Therapy With a Safety Kill Switch

Antiretroviral therapy has improved health outcomes of people living with HIV but cannot sustain life-long remission. Although stem cell transplants with allogeneic CCR5Δ32/Δ32 donors have achieved HIV cure in a few cases, such HLA-matched donors are rare. Hematopoietic stem/progenitor cell (HSPC)-based anti-HIV-1 gene therapy modifies autologous HSPCs with a lentiviral vector and provides long-term anti-HIV-1 immune cells, potentially curing HIV with a single treatment. To ensure safety, incorporation of a kill switch allows elimination of genetically modified immune cells in case of adverse events.

Our multipronged lentiviral vector (LV) exerts anti-HIV-1 effects through different mechanisms comparable to antiretroviral therapy. The LV contains a CD4-based chimeric antigen receptor to attack HIV-1 infected cells, shRNA to knock down CCR5, and C46 fusion inhibitor to inhibit HIV-1 entry. We co-expressed a truncated human epidermal growth factor receptor (EGFRt) as a safety kill switch. Previously we successfully engrafted humanized BLT (huBLT) mice following transplant of gene-modified human fetal liver-derived CD34+ cells. The vector marking was stable at ~2 copies/cell. Viral load was reduced significantly by 1-log up to 8 weeks post-transplant. For safety, we investigated depletion of EGFRt+ cells via antibody-dependent cellular cytotoxicity using an FDA-approved anti-EGFR antibody, Cetuximab. Cetuximab-mediated negative selection significantly reduced EGFRt+ cells in peripheral blood, spleen and bone marrow. EGFRt+ population was reduced in CD34+/CD90+/CD38- HSPC population within the bone marrow as well.

Here, we present transplantation of anti-HIV-1 vector modified HSPC in a more clinically relevant pigtail macaque model. For optimal transgene expression and CCR5 downregulation, we modified our anti-HIV-1 genes to match the natural pigtail macaque sequences. CD4-based chimeric antigen receptor was codon optimized and a single nucleotide of CCR5shRNA was replaced. Our modified-vector showed improved transgene expression and CCR5 downregulation in pigtail macaque PBMCs in vitro. Pigtail macaque peripheral blood-derived (PB) CD34+ cells were transduced and transplanted back to the host. After transplantation of PB-CD34+ cells, vector marking was stable at 0.01 and 0.02 in peripheral blood cells in 2 animals.

Our anti-HIV-1 vector showed stable engraftment, robust HIV-1 inhibition, and safety in huBLT mice. The anti-HIV-1 transgene expression and vector marking persisted after transplant in pigtail macaques. As PB-CD34+ cells are the mainstay in clinical use, further research in improving transduction efficiency and in vivo positive selection methods is needed to enhance transgene expression.

165 Enhancing ADC-Based Non-Genotoxic Conditioning by Targeting Cycling Stem Cells and Lymphocyte Depletion for HSC-Directed Lentiviral Gene Therapy for Hemophilia A

Jennifer Okalova[1]*, Jordan Alexander[2], Gianna Branella[2], Seema Patel[2], Hunter Baldwin[3], Chengyu Prince[2], Andrew Fedanov[3], Harrison Brown[4], Shanmuganathan Chandrakasan[3], Christopher Doering[5], H. Trent Spencer[2]

Hematopoietic stem cell (HSC)-directed lentiviral (LV) gene therapy has shown clinical promise in treating monogenic diseases, and we have recently shown proof of concept in clinical trials for hemophilia A (HA). HSCT therapies utilizing standard non-targeted conditioning with total body irradiation (TBI), or alkylating chemotherapy remain limited by potential genotoxicity-associated infertility and secondary malignancy. Since conditioning is required to create space in the bone marrow (BM) niche for HSC engraftment, non-genotoxic conditioning strategies are under development to advance HSC-targeted gene therapies. We and others have developed an antibody-drug-conjugate (ADC) using anti-CD117 and a ribosome inactivating immunotoxin saporin (sap) to selectively deplete CD117-expressing HSCs and progenitor cells (HSPCs). However, using the ADC alone did not provide sufficient HSC depletion to achieve robust engraftment. We, therefore, initiated studies to investigate the hypothesis CD117-sap is not effective as a single conditioning agent due to a lack of deep HSPC depletion in the BM. Therefore, we first optimized our ADC efficacy by testing various streptavidin linkers, biotinylating strategies, and dosing schedules. Although our optimized ADC achieved robust stem cell depletion, multipotent progenitor cells were not cleared. Interestingly, flow cytometric analysis of murine HSPCs revealed CD117-sap induces nearly complete

residual HSC exit from a quiescence G0 state and entry into a non-G0 proliferative state, in both wildtype and HA mice. Based on these results, we incorporated the timed administration of the antimetabolite 5-fluorouracil (5-FU, which is toxic to cycling cells) post-ADC treatment. Flow cytometry and colony-forming unit assays on BM from treated mice showed 5-FU administration resulted in deep progenitor depletion and decreased colony counts in a 5-FU dose-dependent manner. In addition, CD117-sap/5-FU conditioning prior to HSCT resulted in 80-95% peripheral blood chimerism of unmodified donor cells, but interestingly, the kinetics of this high engraftment, as well as survival, varied among mouse strains. Pre-conditioned wild-type C57Bl mice displayed slow engraftment (4 months to reach >80%) and complete survival. In contrast, HA mice had rapid engraftment in 1 month, but also showed >50% mortality, which could be overcome with factor VIII (FVIII) prophylaxis. We explored these transplant deaths and found our HA mouse strain has substantially lower baseline white blood cell (WBC) counts compared to wild-type mice, and the addition of splenic leukocytes into the regimen also resulted in 100% survival. Also, we have extensively backcrossed our HA strain to C57Bl, which has WBC counts like wild-type mice, and showed 100% survival without FVIII coverage or splenic leukocyte injections. We then tested the conditioning in HSC-directed LV gene therapy for HA using engineered HSPCs transduced with a high-expression FVIII transgene, which resulted in rapid myeloid engraftment at 2 weeks post-HSCT with moderate FVIII plasma activity levels (1-5%). By 4 months post-HSCT these plasma activity levels increased to mild levels (5-40%), and ongoing studies are exploring long-term transgene tolerance. Collectively, we show small molecules targeting stem cell cycling can synergize with ADCs in non-genotoxic conditioning platforms to clear proliferating residual HSPCs and augment LV-engineered HSC engraftment.

166 BCL11A-Deficient Human Erythropoiesis is Impaired in *In Vitro* Culture and Xenotransplanted Bone Marrow

Yoonjeong Jang[1], Ruopeng Feng[2], Lance Palmer[3], Thiyagaraj Mayuranathan[1], Yu Yao[4], Kalin Mayberry[2], Sheng Zhou[2], Jian Xu[2], Yong Cheng[3], Jonathan Yen[2]*, Mitchell Weiss[2]*

Genetic depletion of the transcriptional repressor BCL11A in red blood cell precursors alleviates b-hemoglobinopathies by inducing g-globin gene expression. An alternative strategy for γ-globin derepression is blocking BCL11A-binding motif in HBG1/2 promoter. These strategies demonstrate that BCL11A is a promising therapeutic target for fetal hemoglobin induction. However, the effects of knocking down BCL11A in primary erythroid cells derived from human mobilized peripheral blood $CD34^+$ cells remain insufficiently described.

Here, we examined the effects of BCL11A knock-down in erythroid cells by editing the BCL11A +58 erythroid enhancer in the healthy $CD34^+$ cells and compared it with editing of the CD33 coding region (editing control) and the HBG1/2 promoter BCL11A binding motif. These edits were assessed with and without a competitive environment both *in vitro* and in xenotransplanted bone marrow (BM). BCL11A knockdown significantly impaired overall expansion and increased apoptosis of erythroid progenitors. Using sequencing techniques, we found a substantial amount of differentially expressed genes and binding sites in the BCL11A enhancer-edited group. Mutant colony-forming unit erythroid (CFU-E) cells, proerythroblasts and basophilic erythroblasts exhibited dysregulation of 94 genes (> 2-fold change, FDR < 0.05), including 25 likely direct targets of BCL11A. Differentially expressed genes were associated with a range of biological pathways that impact cell expansion and survival.

Moreover, using a competitive repopulation assay with a 50:50 mixture of CD33- or HBG1/2 promoter- and BCL11A enhancer-edited $CD34^+$ cells revealed that the BCL11A enhancer-edited cells exhibited a competitive disadvantage specifically in erythroid cells compared to CD33 or HBG1/2 promoter-edited cells. These effects were more pronounced in erythroid cells from the BM of xenotransplanted immunodeficient NBSGW mice.

We further investigated sickle cell disease (SCD) patient-derived $CD34^+$ cells under similar competitive conditions. Consistent with healthy donor $CD34^+$ cells, we observed the BCL11A enhancer-edited cells demonstrated reduced erythroid expansion compared to CD33 or HBG1/2 promoter-edited cells. These findings show that BCL11A plays

a broader role in erythropoiesis beyond g-globin gene repression, with potential but yet unknown clinical implications.

167 Myeloid Cell Replacement Therapy Improves Function in Friedreich Ataxia Mice by Intercellular Mitochondrial Transfer

Hyunmin Cho[1], Pasqualina Colella[2], Natalia Gomez-Ospina[3]*
[1]Stanford University Laboratory for Cell & Gene Medicine, Redwood City, CA, [2]Palo Alo, CA, [3]Stanford, Palo Alto, CA
**Corresponding Author*

The primary objective of this study is to evaluate the therapeutic effects of bone marrow transplantation (BMT) or hematopoietic stem cell transplantation (HSCT) in a Friedreich's ataxia (FA) mouse model and to confirm the intercellular mitochondrial transfer from bone marrow-derived donor cells to FA cells. To achieve this, we performed BMT using the human FXN YAC transgenic mouse model (YG8s800) carrying over 800 GAA repeats, following a conditioning regimen with Busulfan and PLX3397 to enhance the engraftment of bone marrow-derived cells in CNS tissues.

We confirmed mitochondrial transfer in multiple tissues, including the brain, following BMT and investigated how this process contributes to functional recovery in the FA model. Using single-cell RNA sequencing, we compared FA cells that acquired mitochondria with those that did not, identifying therapeutic mechanisms across key CNS cell types (neurons, astrocytes, microglia, and oligodendrocytes). This provided critical physiological insights into cell-type-specific therapeutic pathways.

BMT significantly improved neurological and cardiac function in YG8s800 mice, with robust engraftment and differentiation of transplanted cells in hematopoietic and CNS tissues. Additionally, mitochondrial function was restored, leading to enhanced motor coordination and cardiac function. Successful mitochondrial transfer from transplanted cells to FA cells resulted in reduced oxidative stress and the restoration of cellular functions.

To elucidate the mechanisms underlying mitochondrial transfer, we performed transcriptomic analysis of mitochondria-acquiring (mKate2+) and non-acquiring (mKate2−) cells using single-cell RNA sequencing. The results revealed an upregulation of genes associated with ATP synthesis and oxidative phosphorylation (Cox4i1, Ndufv1, Atp5o, Ndufa9) across major CNS cell types, with gene set enrichment analysis (GSEA) confirming significant activation of these pathways. In neurons and astrocytes, genes related to neuroprotection and protein homeostasis (Ttr, Ptgds, Igfbp2, Chchd10) were also upregulated. Overall, 33 enriched pathways were primarily associated with ATP metabolism and proton transport, while pathways related to RNA splicing and translation were downregulated. These findings suggest that mitochondrial transfer may partially restore energy production and regulate diverse cellular functions.

In conclusion, this study demonstrates the therapeutic potential of mitochondrial transfer through BMT in an FA mouse model. By identifying signaling pathways that facilitate mitochondrial uptake, our findings provide novel therapeutic targets for FA. This study serves as a foundational step toward developing treatments for FA and other mitochondrial dysfunction-related disorders.

168 CSF1R Inhibitor Treatment Facilitates Engraftment of Hematopoietic Stem Cell-Derived Microglia-Like Cells in Nonhuman Primates

Nicholas Petty[1], Carl Wolf[1], Greta Kanestrom[1], Mark Mendoza[1], Kyle Swing[1], Robert Murnane[2], Alvin Tong[1], Marlena Starrs[1], Emily Fields[3], Ravishankar Madhu[3], Veronica Nelson[1], Frederick Bennett[4], Scott Furlan[1], Keith Loeb[1], Stefan Radtke[5]*, Hans-Peter Kiem[5]*

Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is the current standard of care for neurotrophic lysosomal storage diseases (LSDs) such as Krabbe Disease and Metachromatic Leukodystrophy. The therapeutic mechanism of action is believed to be through the engraftment of enzyme sufficient, HSC-derived cells throughout the central nervous system (CNS) as microglia-like cells (MLCs). However, allogeneic transplantation is associated with significant morbidity and mortality. Recent work in murine models has demonstrated that MLC engraftment can be enhanced using gene-modified, autologous HSCT (auto-HSCT) paired with depletion of endogenous microglia by CSF1R inhibitors such as Pexidartinib (PLX). Here, we evaluated the engraftment of MLCs post GFP-labelled auto-HSCT in several nonhuman primates (NHPs) with and without PLX-mediated depletion of microglia.

To evaluate the impact of PLX in NHPs, we treated two animals with PLX either intrathecally (IT) or intravenously (IV). Depletion was characterized by FACS as well as immunofluorescent (IF) imaging. We then treated five animals with total body irradiation-conditioned, GFP-labelled auto-HSCT. A sixth animal was similarly transplanted, then treated with IT PLX two weeks post-transplant. We tracked hematologic recovery in all animals in the peripheral blood (PB) and bone marrow (BM) for at least six months post-transplant. At necropsy, engraftment was determined in the PB and BM by FACS and in the CNS by FACS and IF. We further characterized microglia and MLCs by morphological analysis as well as single cell RNA sequencing.

We found that both IT and IV PLX led to robust, region-dependent depletion of endogenous microglia. Maximum depletion was observed in superficial structures with a gradient of depletion to deeper brain structures. We did not appreciate any impact on hematopoietic lineages in the PB or BM due to systemic or local PLX administration. Given prior reports of adverse hematologic effects of PLX, we treated one animal with PLX IT following auto-HSCT. We did not observe any obvious deviations in hematopoietic recovery or behavior due to PLX treatment. At necropsy, we observed a range of engraftment in the PB and BM (10%-50%). However, in non-PLX treated animals we observed a two-log-fold lower engraftment to the CNS (0.1%-0.5%). IT PLX administration enhanced this engraftment four-fold, with the PLX-treated animal showing 20% engraftment in the PB/BM and 1% engraftment in the CNS. Characterization of MLCs demonstrated similarities to endogenous microglia, with up-regulation of homeostatic microglia markers and no significant differences in branching. However, MLCs remained distinct from endogenous microglia, with differential expression of several homeostatic microglial markers and activation-associated markers. This heterogeneity was also appreciated morphologically, with MLCs displaying longer maximum and average branch lengths.

This work stands as a landmark study exploring the application of CSF1R inhibitor-mediated MLC engraftment in a large animal model. Our data demonstrate the feasibility of these studies in NHPs and the potential to further study the safety and impact of MLC engraftment on health and behavior. Ways to further enhance MLC engraftment and functionalize MLCs with gene engineering strategies will pave the way for the application of these technologies for a range of neurotrophic disorders from LSDs to neurodegenerative diseases.

169 Investigating Novel Non-Genotoxic Conditioning Approaches for In Utero Hematopoietic Stem Cell Transplantation

Oluwaseun Babatunde[1], Madeleine Bibby[2], Martin Rodriguez[1], Jonathan Diaz[1], Walaa Mohamed[1], Jovanna Perez[1], J Vaughan[1], Anthony Atala[2], Christopher Doering[3], H. Trent Spencer[4], Christopher Porada[1], M Graça Almeida-Porada[5]

Medicine, Winston-Salem, NC, [3]Emory University, Atlanta, GA, [4]Emory University School of Medicine, Atlanta, GA, [5]Wake Forest School of Medicine, Winston-Salem, North Carolina

Hematopoietic stem cell (HSC) transplantation *in utero* (IUTx) has been performed safely for decades in humans and successfully cured X-SCID, with all the patient's T lymphocytes arising from the donor. However, for reasons that are not well understood, successful HSC engraftment after IUTx has only been achieved in X-SCID fetal recipients. We hypothesize that depletion of endogenous HSC and/or immune cells is necessary to achieve therapeutic levels of donor HSC engraftment following IUTx. Here, we investigated which antibody-drug conjugates (ADC) would be able to create niche availability, eliminate host HSC competition, and thwart nascent immunity, thereby enabling engraftment of adult donor HSC at therapeutic levels following IUTx. Using a fetal sheep model, we used immunohistochemistry to identify which immune cells and/or HSC populations are present in the fetal bone marrow (BM) at the time of IUTx. Flow cytometric analysis of sheep BM was then used to identify antibodies suitable for use as ADC to target HSC (CD45+GPI-80) and immune cells (CD45+IL2RG). Antibody internalization using a pH-dependent dye, and cell death assays using ADC and saporin as a toxin were also performed to confirm internalization and determine optimal concentration of the respective immunotoxins. Sheep fetuses at 55-57 gestational days were conditioned using GPI-80- or IL2RG-saporin ADC and were then transplanted 5-7 days later with human adult donor CD34+HSC, at a dose of 10^7 cells/kg. Engraftment levels of human donor cells were determined in peripheral (PB) and BM samples at 60 days post-IUTx and at various time points post-birth. In all conditioned IUTx recipients, levels of human HSC(CD34+), T(CD3+), (CD7), B(CD10+)(CD20+), and myeloid (CD123+) cells in PB and BM were determined by flow cytometry after exclusion of sheep CD45+ cells. At 60 days post-IUTX, levels of human cells in GPI-80-conditioned recipients were: CD34+(0.5±0.02%;5.8±0.5%), CD3+(5.72±0.4%;14.93±1.0%), CD7+(7.62±3.6%;13.4±0.73%), CD10(3.49±2.0%;9.49±4.9%), CD20+(3.88±0.9%;11.18±2.1%), and CD123+(6.48±0.9%; 6.2±2.1%), in PB and BM, respectively. Similar levels of human T, B, and myeloid cells were observed in IL2RG-conditioned fetuses: CD34+(0.68%;0.95), (CD3+(3.13%;14.2%), CD7+(2.78%;0.15%), CD10 (5.05%,0.59%), CD20+(8.63%,14.4%), and CD123+(6.12%; 3.2%), in PB and BM, respectively. Clonogenic assays in GPI-80- and IL2RG-conditioned IUTx recipients demonstrated the presence of human CFU-GEMM, BFU-E, CFU-GM, and CFU-E, therefore establishing the ability of the engrafted human HSC to proliferate and differentiate into multiple hematopoietic lineages. Total human donor cells in PB of both GPI-80- and IL2RG-conditioned animals at birth (4 months after IUTx) decreased considerably to around 2%. However, at 6 months after IUTx, the levels of human CD3+, CD7+, CD20+, and CD123+ cells in the PB of GPI-80-conditioned animals increased to 5.57%, 5.4%, 2.86%, and 1.12%, respectively, while engraftment in IL2RG-conditioned animals remained low. In conclusion, when compared with historical controls of HSC-transplanted fetuses without conditioning, the depletion of recipient HSC or immune cells prior to IUTx each appear to promote successful short-term donor HSC engraftment, while the selective depletion of recipient HSC seems to be critical to achieve long-term engraftment of donor HSC.

Disease Models and Pre-Clinical Applications for Lysosomal Storage Diseases

170 Persistent Expression of Liver-Directed AAV Gene Therapy Improves Long-term Outcomes in a Mouse Model of Lysosomal Acid Lipase Deficiency

Patricia Lam[1], Deborah Zygmunt[2], Cong Yan[3], Hong Du[3], Paul Martin[4]
[1]Nationwide Children's Hospital, Columbus, OH, [2]Abigail Wexner Research Institute at Nationwide Children's Hospital, Columbus, OH, [3]Indiana University School of Medicine, Indianapolis, IN, [4]The Research Institute at Nationwide Children's Hospital, Columbus, OH

Lysosomal acid lipase deficiency (LAL-D) is a rare autosomal recessive disorder caused by mutations in the lipase A (LIPA) gene, which encodes the enzyme lysosomal acid lipase (LAL). This enzyme is responsible for converting cholesteryl esters and triglycerides in the lysosome to free cholesterol and fatty acids. There are 2 manifestations of this disease: a severe infantile-onset form (formerly Wolman disease) and a later-onset form (formerly cholesteryl ester storage disease). The current standard of care for LAL-D is once-weekly or once-biweekly enzyme

replacement therapy (ERT). Though this treatment is generally well tolerated, there is still a need to develop a more curative therapy, especially for infantile-onset patients that sometimes do not respond well to ERT. We have recently developed a liver-directed AAV gene therapy (rsc.AAVrh74.LP1.*LIPA*) that was shown to improve disease symptoms in a mouse model of LAL-D. Intravenous treatment of *Lipa*$^{-/-}$ mice at 8 weeks of age, when disease is already present, reduced hepatosplenomegaly, serum transaminase levels, organ triglyceride and cholesterol levels, and measures of liver fibrosis and inflammation when mice were analyzed at 24 weeks of age (16 weeks post-treatment). Almost all of these measures in treated *Lipa*$^{-/-}$ mice did not differ significantly from those found in wild-type mice. LAL enzyme activity was also restored at 16 weeks post-treatment (24 weeks of age) in all organs to or beyond levels found in wild type mice. Based on these promising results, we performed a life-span study. Untreated *Lipa*$^{-/-}$ mice show a median survival age of about 33 weeks. 8-week-old *Lipa*$^{-/-}$ mice treated intravenously injected with rsc.AAVrh74.LP1.*LIPA* at a dose of $1x10^{13}$ vg/kg (n=20) all survived past the longest survival age of untreated *Lipa*$^{-/-}$ mice. To date, 5 of the treated mice were euthanized due to moribundity, with an average age at death of 63 weeks, and this level of mortality matches that found in wild-type FVBn mice. When analyzed, none of these mice presented with hepatosplenomegaly or fatty liver disease. Tissue biodistribution of AAV vector genomes showed presence of AAV in key organs such as the liver and spleen at the same levels as mice analyzed at 24 weeks of age. *LIPA* transgene expression also persisted, leading to lasting reduction of cholesterol and triglycerides. LAL enzyme activity in all organs and tissues, including serum, remained at or above wild-type levels. These data demonstrate persistent expression and functional activity from single-treatment rAAVrh74.LP1.*LIPA* gene therapy, suggesting this therapy has the potential to be a curative treatment for LAL-D.

171 Hematopoietic stem cell gene therapy for Mucopolysaccharidosis type IIIC

Mucopolysaccharidosis type IIIC (MPS IIIC) or Sanfilippo Syndrome type C is a severe neurodegenerative lysosomal storage disorder (LSD) caused by loss-of-function of the lysosomal transmembrane protein acetyl-CoA:heparan-ℝ?-glucosamine N-acetyltransferase (HGSNAT). MPS IIIC is characterised by accumulation of the glycosaminoglycans (GAGs) Heparan Sulfate and currently has no treatment. This disease presents with developmental delay and neuronal cell loss leading to death from severe neurodegeneration. Our group has previously shown that transplantation of hematopoietic stem cells (HSPCs) rescue cystinosis, another LSD due to mutations in a transmembrane lysosomal protein. One of the mechanisms of rescue involved lysosomal cross-correction from HSPC-derived macrophages to the disease cells via tunnelling nanotubes. We believe that the same principles could be used to treat MPS IIIC.

We generated a new MPS IIIC mouse model and confirmed disease phenotypes such as GAG accumulation, splenomegaly, neurological defects, and presence of disease specific non-reducing end carbohydrates. To explore a new therapeutic strategy for this condition, we transplanted wild type (WT) hematopoietic stem and progenitor cells (HSPCs) into lethally irradiated 2-month-old *Hgsnat*$^{-/-}$ mice and analyzed the resulting impact 6 months later. Transplanted HSPCs differentiated into macrophages in tissues and microglia-like cells in the brain. This resulted in partial restoration of *Hgsnat* expression and enzymatic activity along with the significant reduction of the MPS IIIC-specific non-reducing end carbohydrate in the treated *Hgsnat*$^{-/-}$ mice compared to untreated *Hgsnat*$^{-/-}$ mice or *Hgsnat*$^{-/-}$ mice transplanted with *Hgsnat*$^{-/-}$ HPSCs. In addition, WT HSPC transplant resulted in improved neurological defects, reduction in splenomegaly and urine retention in the *Hgsnat*$^{-/-}$ mice. Furthermore, presence of glomerular hyaline bodies with focal fibrosis and sclerosis were observed in the kidney of the disease controls whereas these abnormalities were alleviated in the *Hgsnat*$^{-/-}$ mice treated with WT HSPCs.

For the clinical translation of this approach, we are developing an autologous transplantation of *ex vivo* gene modified HSPCs. We have generated self-inactivated (SIN)-lentivirus vector containing human *HGSNAT* cDNA (NM_152419) and performed *in vitro* characterization. Following transduction of murine and patient cells lines, we observed a recovery in *HGSNAT* expression and activity as well as HGSNAT lysosomal localization, decreased GAG storage, decreased lysosomal expansion, decreased autophagosome accumulation. We also transplanted gene-

modified HSPCs in MPS IIIC mice, and have confirmed successful engraftment with vector copy number (VCN) between 1.2 and 3.6. Our preliminary data showed improvement in locomotor phenotypes in MPS IIIC following gene modified HSPC transplantation. Additionally, RNA-seq analysis revealed increased expression of inflammatory genes as well as an increase in synapse pruning, microglial activation and upregulated lysosomal gene expression in the MPS IIIC mice compared to WT mice. Notably, this phenotype was ameliorated following transplantation of gene-modified HPSCs. These data support that HSPC transplantation presents a promising therapeutic avenue for MPS IIIC and represent the first step towards a clinical translation of HSPC-mediated therapy strategy for MPS IIIC.

172 Testing a Dual AAV Gene Therapy Vector Construct to Treat Sialidosis and Galactosialidosis Using Small and Large Animal Models

Jillian Gallagher[1], Judith Gallant[2], Ping Xu[2], Rchael Gately[3], Stephanie Bertrand[4], Rachel Prestigiacomo[5], Erin Hall[2], Abigail McElroy[6], Yvette LOPEZ[2], Jey Koehler[7], Sarah Nath[6], Hector Ribeiro Benatti[2], Leigh Fremuth[8], Diantha Van De Vlekkert[8], Cynthia Tifft[9], Scot Wolfe[1], Alessandra D'Azzo[10], Miguel Sena-Esteves[2], Heather Gray-Edwards[1]

[1]UMass Chan Medical School, Worcester, Massachusetts, [2]UMass Chan Medical School, Worcester, MA, [3]Cummings School of Veterinary Medicine at Tufts University, Grafton, MA, [4]Cummings School of Veterinary Medicine at Tufts University, [5]University of Massachusetts Chan Medical School, [6]University of Massachusetts Chan Medical School, Worcester, MA, [7]Auburn University, Auburn, AL, [8]St. Jude Children's Research Hospital, [9]National Institutes of Health, BETHESDA, Maryland, [10]St. Jude Children's Research Hospital - Alsac, Memphis, TN

Sialidosis and galactosialidosis (GS) are rare lysosomal storage disorders caused by mutations in the *NEU1* and *CTSA* gene, which encode for lysosomal enzyme neuraminidase-1 (Neu1), and it's chaperone protective protein cathepsin-A (PPCA), respectively. Neu1, PPCA and b-galactosidase (b-gal) form a lysosomal multi-enzyme complex (LMC) that together degrade various glycoconjugates within the lysosome. Deficiency in either of these enzymes causes toxic accumulation of glycoconjugates in cells throughout the body resulting in similar but distinct diseases; sialidosis, GS or G_{M1} gangliosidosis. Sialidosis manifests in two forms: type I, is characterized by late-onset symptoms including myoclonus, ataxia, and vision loss; type II, the severe early-onset form, is associated with multi-systemic involvement and childhood mortality. GS is divided into three forms, the early infantile form results in premature death, fetal hydrops, progressive skeletal abnormalities and neurologic disorder, and the late-infantile form being a later-onset, milder phenotype of the infantile disease with no neurological defects. In the juvenile/adult form patients have slowly progressive CNS symptoms, including motor disturbance, mental retardation, skeletal abnormalities, dysmorphism, macular cherry-red spots, and angiokeratoma. Although life expectancy varies by disease type, both GS and sialidosis are ultimately fatal due to lack of existing treatments. Given that Neu1 is dependent on PPCA for stability and enzymatic function and because GS patients have loss of PPCA and Neu1 primarily, our goal is to develop a dual gene therapy to treat both diseases combining *NEU1* and *CTSA* in the same vector design (AAV9-Ctsa-Neu1). Previously our group has shown efficacy in treating sialidosis mice via intracerebroventricular injection (ICV) with our AAV9-Ctsa-Neu1 compared to other single gene vectors (Fig. 1A-D). However, ICV injection was unable to significantly ameliorate kidney pathology and therefore we hypothesize combined ICV and intravenously (IV) delivery will treat both the CNS and peripheral disease of sialidosis and GS. Neu1 KO mice were given a combined ICV (1.6E11 vg) and IV (1.3E12 vg) injection of AAV9-Ctsa-Neu1 at 5 weeks of age and allowed to continue to humane endpoint. Preliminary data shows that combined IV and CSF treated Neu1 KO mice have significantly increased motor ability and decreased anxiety-like behavior in the open field test at 4 months old, compared to untreated Neu1 KO mice as well as overall increased body weight (Fig. 1E-G). Further assessments are still ongoing, as well as initial testing in GS mice using the same delivery method. To facilitate translation to the clinic, large animal models are necessary and due to the lack of neurological pathology in the Neu1 KO mouse model, developing a sialidosis large animal model will be beneficial. We have successfully generated the first two sheep models of sialidosis type I (via knock-in) (Fig. 2D), and type II (via frameshift indel (A320del)), using CRISPR-SpCas9 technology and AAV donor. Homozygous type II sheep recapitulate hallmark disease features, including increased sialic acid levels, reduced Neu1 activity, severe neurological deficits, hepatosplenomegaly, hydronephrosis, skeletal abnormalities and short lifespan (Fig. 2A-C). Collectively, our findings establish a foundation for advancing gene therapy using a dual-gene construct as a viable treatment for GS and sialidosis.

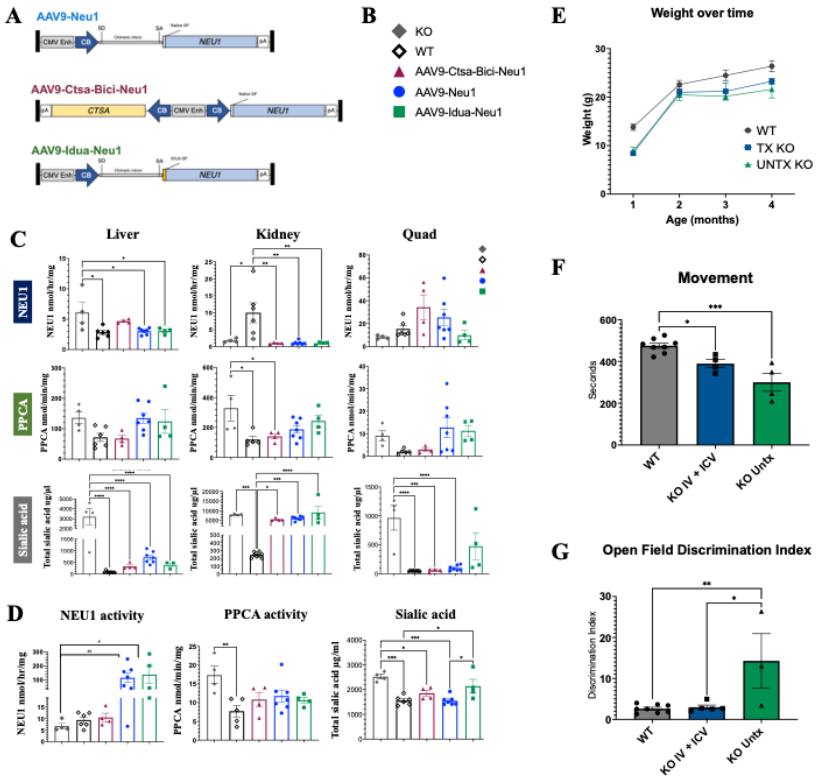

Figure 1: Summary of mouse experiments. *Panels A-D are from preliminary data testing neonatal ICV injections in Neu1 KO mice. Panels E-G are from current experiments using IV + ICV injections of dual gene vector (AAV9-Ctsa-Neu1).* A) Vector construct design: AAV9-Neu1, AAV9-Ctsa-Bici-Neu1 and AAV9-Idua-Neu1 (CMV Enh= cytomegalovirus enhancer, CB = Chicken ß-actin promoter). B) Figure C&D legend. C) Enzymatic activity for Neuy1 (1st row), PPCA (2nd row) and sialic acid levels (3rd row) in the liver, kidney, and quad. In summary, AAV9-Ctsa-Neu1 treated mice have overall increased Neu1 activity and decreased PPCA and sialic acid levels compared to other treatment groups, with the exception of the kidney (One-way ANOVA followed by Tukey's post-hoc analysis *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001). D) Results of enzymatic activity of PPCA and Neu1 and sialic acid levels measured from brain homogenates. In summary AAV9-Ctsa-Neu1 treated mice had more appropriate levels of Neu1, decreased PPCA and significantly decreased levels of PPCA compared to other treated animals (One-way ANOVA followed by Tukey's post-hoc analysis *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001). E) Graph showing weight over time across 4 months for WT (gray), Neu1 KO mice treated via IV + ICV with AAV9-Ctsa-Neu1 (blue) and untreated Neu1 KO mice (green). F&G) Results of Open Field test showing movement (how often the mouse is ambulatory within the arena) and the discrimination index (amount of time spent in periphery/time spent in center). Untreated KO mice move significantly less than WT animals, with treated KO mice having more movement than untreated KO although not significant. Untreated KO mice spend significantly more time in the perimeter of the arena compared to WT and treated KO mice.

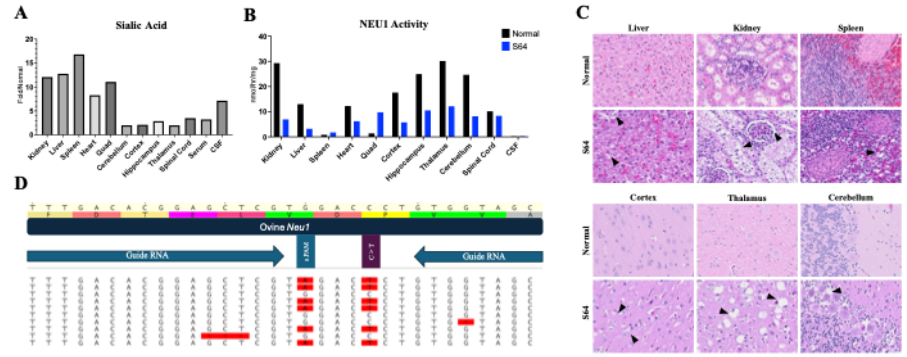

Figure 2 Successful generation of a type II sialidosis sheep model and preliminary results of generating a type I sheep model of sialidosis via knock-in. A) Sialic acid quantification of S64 (A320del homozygous animal) represented as fold over normal, in various tissues. All tissues analyzed showed increased sialic acid compared to a normal control lamb (1 month old). B) Neu1 enzymatic activity measured in various tissues for S64 compared to a normal control lamb. Neu1 activity is moderately increased in all tissues analyzed. C) Representative images of S64 and normal lamb (control) from the liver, kidney, spleen, cortex, thalamus and cerebellum. Black arrows indicate pathology, such as storage and vacuolization. D) Diagram showing representative sequences from nanopore sequencing from an early-stage sheep embryo that had successful insertion of an AAV delivered humanized DNA donor template containing P360S (C>T) mutation. Blue arrows indicate guide location, small blue box indicates silenced PAM (s.PAM), and purple box showing P360S C>T mutation reported in sialidosis patients.

173 Evaluating the Efficacy of iPSC-Derived Neural Stem Cell Transplantation in an MPS I Mouse Model

Caitlin Calhoun[1], Alexander Stover[1], Jerry Harb[1], Evelyn Torres[2], Edwin Monuki[3], Raymond Wang[4], Philip Schwartz[5]*, **Shih-Hsin Kan[6]***
[1]Children's Hospital of Orange County, [2]CHOC Children's Hospital, Orange, CA, [3]University of California Irvine, [4]Campbell Foundation Director, Lysosomal Disorder Program, Orange, CA, [5]Children's Hospital of Orange County, POWELL, OH, [6]Children's Hospital of Orange County, Orange, CA
**Corresponding Author*

Mucopolysaccharidosis type I (MPS I) is a severe metabolic disorder caused by deficient α-L-iduronidase (IDUA) enzyme activity, leading to impaired degradation of glycosaminoglycans (GAGs). This accumulation triggers progressive tissue damage and organ dysfunction, including neurodegeneration. Although FDA-approved treatments such as hematopoietic stem cell transplantation (HSCT) and enzyme replacement therapy (ERT) are available, their efficacy in mitigating neurodegeneration is limited due to their inability to cross the blood-brain barrier (BBB).

To address this challenge, we successfully generated human neural stem cells (NSCs) by differentiating induced pluripotent stem cells (iPSCs) derived from reprogrammed human cord blood cells. These NSCs were purified via fluorescence-activated cell sorting and transplanted into neonatal immunocompromised MPS I (*Idua$^{-/-}$)* mice on a NOD/SCID/Il2rγ (NSG) background. Remarkably, eight-months post-transplantation, the NSCs demonstrated migration, partial restoration of IDUA enzyme activity, and a significant reduction in β-hexosaminidase levels in the brains of the MPS I mice, highlighting their potential for addressing neurodegeneration in MPS I.

Our comprehensive histopathological analyses elucidated the distribution of transplanted human NSCs in MPS I mouse brains with human-*specific antibody, STEM121. The staining highlighted* a widespread migration of *transplanted cells, a critical characteristic ensuring broad distribution of IDUA into the Idua$^{-/-}$ brain. Co-staining of STEM121 with GFAP and Olig2 antibodies demonstrated the differentiation of many transplanted human NSCs into* glial cell types such as *astrocytes and oligodendrocytes. Notably, the presence of engrafted cells was associated with a reduction in certain elevated biomarkers in MPS I mouse brains, including CD68 and LAMP1. These findings suggest a promising therapeutic impact of the transplanted cells in addressing the deficiencies associated with MPS I.*

Further examinations involving *IDUA*-overexpressing NSCs will be conducted to evaluate their efficacy *in vivo* within our platform, paving the way as an alternative option for potential patient-specific cellular therapy for MPS I.

174 Durability of FLT201: an Investigational Gene Therapy for Gaucher Disease Type 1 Encoding an Engineered Variant of the GCase Enzyme

**Corresponding Author*

In Gaucher disease Type 1 (GD1), mutations in the *GBA1* gene attenuate or abrogate the activity of the lysosomal enzyme glucocerebrosidase (GCase-WT). FLT201, a clinical-stage investigational liver-directed gene therapy for GD1, consists of an engineered AAV capsid (AAVS3) containing an expression cassette encoding a novel engineered GCase variant, GCase85, with improved stability compared to GCase-WT. Studies in rhesus macaques have shown that FLT201 resulted in a rapid and robust increase in plasma GCase activity, produced from the liver, when treated with a single infusion of 2×10^{12} vg/kg. GCase activity was observed from day 8 and sustained for 83 days (n=1) and 170 days in six animals (n=3 female and n=3 male). Fluctuations in GCase levels were noted

between day 21 and 43; at day 170, GCase plasma levels ranged from 336–1308 nmol/h/mL, pre-treatment levels ranged from 7.4 to 9.3 nmol/hr/mL. From this study, one male and one female rhesus macaque was retained for ongoing observation up to 60 months, and we present interim 3.5-year data demonstrating durable plasma GCase levels of 388 nmol/hr/mL and 1344 nmol/hr/mL respectively.
FLT201 was well tolerated in rhesus macaques. At 85 days (n=1) and 177 days (n=4) and 1211 days (n=2) following FLT201 infusion, there were no deaths or treatment-related effects on clinical condition, post-dose observations, body weight, food consumption, hematology, blood chemistry, or immunophenotyping of peripheral leukocytes. In FLT201-treated animals terminated at 85 days (n=1) and 177 days (n=4), minimal or mild lymphohistiocytic or lymphoplasmacytic histiocytic infiltrates (slightly increased above known background levels) were observed in the dorsal root ganglia (DRG) (n=4/5) or the kidneys (n=2/5) respectively, were considered not to be adverse and unlikely to be related to the administration of FLT201. A reduction and recovery of plasma GCase activity may be attributed to transient detectable anti-GCase antibodies against the human protein, observed between 42 and 308 days in 3 out of 7 animals. The totality of the data demonstrates that FLT201 was well tolerated with no treatment-related adverse events and results in durable long-term expression.
The impact of a human monoclonal neutralizing antibody (NAb) to GCase on GCase85 uptake and activity in human macrophages and subsequent substrate clearance was determined in a conduritol-β-epoxide (CBE) induced in vitro model and was shown to be minimal. The clinical relevance of this data is discussed.

175 Optimized Liver Targeted GBA Expression via AAV3b for Type 1 Gaucher Disease Treatment

Gaucher Disease (GD) is a lysosomal storage disorder caused by loss-of-function mutations in the *GBA* gene, which encodes the glucocerebrosidase (GCase) enzyme. Approximately 90% of GD patients have Type 1 GD, characterized by lipid-engorged macrophages (Gaucher cells) in multiple organs such as the spleen, liver, and bone marrow, with little to no involvement of the central nervous system (CNS). While enzyme replacement therapy (ERT) provides overall therapeutic benefits for Type 1 GD patients, it involves a burdensome regimen of intravenous infusions every other week and does not improve all clinical manifestations, particularly in the pulmonary and skeletal aspects. We propose a one-time, intravenously (IV) dosed AAV gene therapy approach for liver-targeted sustained expression of GCase. After optimizing capsids and promoters, we selected a liver-tropic capsid (AAV3b) and a liver-targeted promoter to enable sustained expression of a codon-optimized *GBA* transgene. Proof-of-concept studies demonstrate cross-correction across multiple organs, including the spleen, with no overt toxicity as seen in a 3-month GD mouse study and a 6-month non-human primate study. In GD mice 1e13 vg/kg injection achieved a 10x increase in GCase in the liver and normalized elevated glucosphingosine lipid levels to wildtype levels in both the liver and spleen. In NHPs, 3e13 vg/kg treatment resulted in a 100x increase in GCase and a 60x increase in the liver and spleen, respectively. These studies support the liver-targeted expression of GCase as a therapeutic strategy for treating Type 1 Gaucher Disease.

176 An Innovative Platform Approach for the Parallel Development of HSPC-GT for Rare/Ultra-Rare Lysosomal Storage Disorders with Severe Skeletal and Neurological Manifestations.

Lysosomal storage disorders (LSDs) are caused by the deficiency of a specific lysosomal enzyme, causing the accumulation of undigested macromolecules, which results in severe multi-organ damage. Currently approved therapies provide an external source of therapeutic enzyme, but they show several limitations. Previous clinical data from our Institute proved the safety and efficacy of Hematopoietic Stem and Progenitor Cell-Gene Therapy (HSPC-GT) to treat neurological and skeletal manifestations in other forms of LSDs. Building on this experience and the common pathological mechanisms of LSDs, we are developing a HSPC-GT platform approach to treat a group of rare/ultra-rare LSDs with severe skeletal and neurological involvement (MPSIVA, GLB1-related disorders, and a-Mannosidosis), utilizing the lentiviral vector (LV) backbone previously employed in the Institutional clinical trials and a platform standardized transduction protocol. Based on these characteristics, we optimized the Chemistry, Manufacturing and Controls activities, Non-clinical and Clinical Development plans to generate a complete regulatory dataset for the leading disease (MPSIVA), complemented by disease specific data for the other indications with the aim of submitting a single Clinical Trial Application to initiate clinical evaluation. This approach moves towards a simultaneous and parallel developmental approach, making more sustainable the generation of novel therapeutic interventions for ultra-rare diseases. To this aim, we tested and selected the therapeutic LV that allows the supraphysiological release of each specific enzyme in human and murine HSPCs, without inducing in vitro and in vivo toxicity. Both human and murine transduced cells demonstrated clonogenic and proliferation capacities similar to those of control untransduced cells. Furthermore, they properly engrafted in the bone marrow of recipient mice, successfully reconstituting the hematopoietic systems at levels comparable to those of the control cells. We proved that the amount of enzyme released by the progeny of platform LV-transduced human HSPCs induced the metabolic cross-correction of patients' cells, including skeletal cells. To support clinical translation, we developed a transduction protocol using clinical-grade materials combined with transduction enhancers. This protocol achieved high transduction efficiency and showed no signs of toxicity, both in vitro and in vivo. A GLP platform study for parallel evaluation of enzyme overexpression toxicity is ongoing. Moreover, proof of concept studies have started to assess the safety and efficacy of HSPC-GT compared to standard HSPC transplantation in disease-specific murine models. Preliminary data showed that the enzyme activity was restored more effectively in metabolic tissues and bone samples from MPS IVA mice treated with GT than in those receiving donor HSPCs. Additionally, we observed a reduction in urinary GAGs and a downregulation of markers associated with systemic inflammation. Overall, our preliminary data support the platform development of HSPC-GT for LSDs and its clinical application.

Epigenetic Editing and RNA Editing

177 Programmable RNA Writing with Cleavage Enhanced Trans-splicing

Cian Schmitt-Ulms, MIT, Cambridge, MA

Trans-splicing-based RNA editing technologies, which introduce exogenous templates via competition with the endogenous pre-mRNA, have the potential to ntroduce edits, insertions, and deletions into nucleic acid sequence without permanent off-target effects but can be challenging to engineer. Here we describe Programmable RNA Editing & Cleavage for Insertion, Substitution, and Erasure (PRECISE), a versatile and efficient RNA editing method for generating changes of arbitrary length and sequence into existing pre-mRNAs via 5′, 3′, or internal trans-splicing. By cleaving pre-mRNAs with the RNA-targeting CRISPR-Cas effector Cas7-11, we bias towards editing outcomes and boost RNA trans-splicing rates by 10–100 fold to between 5–50% and 85% on endogenous and

reporter transcripts, respectively. We apply PRECISE editing in diverse cell types to 10 distinct endogenous transcripts across a range of expression levels and introduce more than 50 types of edits, including all 12 possible transversions and transitions, deletions, and insertions ranging from 1 to 1,863 nucleotides. PRECISE lacks detectable off targets by whole transcriptome sequencing. To demonstrate clinical relevance, we replace exon 4 of MECP2, addressing most mutations that drive the Rett Syndrome; edit the SHANK3 transcript, a gene involved in Autism; and replace exon 1 of HTT, removing the hallmark repeat expansions of Huntington's disease. To enable protein-free PRECISE, we combine payload engineering and ribozymes to remove the polyA tail of the donor transcript, and show this compact system can edit HTT exon 1 via single-AAV delivery in non-dividing neurons. PRECISE editing markedly broadens the scope of genetic manipulation by enabling both small and large edits without changes to the genome or detectable off-targets, and can be delivered using clinically relevant vectors without exogenous protein expression, creating a new platform for the treatment of genetic and other diseases.

Corresponding Author

Elevated *SNCA* levels are causative in synucleinopathy pathogenesis, specifically, Parkinson's disease (PD) and dementia with Lewy bodies (DLB), while normal physiological SNCA levels are essential to maintain neuronal function. We developed precise neuronal-type specific *SNCA*-targeted epigenome therapies for synucleinopathies that mediates fine-tuning of *SNCA* levels based on CRISPR/deactivated(d)Cas technology. The system is *an all-in-one* lentiviral vector comprises of CRISPR/d*Sa*Cas9 and gRNA targeted at *SNCA*-intron1 fused with a synthetic repressor molecule. To achieve neuronal-type specificity for dopaminergic and cholinergic neurons, the vectors were driven by TH or ChAT promoters, respectively.

We utilized a patient hiPSC-derived dopaminergic and cholinergic neurons to carry out the *in vitro proof-of-concept* studies. The differentiated matured neurons showed an efficient and neuronal-type specific downregulation of *SNCA*-mRNA and protein, and rescued disease-related cellular-phenotypes including, Ser129-phophorylated α-

synuclein, neuronal viability, and mitochondrial dysfunction. Next, preclinical *in vivo* studies were performed by stereotactic injection into the substantia-nigra (SN) of our developed PD-mouse model induced by an AAV/A53T-human (h)SNCA vector that contains the mutated human-*SNCA* coding sequence driven by the human native promoter/intron1 regulatory region. These experiments demonstrated a significant reduction in hSNCA protein in the SN, and ameliorated neuropathological characteristics including, robust reduction in Ser129-phosphorylated and aggregated alpha-synuclein and greater retention of dopaminergic neurons in the SN and striatum. Furthermore, behavioral studies showed significant improvement in motor function. Next, we refined the therapeutics *all-in-one* vector to be compatible for AAV delivery. We employed our recently published AAV-epigenome-editing platform combined with an engineered small dopaminergic-specific regulatory element based on neuronal-specific ATAC-seq profiles. The novel AAV/short(s)THp-dCas-repressor vector recapitulated the significant reduction in total, Ser129-phosphorylated and aggregated hSNCA, and retention of dopaminergic neuron projections in the SN and striatum.

In this study, we demonstrated the therapeutic potential of our *SNCA*-targeted technology for PD, DLB and related disorders, providing the foundation to advance towards IND-enablement and clinical trials. The platform is applicable and can be tailored for the development of other gene-targeted therapies for a spectrum of CNS disorders. In conclusion, Our *all-in-one* AAV platform for gene repression represents the 'next generation' gene therapy approach for AD-PD spectrum diseases and other CNS disorders based on fine-tuning of gene expression via targeted epigenome editing.

179 Efficacy and Long-term Safety of CRISPR/Cas13 RNA-targeting Medicine in Mouse and Non-human Primate Models of Neovascular Age-related Macular Degeneration

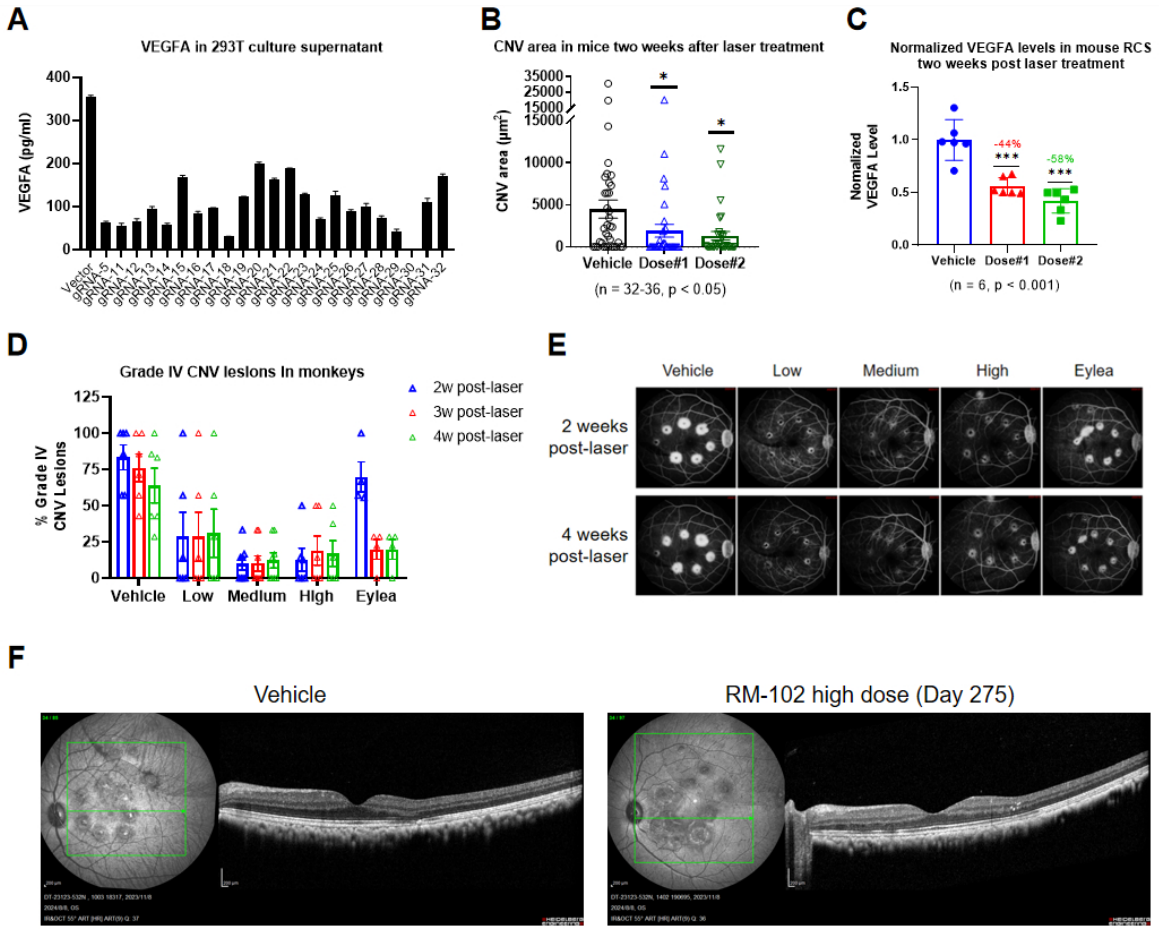
Purpose:
Regular intravitreal injections of anti-vascular endothelial growth factor (VEGF) drugs have proven effective in treating neovascular age-related macular degeneration (nAMD). However, frequent invasive procedures can lead to serious complications, and up to 40% of cases are non-responders, potentially due to immune responses against the injected drugs or anatomical barriers in the retina that hinder drug uptake. Here, we introduce RM-102, a novel AAV and CRISPR/Cas13 (CasRm)-based therapy designed for long-term effectiveness in nAMD.

Methods:
VEGFA-targeting CRISPR/CasRm plasmids, consisting of different sgRNAs, were transfected into 293T cells for sgRNA screening. The most effective sgRNA and CasRm were incorporated into an all-in-one plasmid, packaged into AAV vectors (RM-102), and injected subretinally into VEGFA-humanized mice and non-human primates (NHPs) at different doses. After weeks, choroidal neovascularization (CNV) spots were induced by laser photocoagulation. Fluorescein fundus angiography (FFA) and isolectin-B4 (IB4) staining of the retinal pigment epithelium-choroid-sclera (RCS) tissues were performed to evaluate the suppression of CNV by RM-102. Safety evaluations included ophthalmic examinations, ocular pathology studies, and a biodistribution study in monkeys.

Results:
VEGFA-targeting CRISPR/CasRm plasmids significantly reduced VEGFA levels in culture supernatant, with gRNA-30 being the most effective (Fig. A). In mice, two weeks after laser treatment, FFA showed that lesions indicating the greatest damage (grade 2B) were less frequent in the RM-102-treated groups (1.7% and 5.4%) compared to the vehicle group (14.1%). IB4-stained CNV areas in RCS were significantly reduced by 52% and 71% in the treatment groups (Fig. B), mainly attributed to the downregulation of VEGFA in RCS (Fig. C). In monkeys, the incidence of grade IV lesions in the RM-102-treated groups was significantly reduced, comparable to 2 mg of Eylea administered intravitreally one week post-laser treatment (Fig. D & E). No product-related abnormalities were

found in ophthalmic examinations during the 275-day observation period (Fig. F). Biodistribution results indicated that RM-102 was primarily distributed in the retina and RCS of the subretinal bleb.

Conclusions:
RM-102 effectively suppresses VEGFA expression and laser-induced CNV in NHPs, with excellent long-term safety. These results show that RM-102 is a promising treatment for nAMD and offer an option for non-responders to anti-VEGF therapies.



180 Applying AIMer-Based RNA Editing Technology to Correct a Nonsense Mutation in the Lung

Ian Harding[1], Jack Godfrey[2], Chikdu Shivalila[1], Megan Cannon[3], Jigar Desai[2], Alyse Faraone[4], Carolyn Grimes[2], Naoki Iwamoto[1], Pachamuthu Kandasamy[5], Tomomi Kawamoto[4], Genliang Lu[2], Jake Metterville[6], Prashant Monian[1], Erin Purcell-Estabrook[6], Stephany Standley[6], Hailin Yang[6], Ryan Yordanoff[2], Hui Yu[2], Michael Byrne[1], Chandra Vargeese[1]

AIMers are short, chemically modified oligonucleotides that engage endogenous adenosine deaminase acting on RNA (ADAR) enzymes to induce highly efficient and specific A-to-I RNA base editing. Harnessing endogenous ADAR enzymes using oligonucleotides is an emerging approach to targeted therapeutic RNA editing for the correction of nonsense mutations. However, achieving highly efficient RNA editing *in vivo* is challenging for tissues beyond the liver. Recently, we described the optimization of AIMer design to increase the potency and target space

capabilities of RNA editing and demonstrated the impact of this design in mouse liver. Here, we report the development of optimized AIMers for application to the lung and demonstrate correction of a nonsense mutation and protein restoration of a therapeutically relevant target in human lung cells *in vitro*. We applied AIMer technology in the lung to edit the house-keeping transcripts *Ugp2* and *ACTB* in mouse and non-human primate (NHP), respectively. One week after a single dose of AIMer, we observed 50% editing of *Ugp2* in the lung of transgenic mice expressing human *ADAR1* and 10% editing of *ACTB* in NHPs. To assess AIMer activity against a clinically relevant target, we investigated whether AIMers could be applied to correct the W1282X nonsense mutation in the *CFTR* mRNA, which causes Cystic Fibrosis, a multi-organ disease that ultimately leads to respiratory failure. These AIMers are designed to convert the premature stop codon to tryptophan, promoting transcript stabilization and protein restoration. In human bronchial epithelial cells expressing $CFTR^{W1282X}$, we progressively optimized AIMer chemistry for the *CFTR* mRNA target to enhance editing efficiency. CFTR AIMers with our initial screening AIMer-D design supported 21% (EC50 = 376nM) *CFTR* mRNA editing. Notably, judicious selection of the sugar modification at the position across from the target adenine in the AIMer increased maximum editing from 56% (with 2'deoxy) to 75% (with 2'OMe) in partially optimized AIMers. Further optimization led to AIMers that support maximum editing up to 75% (EC50 =246nM). Treating human bronchial epithelial cells with our highest efficiency CFTR AIMers increased *CFTR* transcript levels by 3-fold and restored CFTR protein levels to 50% of wild-type. These preclinical investigations lay the foundation for the development of AIMers as potential RNA medicines to treat disease in the lung.

181 Molecular and behavioral rescue following dual AAV targeted CRISPR epigenome editing in CDKL5 deficiency disorder patient-derived organoids and transgenic mice

Julian Halmai[1]*, Casiana Gonzalez[2], David Cameron[3], Mandeep Singh[2], Jennifer Waldo[4], Emma Monsen[2], Jill Silverman[5], Kyle Fink[2]*

CDKL5 (cyclin-dependent kinase like 5) deficiency disorder (CDD) is a rare developmental epileptic encephalopathy caused by pathogenic loss of function variants in the *CDKL5* gene. CDD is characterized by onset of medically refractory multifocal and myoclonic epilepsy in the first four to six weeks of life with an estimated incidence rate of one in 40,000 – 60,000 live births. In addition to the early infantile-onset epileptic spasms and tonic seizures, other common features include low muscle tone, intellectual disability, sleep difficulties and cortical visual impairment. In female somatic cells, one *CDKL5* allele is epigenetically silenced by X chromosome inactivation. One potential strategy to treat CDD in females is to reactivate the silenced, wildtype allele in cells expressing the mutant copy of the gene. In contrast to somatic cell gene editing, through which modification of the DNA sequence following genetic intervention is permanent, the advantage of an epigenome editing approach is that these edits are reversible. Following our previously published data demonstrating that targeted epigenetic reactivation of the *CDKL5* gene on the X chromosome is feasible, we have further expanded on the preclinical utility of our targeted gene reactivation approach. In order to deliver large epigenome editors to the central nervous system in the developing brain, we utilize intein-mediated *trans*-splicing of protein, demonstrating *in vitro* reconstitution of full-length dCas9 and *in vivo* distribution and reconstitution of split dCas9 following direct intracranial injection of AAV9 encoded vectors. To further optimize viral genome size, we show multiplexed gRNA expression from a single tRNA-gRNA cassette and utility of a hypercompact super core promoter and synthetic poly(A) vector design demonstrating equivalent *in vitro* editing efficiencies to oversized constructs. Following optimization of this epigenome editing approach, we demonstrate disease-modifying activity in human and mouse models of CDD. To this extent, we have generated cortical organoids from a patient-derived iPSC line carrying a heterozygous *CDKL5* c.1412delA mutation that clonally express either the wildtype or mutant allele. We demonstrate *in vitro* DNA methylation editing of *CDKL5* using split dCas9, as well as highly specific on-target gene regulation of *CDKL5* as measured by whole transcriptome sequencing following AAV transduction of cortical organoids. Reactivation of CDKL5 results in a significant increase in phosphorylation of the kinase substrate EB2-Ser222. Intracerebroventricular AAV delivery of the dual epigenome editors in the exon 6 deletion rodent model of CDD restores *Cdkl5* on the mRNA and protein levels across cortex and whole brain, respectively. *Cdkl5* epigenetic editing *in vivo* results in a significant EB2-Ser222 phosphorylation increase in treated heterozygous mice. Lastly,

treatment of adult heterozygous animals results in rescue of behavioral domains as measured by open field for gross motor activity, clasping, and the Y-maze assay for spontaneous alternations to measure cognition. Our results highlight the preclinical utility of *in vivo* epigenome editing for the treatment of previously undruggable genetic conditions that are, in part, caused by epigenetic silencing mechanisms.

182 Investigator-initiated Development Paths for Oligonucleotide and Epigenetic Therapies in Prion Disease

Fiona Serack[1], Juliana Gentile[2], Alissa Coffey[3], Edwin Neumann[4], Tessa Bertozzi[5], Taylor Corridon[2], Nikita Kamath[6], Meredith Pokatayev[3], Vanessa Laversenne[2], John Harvey[7], Pamela Brauer, Catherine Pirtle[7], Michael Howard[3], Kenia Guzman[3], Dimas Echeverria[8], Ken Yamada[9], Julia Alterman[9], Ken Chan[6], Benjamin Deverman[1], Anastasia Khvorova[9], Jonathan Weissman[10], Eric Minikel[3], **Sonia Vallabh[1]**
[1]Broad Institute, Cambridge, MA, [2]Broad Institute, Cambridge, [3]Broad Institute of MIT and Harvard, Boston, [4]Massachusetts Institute of Technology, Cambridge, MA, [5]Massachusetts Institute of Technology, Cambridge, [6]Broad Institute of MIT and Harvard, Cambridge, MA, [7]Broad Institute of MIT and Harvard, Cambridge, [8]University of Massachusetts Chan Medical School, [9]UMass Chan Medical School, Worcester, MA, [10]University of California, San Francisco, San Francisco, CA

Prion disease is a rapidly progressive neurodegenerative disease that is universally fatal and currently untreatable. Pathogenesis is driven by the misfolding of a single causal protein, the prion protein (PrP, encoded by PRNP), into a self-propagating conformer. Genetic proofs of concept have long shown that reduction of PrP gene dosage is protective against prion disease, with full knockout conferring complete protection. More recent studies have leveraged new PrP knockout animal models and PrP-lowering antisense oligonucleotides to show that this protection is dose-dependent and observable across species and prion strains. At this moment in biotechnological history, it is conceivable that either an oligonucleotide therapeutic or a virally vectored gene therapy could reduce PrP levels in the brain sufficient to treat, delay or prevent prion disease. Our lab is therefore pursuing both strategies. This talk will describe our efforts to advance to small academic-initiated first-in-human studies both a divalent siRNA therapy for prion disease, and a one-time epigenetic therapy called CHARM (Coupled Histone tail for Autoinhibition Release of Methyltransferase). Our di-siRNA molecule consists of two linked siRNA duplexes that target the Prnp RNA, lower total PrP in the mouse brain up to 70% at one month post- dose following naked delivery into CSF, and maintain significant target engagement up to six months post-dose. CHARM, by contrast, is an epigenetic editor that recruits the endogenous DNMT3A methyltransferase to the Prnp promoter, resulting in up to 80% PrP reduction across the mouse brain, stable up to at least six months, when delivered systemically via blood-brain barrier crossing AAV. Both di-siRNA and CHARM have been shown capable of dramatic disease modification in prion-infected mice. As both di-siRNA and CHARM are novel drug types first reported in 2019 [1] and 2024 [2] respectively, our ongoing efforts have the prospect to generate the first human data for both modalities. In the context of these two rapidly advancing programs, this talk will discuss the comparative advantages and disadvantages of oligo and gene therapies for prion disease. Topics will include comparison of single-cell drug activity across cell types and regions in the CNS, and how contrasting target engagement profiles may interact with disease biology; distinct timelines and challenges for manufacturing and IND-enabling studies; and regulatory feedback received to date regarding both programs. Finally, this talk will discuss the central clinical challenge in this rapidly progressive dementia – treating preventively. We will share our work, shaped by FDA input, across the domains of biomarker development, natural history and preclinical studies to enable preventive trials in healthy individuals with known high-penetrance PRNP variants. We will further describe how the mandate to extend healthy life, rather than just illness – one that is shared broadly across the field of neurodegeneration – is guiding our clinical plans. This talk will be delivered from a patient-scientist perspective as Sonia Vallabh is both a prion disease researcher and herself a carrier of a high-penetrance pathogenic PRNP variant causal for genetic prion disease.

183 An epigenetic gene therapy delivered using lipid nanoparticles as a treatment for HPV-associated malignancies

Fan Yang[1], Yan-Ning Yu[1], Liliana Echavarria[1], Leo Holguin[1], Diana Bell[2], Michelle Afkhami[1], Sarah Schroeder[3], Shasha Li[1], Tristan Scott[1]
[1]City of Hope, Duarte, CA, [2]UPMC Presbyterian Hospital, Pittsburgh, PA, [3]University of California, Riverside, Riverside, CA

Human Papillomavirus (HPV) causes a range of epithelial malignancies associated with oropharyngeal, cervical, and anal carcinomas with ~47,000 invasive cases in the USA annually causing significant morbidity and mortality. Despite an HPV vaccine that reduces cancer risk; denialism, cost, and lack of awareness means the continued risk of HPV-related cancers. Integration of the circular, episomal HPV genome into the host's DNA is an essential event in oncogenesis. Out of the episome context, the HPV long control region (LCR) promoter overexpresses the viral E6 and E7 proteins, which inhibits the tumor suppressors, p53 and Rb1 respectively, driving transformation. Furthermore, the viral oncogenes are critical for tumor maintenance and in a state of 'oncogene addiction' making the oncogenes ideal targets for therapeutic intervention. The viral oncogenes are considered undruggable, but ideal for gene therapy interventions. However, a gene therapy faces significant challenges such as targeting multiple HPV oncogenes within sequence-diverse HPV subtypes, which may require a multi-component treatment, complicating clinical translation. Furthermore, the transient epigenetic suppression of the oncogenes would avoid unwanted genotoxicity associated with nuclease-based strategies. Finally, delivery of genetic medicines is a hurdle and a clinically viable mRNA format packaged within a scalable non-viral delivery platform would make a gene therapy for HPV-associated cancers a reality.

To this end, we have exploited a viral self-regulatory genetic circuit to develop a compact, single-component epigenetic repressor targeted to universally conserved sites in HPV's LCR, which can silence multiple viral oncogenes in virtually all HPV subtypes. This epigenetic modality, termed BPV-E2-KRAB, inhibited the proliferation of multiple HPV-associated cancer cell lines including oropharyngeal, cervical, and anal cancer, and in both high-risk HPV16 and HPV18-associted cervical cancers. Furthermore, BPV-E2-KRAB suppressed E6 and E7 expression resulting in the reactivation of the p53 tumor suppressor and caspase-mediated apoptosis. The BPV-E2-KRAB was formulated as mRNA into MC3 lipid nanoparticles (LNPs) and when delivered intratumorally reduced tumor volume *in vivo* in a xenograft HPV-associated oropharyngeal carcinoma model with improved clinical scores and survival in the treated mice compared to controls. Furthermore, safety profiling showed no effects on the proliferation of a non-HPV cell line, serum ALT/AST levels, or liver histology. Finally, global mRNA profiling reveal upregulation of interferon pathways by the BPV-E2-KRAB, which may additionally contribute to the anti-proliferative effects in HPV-associated cancers. Overall, as a transient, druggable, scalable LNP-mRNA formulation, the BPV-E2-KRAB represents a promising new epigenetic mRNA treatment towards a generalizable gene therapy for HPV-associated malignancies.

Novel Approaches to Gene Targeting and Gene Correction

184 Essential HDRescue: Enhancement of Genome Editing by Harnessing Cellular Vulnerabilities

Jamaica Siwak[1], Jon Connelly[2], Shondra Pruett-Miller[1]*
[1]St. Jude Children's Research Hospital, Memphis, TN, [2]St. Jude Children's Research Hospital, Memphis, TN
**Corresponding Author*

Homology-directed repair (HDR) is a DNA repair pathway required to install precise, user-defined alterations in the genome following a nuclease-induced DNA double-stranded break (DSB). Although HDR can install precise edits at a locus-of-interest (LOI), mutagenic non-homologous end-joining (NHEJ) occurs more frequently than error-free HDR in mammalian cells. This higher rate of NHEJ limits the ability to identify and select precisely edited cells. Existing genome editing selection strategies improve HDR efficiencies by introducing a selectable transgene or

marker, such as drug resistance, that is tied to a user-defined modification. These selection methods require the use of small molecules or specialized equipment to isolate cells containing the intended edit and may also require labor-intensive cloning techniques. Selective agents also risk unwanted phenotypic changes to targeted cells and are not ideal for pre-clinical applications in genome editing, particularly if the modified gene is not under the control of its endogenous regulatory elements. Therefore, there is a need for a broadly applicable and practical method to improve the frequency of user-defined editing events in a cell-intrinsic manner.

To address this problem, we developed a novel enrichment method, termed Essential HDRescue, to increase the frequency of precise editing events at a LOI by co-targeting an essential genomic locus. We hypothesized that using intrinsic positive and negative selection at a common essential gene would enable enrichment of precise editing events at a separate LOI. To select against cells that have undergone NHEJ, an essential gene is targeted using CRISPR to induce gene knockout via NHEJ repair, resulting in rapid cell death. To enrich cells that have undergone HDR, a donor template installs a silent mutation to rescue the essential gene function and prevent recutting and subsequent NHEJ repair. Using targeted next-generation sequencing, we demonstrate that co-targeting essential genes *SF3B1*, *RAN*, or *GAPDH* in cancer cell lines and iPSCs significantly increases HDR rates—up to 30% precise editing—without the need for an exogenous reporter or selective drug. Further analysis of single-cell-derived clones showed that up to 52% of clones contained at least one precisely edited allele, and up to 21% of iPSC clones contained a homozygous precise mutation, representing a nearly 6-fold and 4-fold increase in clones with the respective edit compared to single-targeted control cells. Off-target activities and translocations were observed in less than 1.0% of edited clones with our top Essential HDRescue single-guide RNAs. We demonstrate enrichment of HDR-mediated small inserts and large protein tags using both single-stranded and double-stranded DNA donors and across several LOI with Essential HDRescue. These results suggest that Essential HDRescue is an effective strategy to boost HDR rates, without bearing deleterious consequences at on- or off-target sites, particularly in cell types, such as iPSCs, which are advantageous for authentic *in vitro* model creation.

Essential HDRescue allows for the enrichment of endogenously edited loci and does not require the use of an exogenous reporter or selective drug. Instead, this technique harnesses intrinsic cellular vulnerabilities caused by DSB repair at essential loci, making Essential HDRescue a widely applicable approach to enhance genome-editing outcomes in mammalian cells.

185 Precise Removal of a Large Pathogenic Repeat Expansion *In Vitro* and *In Vivo* Using a Dual-guided TevCas9 (Dualase®) Genome Editor Encoded in a Single AAV

Thomas A. McMurrough[1], Weijuan Shao[1], Olha Haydaychuk[1], Doug McMillan[2], Mary Morrison[1], Sin Kwon[1], Heyuan Qin[1], Marjan Tavassoli[1], Samin Ahmed[1], David R. Edgell[3], Brad Geddes[1], **Brent Stead**[1]
[1]Specific Biologics Inc., [2]adMare BioInnovations, [3]Western University

Repeat expansion disorders (REDs) are challenging targets for current genome editing approaches since the pathogenic repeated nucleotides are often hundreds of bases to kilobases long. Furthermore, the repeat lengths can vary widely between patients and even between affected cells within a single patient. RNA-programmable genome editing using CRISPR-Cas nucleases creates double-strand breaks at a target site, which are predominantly resolved through error-prone non-homologous end-joining (NHEJ), a process that introduces random insertions or deletions (indels). Efforts to excise these repeats using two nucleases targeting non-repeat regions flanking repetitive sequences have been reported but can be limited by low efficiency and unintended indels around either cut site, which may affect the function of nearby regulatory or coding sequences. Additionally, the large coding size of many gene editors necessitates splitting the editor between two adeno-associated virus (AAV) vectors. This creates challenges for editor design optimization and *in vivo* delivery, as well as increasing the costs of production. A genome editing therapeutic capable of precise repeat sequence removal and in which the regulatory sequences, gene editor and guide RNA(s) could be packaged and delivered within a single AAV would have several important advantages over existing systems.

Here, we present proof-of-concept using an RNA-guided TevCas9 gene editor for the efficient and precise removal of repeat sequences in patient cells and in a humanized murine model. The previously reported TevCas9 gene editors are fusions of the GIY-YIG family I-TevI nuclease and linker domains to RNA-programmable nuclease

domains, which in this study is *Staphylococcus aureus* Cas9. I-TevI functions as a monomeric nuclease targeting a preferred 5'-CNNNG-3' motif that is appropriately spaced from the Cas9 binding site. I-TevI-mediated cleavage at the target site leaves a 2-nucleotide 3'-overhang. We use a version of TevCas9 in which the Cas9 domain is inactivated by mutation and use two guide RNAs that direct the Dualase to flank the repeat region and orient the active I-TevI domains into the repeat sequences. Cleavage by both I-TevI domains leaves complementary 2-nucelotide 3'-overhangs that, when joined, result in precise removal of the large, intervening repeat to leave a non-pathogenic number of repeats.

TevCas9 genome editors are approximately 3.7 kilobases of coding sequence and can be encoded in a single AAV together with two or more targeting guide RNAs in one construct ("all-in-one") and can be specifically directed to virtually any target. Using such an all-in-one AAV9-encoded TevCas9 editor programmed with two guide RNAs to target a pathogenic repeat expansion, we show genotypic and phenotypic correction in patient-derived differentiated cells in culture. In a humanized mouse model of the same repeat expansion disorder, we also demonstrate removal of the repeat sequence as well as correction of pathologic phenotypes. Additionally, we report optimizations of the all-in-one construct that improve the performance of AAV9 encoded TevCas9 to remove repeats in patient-derived cells. Our AAV-encoded, dual-guided TevCas9 genome editors are capable of precise, therapeutic removal of pathogenic genomic repeat expansion sequences for a broad range of REDs.

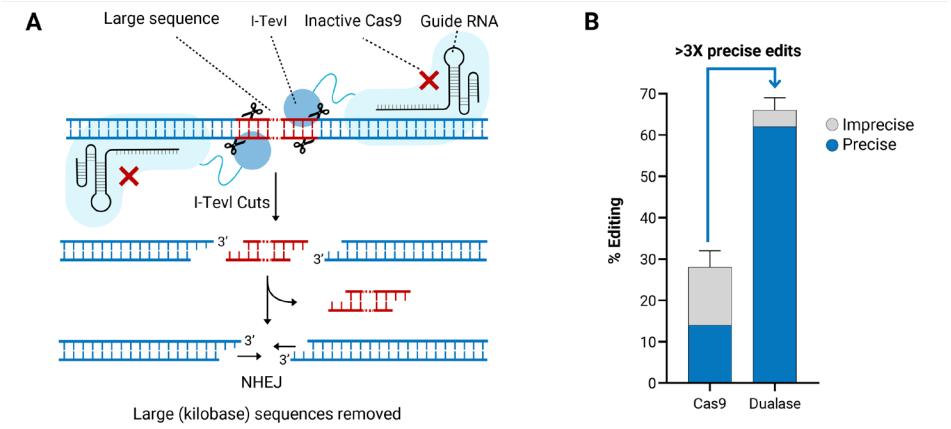

FIG 1. Dual-guided I-TevI for efficient & precise large sequence removal. **A.** Inactivating mutations are introduced into an RNA-guided Cas9 domain in TevCas9 such that active I-TevI domains are oriented into either side of a large repeat sequence with two guide RNAs. Upon cutting at both I-TevI sites, the intervening large repeat sequence is removed and the two complementary 2-nucleotide 3'-overhangs are joined to leave a non-pathogenic number of repeats. **B.** Editing outcomes in AAV-transduced a patient-derived cell model of a large repeat expansion show the precision of repeat removal based on clonal sequencing and efficiency based on percent of repeat vs non-repeat sequences. TevCas9 ("Dualase") results in 3-times more precise edits when compared to dual-guided saCas9 alone.

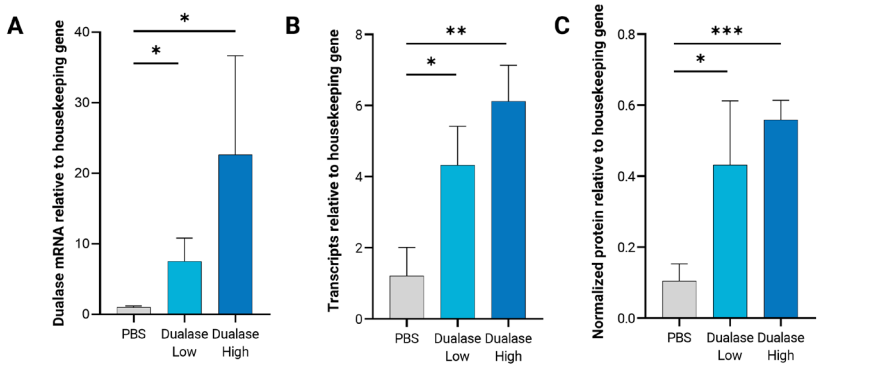

FIG 2. A. Humanized repeat expansion mice were intracerebroventricular (ICV) injected with AAV9-encoded dual-guided TevCas9 ("Dualase"). A dose-dependent increase in expression of TevCas9 relative to a housekeeping gene was confirmed by quantitative reverse transcription PCR (RT-qPCR) in bulk cerebellum tissue relative to mice injected with phosphate buffered saline (PBS) as a control. **B.** The mRNA transcripts of a downstream missing enzyme suppressed by the repeat expansion was measured by RT-qPCR relative to a housekeeping gene. A TevCas9 dose-dependent increase in the transcripts was observed, with a greater than 6-fold increase at the highest TevCas9 dose relative to PBS-treated mice. **C.** The expression of the downstream enzyme was also assessed by Western Blot relative to a housekeeping gene in cerebellum tissue. Similar to the recovery in transcription observed in panel B, an increase in the levels of the missing enzyme was observed, with up to a 5-fold recovery at the highest dose of TevCas9 relative to PBS-treated mice. N=3; * P<0.05, ** P<0.01, *** P<0.001.

186 In Cellulo DNA Assembly for Targeted Genomic Integration in Human Cells

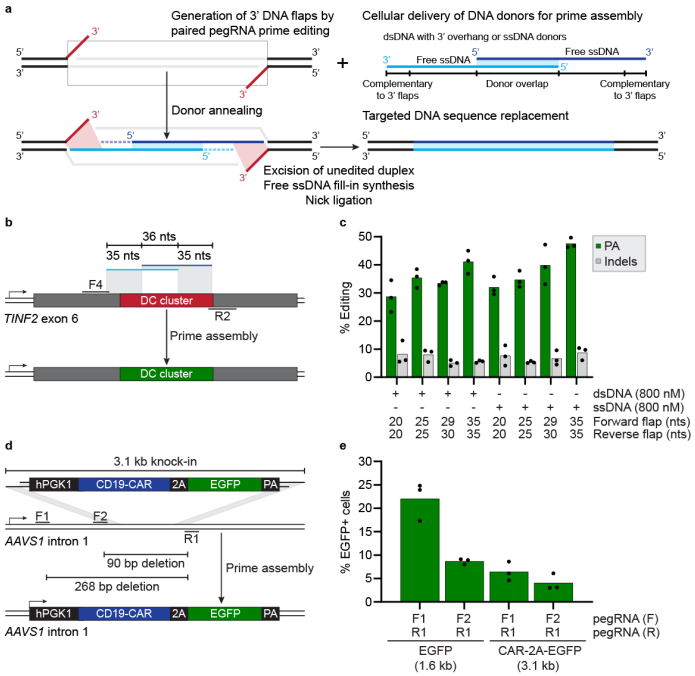
Therapeutic genome editing holds great potential to remedy diverse severe Mendelian disorders. Although progress has been made, multiple cell type-specific barriers constrain the installation of medium to large genomic modifications in therapeutically relevant hematopoietic cells. To expand the genome editing toolkit, we developed an approach that enables DNA sequence assembly and integration in human cells using CRISPR-targeted flap synthesis. Denoted as prime assembly (PA), our approach enables the integration of single- or double-stranded DNA (ssDNA and dsDNA) donors to specific genomic loci. As a proof of concept, we devised and optimized a therapeutic exon recoding strategy for *TINF2* dyskeratosis congenita (DC) to potentially correct almost all known gain-of-function mutations associated with this short telomere syndrome, achieving an average efficiency of 47.6% in K562 cells, as determined by amplicon sequencing. Using this approach, we established design rules and demonstrated the capacity of PA to accommodate different types of donors, including synthetic ssDNA donor libraries that can be directly integrated to the genome for functional genomics applications.

To highlight the potential of PA for targeted transgene integration, we developed strategies to integrate reporter transgenes at the *TRAC*, *AAVS1*, and *IL2RG* loci. At the *AAVS1* locus, we achieved average efficiencies of 22.0% and 6.4% $EGFP^+$ cells for the integration of 1.6 kb and 3.1 kb transgene cassettes, respectively. Using a CDK4/6 inhibitor and cell cycle analysis, we observed efficient PA in non-dividing cells arrested in G0/G1. Under selective pressure, we also demonstrate the assembly and integration of up to four ssDNA fragments at the *ATP1A1* locus. Finally, we successfully targeted a reporter transgene to the *IL2RG* locus using ssDNA donors in hematopoietic stem and progenitor cells from different healthy donors, albeit with low efficiency without optimization. Together, prime assembly enables site-specific DNA integration without requiring homology-directed repair, cell cycle progression, recombinases, or donor dsDNA, providing a new tool for functional genomics and therapeutic genome editing.



Prime assembly enables efficient site-specific DNA integration in human cells. (a) Schematics representation of prime assembly (PA). (**b**) Schematics of *TINF2* DC cluster recoding using PA. (**c**) PA and indel quantification at *TINF2* as determined by CRISPResso2 analysis from amplicon sequencing. K562 cells were electroporated with PA vectors and donors, and genomic DNA was harvested 3 days post-nucleofection. $n = 3$ independent biological replicates. (**d**) Schematics representation of targeted transgene integration at the *AAVS1* locus using PA. (**e**) Percentage of EGFP+ cells as determined by flow cytometry. K562 cells were electroporated with PA vectors and donors targeting *AAVS1*, and the percentage of EGFP expressing cells was quantified 21 days post-nucleofection. $n = 3$ independent biological replicates.

187 Development of Novel HDAd Vectors for Efficient Targeted Integration via Prime Editing and Site-Directed Recombination

Chang Li[1]*, Anna Anderson[2], Andre Lieber[3]

Targeted transgene integration into pre-selected genomic sites is critical for precise, safe, and predictable gene therapy outcomes. Unlike random integration, which risks insertional mutagenesis or variable expression, targeted strategies aim to insert transgenes at specific "safe harbor" loci (e.g. *AAVS1*, *ROSA26*) or disease-relevant sites. Conventional CRISPR-mediated HDR (homology-directed repair) is inefficient in non-dividing cells, such as primitive hematopoietic stem cells (HSCs), and suffers from genotoxicity associated with double-strand DNA breaks generated by CRISPR. Helper-dependent adenovirus (HDAd) vectors have a payload greater than 30 kb, are devoid of viral coding genes, and can efficiently transduce HSCs for *in vivo* applications. Here, we aim to develop novel helper-dependent adenovirus (HDAd) vector systems carrying a donor cassette, a prime editor (PE), and a highly efficient serine recombinase Bxb1 for targeted transgene integration. The prime editor is responsible for installing one or two Bxb1 attachment sites (attP) at the *AAVS1* locus; while the Bxb1 mediates insertion of the donor DNA linked with one or two attB sequences. We designed three strategies with different mechanisms for circularization of the donor DNA. Each included two vectors: one expressing the PE elements and the Bxb1 recombinase; the other containing the donor cassette joined to a Bxb1 attachment site. Specifically, strategy A featured a flippase to generate the donor minicircle. Strategy B installed two heterologous attachment sites *in cis* and capitalized on the recombinase-mediated cassette exchange (RMCE) for donor integration. Strategy C included one attachment site (attP-GA) and its cognate attB-GA for donor DNA circularization, while utilizing a heterologous attP-GT/attB-GT pair for integration. We demonstrated that, without the formation of donor minicircles, linear HDAd viral DNA linked with only one attachment site did not stably integrate. This is consistent with the mechanism of Bxb1-mediated recombination. By transfection in cell lines, we observed that all three strategies

resulted in similarly efficient integration of the donor template. Compared to the random integration mediated by a Sleeping Beauty transposase (SB100x) and a CRISPR-based HDR, the frequency of integration by the three strategies was approximately two and three-fold higher. We successfully produced HDAd vectors for strategy B, except the PE vector, which showed significant rearrangement, likely due to repetitive sequences of the four U6 promoter-epegRNA elements. We are attempting to switch to alternative type III RNA polymerase promoters to reduce sequence repetition in this vector. By HDAd transduction, we found that the PE vector generated near saturating levels of attP docking site installation. With regards to integration, strategy C outperformed strategy A, suggesting that the flippase in the latter strategy is likely to limit its efficiency. Targeted integration was confirmed by in-out PCR and inverse PCR. Additionally, single cell derived clones demonstrated that the overwhelming majority clones had at least one copy of transgene integration at the target site. Building on these strategies, ongoing studies are testing novel HDAd vectors expressing therapeutic transgenes for HIV-1 infection and hemoglobinopathies.

188 Engineering High-Efficiency, High-Specificity Recombinases for Therapeutic *In Vivo* Genome Engineering

Genomic medicine promises to revolutionize human health by enabling off-the-shelf therapies that cure disease with a single treatment. However, current gene delivery approaches are hobbled by fundamental limitations in potency and safety and are failing to deliver on this promise.

Large serine recombinases (LSRs) offer a path forward. LSRs mediate high-fidelity, site-specific integration of large genetic payloads without exposing double-strand breaks and can be delivered by lipid nanoparticles. Naturally occurring LSRs lack the specificity and/or activity necessary for use as genomic medicines without cumbersome workarounds to insert native attachment sites. We hypothesized that engineered, site-specific, therapeutic-grade recombinases could be designed to integrate payloads at therapeutically relevant sites within the human genome.

Here we report a high-efficiency, high-specificity recombinase targeted to a safe harbor locus in the human genome with broad applicability for genomic medicine. It is the output of an iterative design-build-test-learn process that leverages a platform of structure-guided design enabled by insights from proprietary cryo-EM structures, bacterial directed evolution screens, and real-world AI/ML-based protein design and data analysis.

The modular LSR architecture facilitates parallel subdomain evolution and optimization. We identified efficiency-enhancing mutations throughout the protein and found that combining individually identified variants resulted in cumulative improvements. For example, insertional efficiency at the primary safe harbor site was increased sevenfold, reaching over 50% in human cells. Specificity-enhancing mutations were predominantly confined to DNA binding regions, where bacterial evolution selections were critical for engineering. We identified LSR variants for which primary site insertion efficiency exceeded that at all secondary sites by more than 10-fold as evaluated in an unbiased NGS cell-based readout and, specificity relative to the top three secondary sites improved by 90x, 391x, and >500x – all while retaining high insertional efficiency at the safe harbor site.

When electroporated into primary human T cells with a CAR payload, our engineered LSR resulted in over 40% CAR-positive cells with more than 25% integration by ddPCR. Additionally, payloads ranging from 3 kb to 13.5 kb were integrated with no loss in efficiency relative to size.

The design of therapeutic-grade recombinases for predetermined sites in the human genome represents a novel and powerful avenue for precise, non-viral genomic engineering. We are now applying this strategy to develop recombinases targeted to additional therapeutically relevant sites in the genome. This work lays the foundation for a genomic medicines platform capable of enabling off-the-shelf, in vivo LNP-based therapies that are both highly

effective and broadly accessible.

189 Alemtuzumab-Resistant Virus-Specific T (VST) Cells Developed for the Prevention of Viral Infections After Hematopoietic Stem Cell Transplantation Retain Antiviral Activity In-Vivo and In-Vitro

Daisy Ayala-Gomez[1]*, Cecilia Motta[1], Susan Conway[1], Pamela Chansky[1], Nethaji Muniraj[1], Samantha Murphy[1], Naseem Maghzian[1], Gloria Pezzella[1], Joshree Shrestha[1], Haili Lang[1], Catherine Bollard[3], Wei Li[2], Conrad Russell Cruz[3], Allistair Abraham[1], Michael Keller[1]

Hematopoietic stem cell transplantation (HSCT) is a curative treatment for many malignant and non-malignant hematologic conditions. Alemtuzumab is often used as conditioning pre-HSCT but is associated with delayed T cell reconstitution and an increased risk of infections. Virus-specific T cell (VST) immunotherapy enhances immune reconstitution post-HSCT but may be eliminated by the use of alemtuzumab. CD52, the target of alemtuzumab, has no known crucial role in the immune system and CD52 knockout (CD52-KO) may allow generation of alemtuzumab-resistant VSTs. We proposed to use CRISPR/Cas9 gene editing to develop a "next generation" VST product with broad applicability and efficacy. Furthermore, we anticipated CD52-KO VSTs to exhibit similar efficacy and persist in NOD SCID Gamma (NSG) mice after alemtuzumab treatment.

Design/Method:
Peripheral blood mononuclear cells were isolated from CMV positive donors and incubated with CMV-specific peptides pp65 and IE-1 to create CMV-specific VSTs. CD52-KO VSTs were generated by nucleofection of sgRNA (UUACCUGUACCAUAACCAGG) and Cas9 protein. VSTs were analyzed via flow cytometry to determine knock out efficiency, phenotype, and cytokine expression on a cellular level. Additionally, DNA was extracted to determine knock out efficacy on a genetic level by using Interference of CRISPR Edits (ICE) Analysis.

VSTs were tested with 5 groups of NSG mice. Groups 1 and 2 were injected intravenously with 10E6 CD52-KO VSTs, while groups 3 and 4 received 10E6 nonedited VSTs, and group 5 received phosphate-buffered saline (PBS) only. Following VST injection, groups 1 and 3 were treated with a single intraperitoneal injection of alemtuzumab at 5mg/kg while remaining groups were treated with PBS. Mice were sacrificed at 72 hours for the harvest of spleen, bone marrow, and PBMCs to determine knock out efficacy and replicability in-vivo using flow cytometric analysis.

Result/Discussion:
Across 3 runs, CD52-KO efficiency, determined by surface staining of CD52 and ICE analysis, ranged from 58-85% (mean = 71.5%) with no significant off-target edits predicted by Change-seq, CRISPRme, or COSMID. Additionally, intracellular cytokine staining for IFNg and TNFa demonstrated that CD52-KO VSTs retained antiviral activity comparable to non-edited VSTs in the presence of alemtuzumab in-vitro (Figure A). Furthermore, CD52-KO VSTs were detectable in vivo (Figure B). Mice who received CD52KO VSTs and no alemtuzumab treatment had significantly fewer CD52+ T cells (n=7; CD3+/CD52+ 15.73%) than those receiving non-edited VSTs (n=5, CD3+/CD52+ 70.78%, $p<0.0001$). After treatment with alemtuzumab, mice who received CD52KO VSTs maintained a significantly higher percentage of CD3+CD52- T cells (n=8, mean CD3+/CD52- 63.33%) compared to mice receiving nonedited VSTs (n=7, mean CD3+CD52- 3.74%, $p < 0.0001$).

Our study suggests that CD52-KO VSTs, in combination with alemtuzumab, could offer a potential approach to restore antiviral immunity while preventing graft versus host disease after HSCT. Long term persistence and antiviral function of cells in-vivo, as well as multiviral CD52-KO VSTs are being investigated with the eventual intent to create a readily available CD52-KO VST that can fight infection while resisting T cell depletion after HSCT.

190 Nuclease-Free In Vivo Genome Editing of the CNS Following Systemic Administration of AAVHSC15 Vectors

Swati Bijlani[1], Ka Ming Pang[2], Lakshmi Bugga[2], Amin Kudsi[2], Saswati Chatterjee[3]*
[1]City of Hope, Duarte, California, [2]City of Hope, Duarte, CA, [3]Beckman Research Institute of City of Hope, Duarte, California
**Corresponding Author*

The development of genetic therapies for central nervous system (CNS) diseases and for neurologic manifestations of systemic diseases has generally proven challenging. While gene augmentation strategies work well for diseases where over- or under-expression is not toxic, the lack of native physiologic regulation can be pathogenic where highly regulated transgene expression is required. This is compounded by the incomplete identification of precise regulatory elements for many disease-associated genes, further complicating the design of therapeutic gene transfer vectors. In addition, the episomal nature of many gene transfer vectors creates uncertainty regarding the long-term stability of gene augmentation. In contrast, the ability to directly correct mutations at the level of the genome offers significant advantages for both the retention of all known and unknown regulatory signals as well as durability. Here, we evaluated the potential of systemic in vivo genome editing to insert promoterless sequences at specified genomic locations within the CNS and in peripheral tissues. We utilized the single component nuclease-free AAVHSC editing platform which edits via the high-fidelity BRCA2-dependent homologous recombination. AAVHSC editing is cell cycle independent and functions in both dividing and non-dividing cells. Genome editing was evaluated in the CNS and peripheral tissues at 2 different loci, the murine Mecp2 and Rosa26 loci following intravenous (IV) delivery. Genome editing was assessed by the insertion of a promoterless luciferase open reading frame downstream of Exon 4 of the murine Mecp2 gene or within Intron 1 of the Rosa26 gene such that expression would be driven by the native chromosomal promoters. Results revealed that IV injection of AAVHSC15 editing vectors resulted in specific in vivo luciferase expression from both Mecp2 and Rosa26 genes. Systemic genome editing was observed both within the CNS and in peripheral tissues. Sequence analyses revealed that editing was precise. No insertion / deletion mutations or ITR insertions were observed at the target site. Transcriptional analyses

revealed that the edited Mecp2 and Rosa26 transcripts were expressed in both the CNS as well as peripheral tissues including liver and heart. Importantly, widespread editing of neurons, astrocytes, and microglia was observed in different regions of the CNS following systemic administration, including the cerebellum, mid brain, medulla, pons, striatum and hippocampus. These results indicate that AAVHSC editing offers a promising platform for the treatment of neurologic diseases that require correction of neurons and glial cells. Based on our overall results, we conclude that in vivo systemic AAVHSC genome editing represents an attractive therapeutic platform for the universal systemic correction of disease-associated mutations.

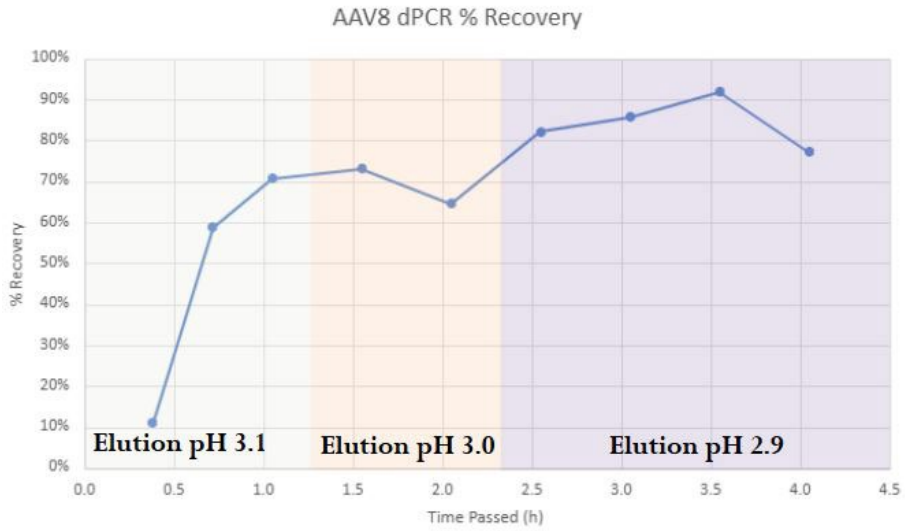
Downstream Manufacturing for AAV Vectors

191 Integrated AAV Capture and Polishing via BioRMB™, a Continuous, Column-free Chromatography Platform

Thiago Millen[1], **Dalton Kinnard**, Oleg Shinkazh, Alex Schaffer[2], Sreeja Edara, Dwayne Kenney, Collin Britten[3]
[1]ChromaTan, Ambler, PA, [2]ChromaTan Inc., Ambler, PA, [3]Waters/Wyatt, Philadelphia, PA

BioRMB™ is a column-free and steady-state purification platform that is specifically tailored for sensitive modalities such as gene therapies, vaccines, mRNA, and complex antibodies, which combines the principles of Real Moving Bed (RMB) and columnless chromatography, allowing different operations to be performed simultaneously on the resin slurry as it is pumped in a continuous loop like a conveyor belt. BioRMB™ overcomes many limitations of batch columns as well as circumventing the drawbacks of multi-column systems, all while providing 5-10x greater productivity with a fully disposable, single-use flow path. Additionally, BioRMB™ demonstrates >80% reduction in resin volume vs. batch columns, higher recoveries and lower HCP.

Previously, we have demonstrated integrated mAb capture and polishing using BioRMB™. In this work we will present capture data for two different serotypes of AAV, using titers obtained by dPCR, qPCR, BLI (Bio-layer interferometry), as well as impurity removal characterized by HCP ELISA, and Host cell DNA by dPCR. We will also be presenting preliminary findings on a proof-of-concept data set for a novel PAT technique for real-time monitoring of AAV whole capsid titter as well as a strong application for real-time AAV empty-full analysis on a continuous purification platform, by integrating BioRMB™ and Real-Time MALS. This will be compared with data acquired by both mass photometry and SEC-MALS.



192 Data-Efficient and Adaptive Machine Learning Framework for Accelerated AAV Downstream Processing.

**Corresponding Author*

Optimizing downstream purification of adeno-associated viral (AAV) vectors remains a fundamental challenge in advancing gene therapy development and commercialization. We have developed a machine learning approach utilizing Gaussian process (GP) surrogate models coupled with quasi-Monte Carlo acquisition functions to predict and optimize AAV vector yield during downstream processing. Our method involved training GP models on critical chromatography parameters across seven clinically relevant serotypes (AAV10, AAV2, AAV5, AAV6, AAV9, AAV3, and AAV8). These parameters included fixed conditions such as a 306 cm/h system flowrate and equilibration conditions set to pH 7.0 with 2.5 conductivity. The optimization space explored three AAV serotypes (AAV2, AAV5, AAV6, and AAV9) with variable elution and wash pH ranging from 5.0 to 9.0 in 0.5 increments. Elution conductivity was varied continuously between 10.0 and 100.0 mS/cm, while wash conductivity was adjusted in 1.0 increments from 1.0 to 15.0 mS/cm. Sample volumes were tested at discrete intervals of 5 mL between 5 and 30 mL, and sample flowrates were continuously varied between 130 and 600 cm/h. All purifications were done using Toyopeal-NH2-750F resin conjugated with the peptide CVIDGSASTDDDRIC. The GP model, integrated with the acquisition function, guided an iterative Bayesian optimization process that efficiently sampled the search space of process parameters to find specific values of those that significantly optimized quality attributes of the purification process (Fig. 1). The model achieved remarkable accuracy for yield prediction predictive accuracy with a coefficient of determination (R^2) of 0.92 across all serotypes tested. The model converged on parameters to maximize yield and purity by more than 98% in only three experimental iterations, outperforming traditional process development methods that typically yield around 70% (Fig 2). This data-driven strategy significantly accelerates process optimization while enhancing critical quality attributes of AAV vectors. To add a layer of process understanding, we used SHAP (SHapley Additive exPlanations) to assess how each process parameter affects the model's predictions. This gave qualitative and quantitative insight into how each input parameter affected the process yield. Our analysis revealed that sample volume was the dominant process parameter affecting capsid yield, with higher volumes positively correlating with increased production. Other parameters, such as wash conductivity and elution flowrate, had moderate effects: higher wash conductivity reduces capsid yield, while lower conductivity increases it; and higher sample flowrate increases capsid yield, while lower flowrate decreases it. Wash pH demonstrated minimal impact on the process outcome. This analysis provides quantitative insight into each parameter's importance for process optimization. Beyond improving manufacturing efficiency and product quality for gene therapy programs, our methodology shows promise for broader applications in biomanufacturing process optimization. These advances directly address current manufacturing bottlenecks that impact the availability and cost of gene therapies for patients.

193 Combining Steric Exclusion with Anion Exchange Chromatography – Development of an Innovative, Affinity-Independent, and Scalable AAV Downstream Process

Benjamin Graf[1], Frederik Meierrieks[2], Andreas Pickl[3], Michael Wolff[4], Karl Pflanz[5], Juan-Carlos Rosario[6], Kathrin Kusch[7], Lena Rübeling[8], Hatice Asikoglu[8]

[1]Sartorius Lab Instruments GmbH & Co KG, Göttingen, Niedersachsen, Germany, [2]Sartorius Lab Instruments GmbH & Co. KG, Göttingen, Outside USA, GERMANY, [3]Sartorius Lab Instruments GmbH & Co. KG, GERMANY, [4]University of Applied Sciences Mittelhessen, GERMANY, [5]Sartorius Stedim Biotech GmbH, GERMANY, [6]Eli Lilly and Company, Indianapolis, IN, [7]German Primate Centre Leibniz Institute for Primate Research, GERMANY, [8]Sartorius Lab Instruments GmbH, Göttingen, Niedersachsen, Germany

Adeno-associated viruses (AAV) are prominent vectors in the field of in vivo gene therapy, yet their purification remains a major challenge due to the need for multiple process steps, often leading to product loss and high costs. Traditional downstream processes are typically serotype-specific and heavily reliant on costly affinity resins (**Figure 1 A**). To overcome these challenges, we have developed a serotype-independent purification method utilizing steric exclusion chromatography (SXC), which can be seamlessly integrated with a subsequent anion-exchange polishing step (**Figure 1 B**). AAV elution from the SXC column can be realized with a buffer of choice. This in turn eliminates the need for intermediate concentration and buffer exchange steps, thereby reducing the overall number of process steps while achieving high-purity enrichment of filled AAV particles.

In the initial phase of process development, we optimized AAV capturing via SXC using a design of experiment (DoE) approach (**Figure 2 A**). The AAV particles captured via SXC were further purified using anion-exchange chromatography with a monolithic stationary phase. This step not only removed unspecific impurities but also enriched filled AAV particles. The process achieved a viral genome recovery rate of 51.7%, with impurity reductions of 99.9% for DNA and 99.8% for protein (**Figure 2 B**). The method was successfully adapted to various AAV serotypes and different genes of interest, demonstrating its robustness and versatility. Additionally, the scalability of SXC was confirmed, underscoring its potential for large-scale manufacturing.

This streamlined, universal, and scalable process offers a robust and efficient alternative to traditional AAV purification methods, addressing critical challenges in gene therapy production and paving the way for broader implementation in both research and manufacturing environments.

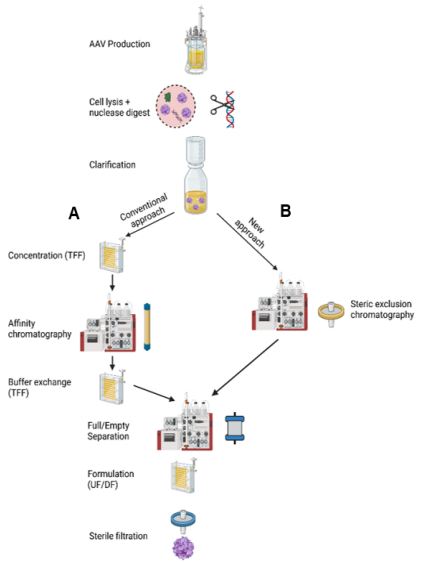

Figure 1: Schematic representation of a standard AAV downstream process. A) Two tangential-flow filtration (TFF) steps are mostly used to reduce the loading volume before the affinity column and to achieve a buffer exchange for the anion-exchange based empty/full separation. B) AAV capture using SXC allows an elution with a buffer of choice. The eluate can be directly applied to the anion-exchange column for empty/full separation.

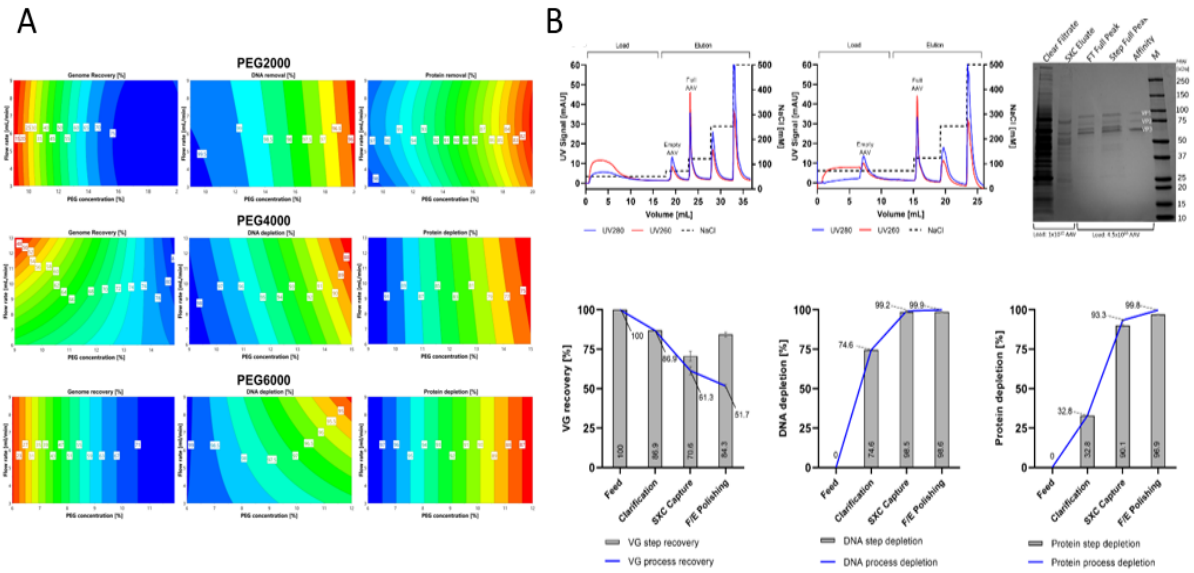

Figure 2: **A**) DoE results of three different PEG variants (PEG2000 (top), PEG4000 (middle) PEG6000 (bottom). Genome recovery, DNA removal and protein removal were used for multivariant statistical analysis and process optimization. **B**) Top left and middle shows two chromatograms of empty/full separation of SXC purified AAV samples. Top right shows an SDS-PAGE of different process steps. The histograms on the bottom show the stepwise VG recovery, DNA depletion and protein depletion.

194 Neutral pH Elution of AAV using Affinity Liquid Phase Separation (ALPS) in Centrifugation and Tangential Flow Filtration (TFF) Formats for Flexible Downstream Processing

Jennifer Haley, Isolere Bio, Durham, NC

The purification of adeno-associated virus (AAV) using Affinity Liquid Phase Separation (ALPS) introduces a novel method that challenges traditional gene therapy production paradigms. The IsoTag™ AAV reagent combines an affinity ligand with a stimulus responsive, phase separating biopolymer to purify AAV based on size and affinity in a single process without chromatography. The ALPS process was implemented in a centrifugation format to screen binding and elution conditions for AAV9 in parallel, utilizing only 1mL of harvest per condition. This screen identified a neutral pH elution buffer that allows for >90% recovery of AAV9, comparable to results achieved with a standard pH 3.0 elution. This elution buffer was tested in a tangential flow filtration (TFF) setup utilizing hollow fiber filters, demonstrating centrifugation screening results were translatable to scalable ALPS-TFF process. The ALPS TFF process developed at the 1L scale was then scaled to 2L and 16L by maintaining a constant filter loading, shear rate and flux for viral genome capture and recovery >95% by ITR2 qPCR in less than 4 hours for all three scales. Finally, an ALPS-TFF process was developed using flat sheet cassette format with externally validated data, demonstrating flexibility of the IsoTag™ AAV ALPS technology for AAV affinity purification. The IsoTag™ AAV reagent allows for neutral pH elution of AAV in a high throughput centrifugation format as well as scalable TFF processes to address a wide range of AAV affinity purification applications.

195 Development of a Scalable and Cost-Effective Clarification Strategy for Adeno-Associated Virus Bioprocessing Using Single-Use Anion Exchange Fibrous Technology

Qiuge Zhang[1], Morgan Ludwicki[1], MAUHAMAD BAARINE[2], Masa Nakamura[3], Jacob Calhoun[1]
[1]Solventum, Saint Paul, MN, [2]Solventum, Watertown, MA, [3]Solventum, Saint Paul, MI

Adeno-associated virus (AAV) is widely used in gene therapy, but its bioprocessing is less mature than recombinant proteins. This is primarily attributed to the structural complexity of AAV particles and challenges in removing

impurities, particularly soluble host cell DNA (hcDNA) that associates with AAV particles. These challenges necessitate dedicated and systematic development of clarification strategies for an efficient AAV bioprocess platform.

First, this study systematically evaluated the effects of diverse system variables (e.g., ionic/non-ionic and zwitterionic lysis reagents, nucleases, clarification methods) and process variables (e.g., incubation time, conductivity) on host cell lysis in a model HEK293 expression system. Key metrics such as lysis efficiency, AAV recovery, hcDNA size and concentration, and particle size distribution were assessed. Additionally, the impact of lysis methods on AAV quantification by ELISA and PCR was investigated to develop a robust quantification workflow for various metrics. Then, we processed lysates (with varying AAV serotypes, hcDNA concentrations, and residual detergents) to screen for a scalable and platform-compatible clarification strategy suitable for diverse feed streams. A single-use anion exchange (AEX) technology with quaternary amine-grafted synthetic fibers, was identified as an attractive solution enabling single-stage, nuclease-free lysate clarification. Systematic operating parameter optimization (e.g., resident time, conductivity, etc.) achieved consistent performance (>90% AAV recovery, >95% turbidity reduction, and >2-log hcDNA reduction) across diverse lysate feed streams and scales. Notably, this charge-based clarification method, leveraging ionic interactions to capture hcDNA in a flow-through mode, eliminated the need for nuclease digestion, delivering comparable results to nuclease-treated workflows while reducing estimated costs by >35% relative to conventional depth filter-based processes requiring nuclease treatment.

After processing various clarified fluids with AAVX affinity chromatography, we evaluated the purified AAV quality, residual hcDNA/plasmid DNA concentration, and hcDNA size distribution across unit operations in the AAV bioprocess. The analytical results identified the key clarification step to address downstream purification challenges. Overall, our study developed a novel, versatile and single-stage nuclease-free AAV clarification approach that effectively processes feed streams with varying detergent types, conductivity, and impurity profiles. The approach integrates seamlessly with downstream capture chromatography, ensuring purified AAV yield and quality. With its demonstrated scalability from laboratory to manufacturing scales, this single-use AEX fibrous clarification offers an efficient and robust solution for AAV bioprocessing.

196 Purification of a broad range of adeno-associated virus serotypes from HEK293 cell lysate using peptide-based affinity *AAVW*$_{II}$ adsorbent and quantitative proteomic analysis of residual host cell protein via LC-MS/MS technology

Wenning Chu[1], Eduardo Barbieri[2], Yuxuan Wu[2], Sara Siegel[3], Qingbo Shu[2], Arjun-Shriarjun Shastry[2], Taufika Islam Williams[2], Gary Gilleskie[2], Stefano Menegatti[2]*

**Corresponding Author*

Cell and gene therapies (CGTs) are at the forefront of innovation to treat rare degenerative & dysregulation diseases, immunological disorders, and genetic defects diseases, such as Hemophilia. Adeno-associated viruses (AAVs) have been widely utilized as delivery vectors for in-vivo replacement of functional genes to target cells for gene therapy. Currently, commercialized affinity resins have been utilized for the capture step of downstream manufacture of AAV vectors, but the expensive price and extremely acidic elution would limit their application on the biomanufacturer of AAV-base gene therapy products. To support the development of CGT products, innovative peptide-based affinity ligands, specifically designed to capture a broad range of adeno-associated virus serotypes from human embryonic kidney 293 (HEK293) cell lysate with high binding affinity and selectivity, were developed through high-throughput screening technology via microfluidic device in the previous work (Chu, Shastry et al. 2023). Due to high AAV binding capacity of above 1×10^{13} vp/mL, a broad range of binding affinity (serotype 1, 2, 4, 5, 6, 8, 9, and rh10), comparable AAV recovery of above 40%, and excellent pertaining of transduction activity of above 60% of AAV particles at near physiological pH of 7.0, *AAVW*$_{II}$-Toyopearl resin was selected for the product purity optimization (Fig. 1). AAV elution with high-purity could be achieved using 10 CVs of stepwise elution of 100% buffer A (ddH_2O) and 5 CVs of stepwise elution of 5% buffer B (1 M $MgCl_2$ in 20 mM Bis-Tris HCl buffer at pH 6.0) at the resident time of 2 min. Furthermore, seven other AAVs were purified from crude or Charcoal-treated HEK293 cell lysate via *AAVW*$_{II}$-Toyopearl resin under optimized elution strategy. Regardless of viral serotypes in

Fig. 2(A), *AAVW*$_{II}$-Toyopearl shows high dynamic binding capacity (DBC) of AAV of above 1×10^{13} vp/mL with strong salt-tolerance, ranging from 10-30 mS/cm, and excellent purity of over 200-fold reduction of HEK293 HCPs, in accordance with normalized SEC-UPLC analysis in Fig. 2(B). Noteworthily, it provides 10-fold higher DBC of AAV8 (~1×10^{14} vp/mL) regardless of transgene payload size (2.5~4.7 kb). Except AAV5 and AAV9, it provides comparable recovery of over 50% and high retaining of transduction activity (above 90%) of AAV particles under physiological elution pH of 7.0 and conductivity of below 7 mS/cm. CE-SDS analysis in Fig. 2(C) was performed for the elution fraction of AAV8 (Luc) from *AAVW*$_{II}$-Toyopearl resin with a VP1:VP2:VP3 ratio of 1: 1.07: 9.87, closing to typical 1: 1: 10 for a high transduction activity. Finally, the feedstocks and elution fractions from *AAVW*$_{II}$-Toyopearl resin were analyzed via nanoLC-MS/MS using a Thermo Scientific VanquishNEO UHPLC interfaced with a Orbitrap Eclipse™ Tribrid™ Mass Spectrometer to quantify the total removal of the AAV product-related impurities, such as green fluorescent protein (GFP, transgene plasmid), Rep78 (AAV2S Rep gene), Early E2A DNA-binidng protein and Early 4 ORF6 protein (AAV helper plasmid), the individual host cell proteins of HEK293 cell line, such as histone-related proteins, Ubiquitin-related proteins, and phosphatase-related proteins, as well as the co-eluted problematic residuals, such as cathepsin, catalase and autotaxin. In sum, the peptide ligand of *AAVW*$_{II}$-enables an economical, fast, robust, and platformable purification technology for a broad range of AAV serotypes under physiological condition.

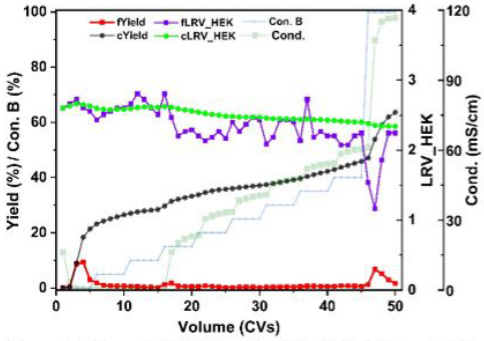

Figure 1. *Values of fYield (%), cYield (%), fLRV_HEK, and cLRV_HEK of AAV8 purified from a clarified HEK 293 cell lysate using AAVW$_{II}$ -Toyopearl resin with the increase of the stepwise elution volume, concentration of buffer B (Con. B, %), and sample conductivity (Cond., mS/cm). Note: stepwise elution with respective 5 CVs of 0%, 5%, 10%, 15%, 20%, 25%, 30%, 35%, 40%, and 100% buffer B for final regeneration.*

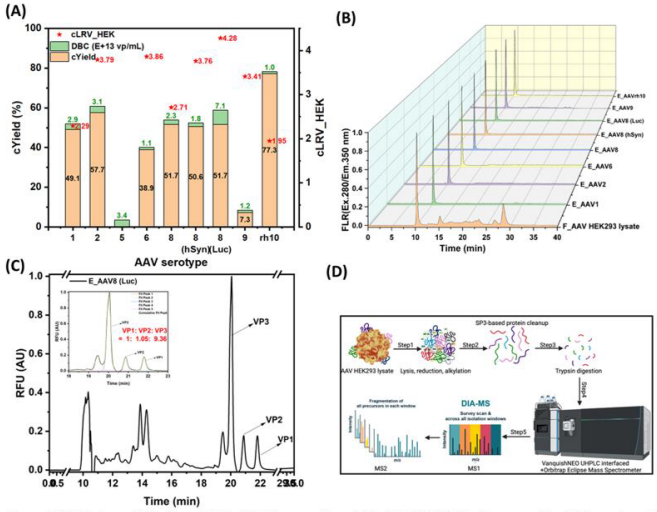

Figure 2. ***(A)*** *Values of cYield and DBC of AAVs, as well as cLRV of HEK293 HCPs for respective AAV serotype 1, 2, 5, 6, 8, 8 (hSyn), 8 (Luc), 9, and rh10 obtained via chromatographic purification from a clarified HEK 293 cell lysate (AAV titer: ~1×10^{12} vp/mL; HCP titer: ~0.2 mg/mL) using AAVW$_{II}$- Toyopearl resin;* ***(B)*** *normalized Size Exclusion Chromatography - Ultra Performance Liquid Chromatography (nSEC- UPLC) analysis of feedstock of AAV HEK293 cell lysate (F_AAV HEK293 lysate), and elution fractions of respective AAV1, AAV2, AAV6, AAV8, AAV (hSyn), AAV8 (Luc), AAV9, and AAVrh10 from AAVW$_{II}$- Toyopearl resin;* ***(C)*** *Capillary Electrophoresis-Sodium Dodecyl Sulfate (CE-SDS) analysis of elution fraction of AAV8 (Luc) from AAVW$_{II}$- Toyopearl resin with a VP1:VP2:VP3 ratio of 1: 1.05: 9.36;* ***(D)*** *Proteomic analysis workflow for the characteristics and quantification of HEK293 HCPs from respective feedstocks and elution fractions of AAVW$_{II}$- Toyopearl resin.*

197 Novel anion exchange chromatography elution approach to improve the Adeno-associated virus process robustness

Arjun Bhadouria[1], Jason Morais[2], Chen Wang[3]
[1]Sanofi, Waltham, MA, [2]Sanofi US, Framingham, MA, [3]Genzyme, a Sanofi Company, Waltham, MA

Adeno-associated virus (AAV) based therapeutics are emerging as novel modalities for the treatment of genetic diseases. AAV manufacturing processes produce the desired full capsid containing the target vector genome along with various product-related impurities, e.g., empty capsids, which lack the vector genome required for function, and partial capsids, which are a heterogeneous mixture of capsids containing truncated vector genomes, residual host cell DNA, etc. It is imperative that the purification process for AAVs removes these impurities to a sufficient degree to ensure safety and efficacy.

A common purification technique for the enrichment of full capsids leverages anion-exchange chromatography to exploit charge differences among the capsid species. Typically, an increasing salt gradient is employed to separate full capsid populations from other product variants. Since achieving high resolution during the separation can be a challenge, the ability to effectively control product collection during elution is critical to ensure consistent full capsid enrichment and recovery from batch to batch.

In this work we present a novel approach for elution by leveraging a conductivity signal to trigger the start and end of product collection. Conductivity-based collection has the advantage over other signal-based methods, including UV, since the signal itself is independent of common chromatography variables such as column load density and starting material variability. We have demonstrated this method to be highly reproducible and effective across a wide range of process scales. Additionally, the effectiveness of this approach has been demonstrated for several AAV capsid serotypes and with different elution salt/buffer combinations.

Viral Vector and Transgene Biology

198 Engineering of Next-Generation Bocavirus Vectors by Surface Loop Modification and Peptide Insertion

Yumi Sano[1], Anna Schneider[2], Emma Gerstmann[3], Sergio Moreno Velasquez[4], Dirk Grimm[5]
[1]Heidelberg University, Heidelberg, Baden-Wurttemberg, Germany, [2]Heidelberg University, Heidelberg, Baden-Wuerttemberg, Germany, [3]University Hospital Heidelberg, Heidelberg, Baden-Wuerttemberg, Germany, [4]University Hospital Heidelberg, GERMANY, [5]Heidelberg University Hospital, Heidelberg, Baden-Wuerttemberg, Germany

Adeno-associated virus (AAV) has emerged as the leading candidate for virus-mediated *in vivo* gene therapy as illustrated by hundreds of clinical trials and the rapidly increasing number of approved AAV-based therapeutics. Yet, its DNA packaging capacity of ~4.7 kb hampers its use for the delivery of larger genes including base editors and some clinically relevant cDNAs. Our group has previously demonstrated that bocavirus, another member of the Parvoviridae family, can encapsidate larger AAV vector genomes of up to ~6 kb and transduce various cells including human primary airway epithelia. Moreover, others reported potent *in vivo* gene delivery with recombinant Human Bocavirus 1 (HBoV1) encoding AAV genomes to the lungs of ferrets and non-human primates, underscoring the promise of bocaviruses as alternative gene therapy vectors. However, the current first generation of bocavirus vectors suffers from a low transduction efficiency, in turn necessitating the administration of high vector doses. In particular, *in vitro* transduction in cell lines is often inefficient, which hampers basic research on molecular virus-host interactions or high-throughput screenings of capsid variants. Thus, we aimed to fill in the gaps in our knowledge of bocavirus biology by identifying residues that govern the transduction. Interestingly, Gorilla Bocavirus 1 (GBoV1) exhibits significantly higher transduction efficiencies in multiple cell lines compared to HBoV1, despite the high amino acid identity of these variants (86%). Following our hypothesis that distinct residues on the capsid surface loops explain this difference, we replaced each variable region (VR) of GBoV1 with that of

HBoV1 and measured the transduction efficiency of the ensuing chimeras in Huh-7 cells. Unexpectedly, several variants yielded better transduction, including GBoV1 vectors carrying VRIII or VRVI from HBoV1 that outperformed genuine GBoV1 by up to four-fold. Remarkably, VRVI of HBoV1 and GBoV1 are almost identical except for one amino acid (Asp to Asn). Based on this, we concurrently replaced VRIII and VRVI with those of HBoV1 in the same GBoV1 capsid and found that the resulting double-swap chimera transduces the cells even better, as much as 15-fold compared to the GBoV1 wild-type. A similar trend was also observed in HEK293T cells. Furthermore, we hypothesized that insertion of peptides known to boost AAV transduction would also enhance bocavirus vectors considering the similarity in capsid structure. First, we assessed two 7-mers with an NXXRXXX motif (X = any residue) reported by our group to improve transduction of multiple AAV serotypes in Huh-7 cells. As hoped for, insertion of either peptide into GBoV1 VRIV enhanced transduction by roughly four-fold. This motivated us to insert a longer, melittin-derived peptide (>20 residues) reported to aid endosomal escape of AAV when displayed on its surface. Strikingly, this peptide not only boosted the GBoV1 wild-type by five-fold but it yielded an up to 30-fold improvement in transduction when inserted into the VRIII-VI GBoV1/HBoV1 chimera. To our knowledge, this is the first study reporting successful rational engineering of bocavirus capsid variants through domain swapping and peptide display. Granted their superior efficacy can be confirmed in primary cells and animal models, this work could pave the way for a new generation of parvoviral gene therapy vectors with significant potential to overcome some of the shortcomings of AAV.

199 Investigating the Influence of Viral and Cellular Insulators on Stable HSV-1 Vector-Mediated Transgene Expression in Various Tissues

Selene Ingusci[1], Pankaj Singh[2], Donna Neumann[3], Joseph Glorioso[1]
[1]University of Pittsburgh, Pittsburgh, PA, [2]University of Wisconsin-Madison, Madison, WI, [3]University of Wisconsin-Madison

Controlling the epigenetic environment is crucial for the successful long-term expression of therapeutic gene cassettes in gene therapy platforms. Unlike other gene therapy platforms that are constrained by the inclusion of insulator sequence, replication defective (rd) HSV vectors offer the unique advantage of a large payload capacity, allowing direct intervention and manipulation of the transgene cassette epigenetic environment. To enhance the safety and efficacy of rdHSV vectors, we have developed a novel gene transfer platform by functionally deleting all immediate-early (IE) genes and the reiterated JOINT region flanking the unique long (U_L) and unique short (U_S) genomic components, resulting in a payload capacity of ~30-kbp. However, in the absence of ICP0 expression, transduced cells rapidly silence the viral genome, including the transgene cassettes. Our preliminary data indicate that sustained transgene expression requires strategic flanking of the transgene cassette with natural viral insulators, such as those near the IE and latency-associated transcript (LAT) loci. HSV viral insulators contain multiple recognition motifs for the CCCTC-binding factor (CTCF), a key regulator of chromatin structure. These modifications rendered the vectors devoid of viral gene expression while leveraging the insulator sequences to enable robust transgene expression in neuronal and non-neuronal cells *in vitro.* Furthermore, *in vivo* delivery to skeletal muscle demonstrated stable transgene expression from the LAT locus for at least one year, whereas persistent but declining expression from the ICP4 locus was observed in the mouse hippocampus over five months. While the role of HSV insulators in regulating wild-type HSV transcription during latency and reactivation has been studied, the binding of CTCF to viral insulators in rdHSV vectors and its impact on transgene expression remains unexplored. Here, we provide the first evidence of CTCF occupation of two CTCF binding clusters in rdHSV vectors. Moreover, we evaluated the influence of insulators on transgene activity across multiple cell types, including neurons, muscle, retinal pigment, and bronchial epithelial cells. Recognizing the importance of viral insulators, we further evaluated additional anti-silencing elements to sustain high-level expression. A novel insulator design incorporating scaffold/matrix attachment regions (SMARs) and tRNA sequences significantly enhanced and stabilized transgene expression, underscoring the potential of insulator selection in regulating transgene activity in rdHSV vectors. Notably, *in vivo* delivery of this optimized insulator design yielded substantially higher transgene expression in the brain compared to viral insulators alone, maintaining robust expression for at least one year. These findings highlight the critical role of epigenetic modifiers in advancing the reliability of gene therapy. By integrating optimized insulator sequences, this new cassette design ensures high, durable transgene activity across multiple tissue types, offering promising therapeutic potential for treating complex diseases affecting neurons and other tissues.

Corresponding Author

The adenoviral (Ad) vector based AstraZeneca and Janssen COVID vaccines have been linked to rare cases of vaccine-induced thrombotic thrombocytopenia (VITT), a condition that appears to be linked to Ad binding to the blood protein Platelet Factor 4 (PF4). Meanwhile, several adeno-associated virus vectors (AAVs) in clinical use for gene therapy have been associated with cases of thrombotic microangiopathy (TMA), although a potential link to PF4 binding remains yet to be identified.

Harnessing the broad diversity of natural and synthetic Ads and AAVs, we strived to identify vectors that do not interact with PF4, to locate the binding site of PF4 on commonly used Ad vectors and to establish vaccine vector platforms using these PF4-non-binding Ad vectors.

Using a range of techniques, including SPR and ELISA-qPCR, we assessed the PF4 binding ability of 12 AAV and 50 Ad vectors including genetically or chemically modified Ad5 hexon or fiber variants. Unlike most of the vectors tested, AAV1, AAV6 and AAV7, as well as Ad34 and Ad80 did not bind to PF4. Likewise, the deletion of the hexon hyper-variable region (HVR) 1 of Ad5 or its shielding by PEGylation ablated the vector's PF4 binding. This suggests that HVR1 is the primary binding site of PF4 on the Ad5 capsid, which was supported by Brownian Dynamics (BD) modeling of molecular interactions. These simulations indicated further that PF4 binding is primarily driven by HVR1 loop steric occupancy of the hexon surface rather than by its electrostatic potential, suggesting that genetic manipulations that modify HVR1 surface charge are unlikely to ablate Ad binding to PF4 unless the loop is also shortened.

We then constructed PF4 non-binding Ad vaccines expressing the SARS-CoV-2 spike S1 domain and tested their immunogenicity in mice. The candidate COVID vaccine vector derived from HVR1-deleted Ad5 induced robust S1-specific CD8 and CD4 T cell responses matching those elicited by the parental Ad5 vector. Interestingly HVR1-deleted Ad5 did not induce detectable vector-binding antibody titers, suggesting an improved potential for homologous prime-boost vaccination. The Ad34-based vaccine vector also induced anti-spike antibody responses, although at lower levels than those elicited by the parental Ad5 vector.

Taken together, we document important advantages of novel PF4-non-binding adenovirus vectors for vaccine delivery, raising expectations for safer vector platforms with decreased risk of VITT in prophylactic as well as therapeutic applications.

201 Understanding the Clinical Immunogenicity of Locally Injected HCAd Vector Provides Insight Into Optimizing Dosing Strategy

MIJEONG KIM[1], Nino Joy[2], Masato Nakazawa[3], Mary DiGiorgi[4], Jonathan Slonin[5], Derek Jackson[6]
[1]Pacira Biosciences Inc., Arlington, MA, [2]Pacira BioSciences, Inc., Fuquay Varina, NC, [3]Pacira Biosciences, San Diego, CA, [4]Pacira Biosciences, Parsippany, NJ, [5]Pacira BioSciences, Inc., Tampa, [6]Pacira, Lexington, MA

Introduction: Gene therapy using viral vectors has potential to treat many diseases. However, vector immunogenicity could affect transduction, efficacy, safety, and durability, limiting successful gene therapy development. PCRX-201 (enekinragene inzadenovec), a novel high-capacity adenovirus serotype 5 (Ad5) vector carrying a transgene encoding for the inflammation-inducible expression of interleukin-1 receptor antagonist (IL-1Ra), is locally injected to the intra-articular (IA) joint space to treat osteoarthritis (OA) of the knee. In the open-label phase 1 trial (NCT04119687), PCRX-201 proved safe and beneficial in pain and function. Here we evaluate the role of clinical immunogenicity in safety, efficacy, and durability and its impact on PCRX-201 dosing and redosing strategy.

Methods: Patients aged 30-80 years (N=72) with painful OA of the index knee and Kellgren/Lawrence grade 2, 3, or 4 were eligible. The first cohort received IA injection of PCRX-201 (n=36) in the target knee at 1 of 3 doses (low: 1.4E10 genome copies [GC]; middle: 1.4E11 GC; high: 1.4E12 GC); the second cohort was pretreated with IA methylprednisolone 40 mg immediately before PCRX-201 administration (n=36) at the same doses. Western Ontario and McMaster Universities Osteoarthritis Index pain (WOMAC-A) and stiffness (WOMAC-B) scores were measured up to 104 weeks. Anti-Ad5 neutralizing antibody (NAb) titers in serum and synovial fluid (SF) and payload protein IL-1Ra levels in SF were measured up to 52 weeks.

Results: Preexisting serum or SF NAb did not affect PCRX-201 efficacy (Figure 1). There was no difference in pain or stiffness scores across NAb titers (serum: 0, 1-499, 500-5000, >5000; SF: ≤500, >500) (Figure 2). Serum NAb titers induced by PCRX-201 injection were highest at 4-12 weeks in both cohorts, and by 38-52 weeks, most serum NAb titers fell below the highest NAb titer observed in a PCRX-201 patient responder. Clinically observed NAb resolution rates to below maximal baseline thresholds highlight the possibility of redosing PCRX-201 at some defined point after initial IA injection. Pretreated patients receiving the middle and high doses showed faster reduction of serum induced NAb titer over time than those not pretreated, indicating that steroids lower the overall immune response to viral vectors. Additionally, a positive correlation between serum and SF NAb titers indicates that less invasively obtained serum can be used as a representative matrix for NAb measurement in the clinical setting. The most commonly reported adverse event (AE), treatment-related index knee effusion, occurred less frequently for participants in the pretreated (13/36; 36%) than the not pretreated cohort (22/36; 61%). Steroid pretreatment delayed effusion onset, indicating that effusion may be driven by immune activation. Because transgene expression is triggered by nuclear factor κB–inducible promoter, effusion-related immune activation may be quickly suppressed by IL-1Ra expression by PCRX-201. Effusion onset was earlier in the high- versus the lower dose groups, highlighting a positive correlation between dose and immune activation.

Conclusion: Preexisting NAb did not affect PCRX-201 efficacy or safety at all 3 doses, and steroids helped to reduce induced NAb titers and dose-related AE incidence. These results support the planned phase 2 study strategy of PCRX-201 with 10-fold lower dose (1.4E11 GC), steroid pretreatment, and potential for PCRX-201 redosing in future trials.

202 Suspension Cell Platform for the Production of Cocal-pseudotyped Lentiviral Vectors

Megha Gupta[1], Zach Burger[2], Hargis Logan[2], Hans-Peter Kiem[3]
[1]Fred Hutchinson Cancer Center, Issaquah, WA, [2]Fred Hutchinson Cancer Center, Seattle, [3]Fred Hutchinson Cancer Center, Seattle, Washington

Cocal-pseudotyped lentiviral vectors offer significant advantages for ex vivo engineering of hematopoietic stem cells (HSCs) and T cells, as well as in vivo gene delivery. Compared to their VSV-G counterparts, Cocal-pseudotyped vectors demonstrate broader species and cell tropism, enhanced serum stability, and reduced serum neutralization in patient samples. Furthermore, their significance in in vivo gene therapy is emphasized by the studies conducted by Hans-Peter Kiem's group and Umoja Biopharma in dog and NHP models, respectively, using Cocal-pseudotyped lentiviral vectors. However, therapeutic potential of viral vectors is often hindered by low-yield manufacturing processes.

As a proof of concept, we developed a robust and scalable suspension-cell platform to produce third-generation Cocal-pseudotyped lentiviruses. Using commercially available producer cells that grow in chemically defined serum free media, we optimized production conditions to enhance viral yield. 0.5ug of total plasmid DNA per million cells was used for PEI-mediated transfections, leading to reduction by 80% when compared with the total DNA that was used for vector production using adherent cells. A single harvest at 56 hours post-transfection, followed by concentration, yielded viral titers that were twice as high as those obtained from adherent producer cells. The suspension cells produced vector until passage 60-65 enabling 20 cycles of production, after which the cell viability started declining.

Transduction experiments revealed no evident cellular toxicity. Functional and physical titrations indicated a higher infectivity index for Cocal-pseudotyped lentiviral vectors compared to VSV-G equivalents. Notably, scaling up production from 20 mL to 200 mL cultures maintained both viral titers and infectivity.

These findings highlight the potential of this scalable suspension-cell platform to enable high-yield production of Cocal-pseudotyped lentiviral vectors, offering a viable solution for therapeutic applications in gene therapy.

203 Widespread AAV chimerism and other sources of noise confound multiplexed enhancer screening in brain

Cis-acting regulatory enhancer elements are valuable tools for gaining cell type-specific genetic access. Leveraging large chromatin accessibility atlases, putative enhancer sequences can be identified and deployed in adeno-associated virus (AAV) delivery platforms. However, a significant bottleneck in enhancer AAV discovery is charting their detailed expression patterns *in vivo*, a process that currently requires gold-standard one-by-one testing. Here we present a barcoded multiplex strategy for screening enhancer-AAVs at cell type resolution using single cell RNA sequencing and taxonomy mapping. We executed a proof-of-concept study using a small pool of validated enhancer AAVs expressing in a variety of neuronal and non-neuronal cell types across the mouse brain. Unexpectedly, we encountered substantial technical and biological noise including extensive chimeric packaging products (scrambled barcodes, from 37% to >60% of packaged molecules). We observed this AAV chimerism in

parallel lines of experimentation at two separate institutions. We found through dedicated barcode-swap experiments that this chimerism is sequence homology-dependent but capsid-independent. To circumvent these problems we developed novel techniques to accurately deconvolve enhancer-AAV expression patterns in brain. Overall these results underscore the need for carefully designed reporter architectures and improved noise mitigation strategies, and highlight the complexity of enhancer-AAV biology *in vivo*.

204 PACS1 Gene Integration and Clonal Expansion in HIV-1 Persistence: Insights from Longitudinal Analysis of HIV Patients

Introduction: HIV persistence is a major challenge in current HIV treatment. Despite the effectiveness of antiretroviral therapy (ART) in suppressing viral replication, HIV continues to persist in latent reservoirs within the host genome. Recent studies have shown that specific HIV integration sites are linked to clonal expansion and persistence of infected cells. These integration sites may confer a survival advantage to CD4+ T cells, allowing them to resist current treatments and persist indefinitely.

Methods: To investigate the impact of HIV integration on cellular persistence and clonal expansion, we use LAM-PCR (S-EPTS/LM-PCR) to analyzed integration sites in over 100 HIV patients from Germany and China. We mapped viral integration sites within the host genome and identified common integration sites (CIS). Our analysis focused on the PACS1 gene, which has been identified as a significant CIS for HIV-1 integration. We correlated our findings with clinical data to assess the impact of PACS1 integration on clonal expansion and cellular fate.

Results: Our analysis revealed several key findings: 1. PACS1 Gene as a CIS Hotspot: The PACS1 gene was identified as a significant hotspot for HIV-1 integration, with a high frequency of integration events. 2. Clonal Expansion and Cellular Fate: Cells with HIV-1 integration in the PACS1 gene were more likely to form dominant clones, suggesting that integration within PACS1 confers a selective advantage, promoting clonal expansion and potentially influencing cellular fate. 3. Temporal Dynamics of Integration: We observed a competitive interaction between integration sites in the PACS1 gene during the early and late stages of infection, indicating that the integration landscape evolves over time. 4. Validation with External Datasets: Our findings were validated using independent external datasets, confirming that PACS1 integration is associated with clonal dominance and supporting the link between PACS1 integration sites and clonal expansion. In conclusion, our study highlights the role of the PACS1 gene in HIV-1 integration and clonal expansion. Integration within PACS1 may influence cellular proliferation and survival, providing infected cells with an evolutionary advantage. This insight is crucial for understanding HIV persistence and developing strategies to target and eliminate latent reservoirs.

Novel Genetic Approaches for Muscle and Skeletal Diseases

205 Non-human primate muscle gene editing via single systemic AAV delivery of ultra-compact CRISPR nuclease

Renan Sper[1], Christopher Schmitt[1], Jason Li[1], Ning Chai[2], Winston Chang[1], Ngan Nguyen[1], Aashish Lamichhane[1], Danni Frimannsson[1], Clarissa Rhines[1], Julia Nussbacher[1], Matan Retwitzer[1], Aaron DeLoughery[1], Sara Ansaloni[2], Emel Alpay[1], Bridget Mckay[1], Sahana Somaiah[1], Maggie Bobbin[3], Megan Masnaguetti[1], Keith Abe[2], Gabor Veres[4], Bohong Zhang[2], Lucas Harrington[2], Subhadra Jayaraman[1], Benjamin Rauch[1]

In vivo therapeutic gene editing of muscle tissues holds great promise for the development of genetic medicines for a variety of genetically inherited muscle degenerative diseases including Duchenne Muscular Dystrophy (DMD), Myotonic Dystrophy Type 1, and Facioscapulohumeral Dystrophy, among others. The use of adeno-associated virus (AAV) represents a valuable option for gRNA and nuclease co-delivery in a clinical setting, considering various gene therapy clinical trials have demonstrated improved muscle function following systemic AAV transgene administration. However, the size constraints of AAV has limited its application for CRISPR-based gene editing. Here we describe a novel ultra-compact nuclease named NanoCas^{TM} and test its ability to edit muscle cells via single AAV delivery. To explore the editing capacity of the AAV-NanoCas, we targeted the human *DMD* locus. We developed a single AAV construct co-expressing gRNA and NanoCas, and designed 3 gRNAs targeting the splice acceptor and/or predicted premature stop codon of 3 different exons of the human *DMD* locus, and compared with single AAV saCas9 control. AAV particles were evaluated in vitro via myotube transduction, in vivo in a DMD mouse model, and in NHP. Human myotube transduction resulted in *DMD* editing levels ranging from 20 to 40%, while mice in vivo dosing led to editing in the heart, gastrocnemius, and quadriceps, ranging from 10 to 40% indel. AAVs were administered intravenously to male cynomolgus macaques. Muscle biopsy analysis was performed at 4 and 8 weeks and at 12-week necropsy. NGS analysis of multiple muscle tissues resulted in a broad range of indel activity, reaching as high as 46%, while liver editing remained low. In summary, we described an ultra-compact nuclease for in vivo therapeutic proof-of-concept and demonstrated significant in vitro activity in human myotubes, in vivo activity in mice, and in NHP. To our knowledge, this is the highest skeletal muscle editing demonstrated in NHP following systemic AAV delivery of any CRISPR nuclease. Importantly, the NanoCas gene is extremely compact, leaving ample space within the AAV design for additional regulatory elements and fusion proteins for things like RT and Epigenetic editing. NanoCas represents a valuable therapeutic nuclease for in vivo muscle editing via single AAV delivery.

206 Rescue of Full-Length Dystrophin Protein and Motor Performance in a Mouse Model of Duchenne Muscular Dystrophy Using an AAV-tRNA Therapeutic

Duchenne muscular dystrophy (DMD) is a fatal X-linked disorder caused by the absence of functional dystrophin, a large structural protein critical to the integrity of skeletal and cardiac muscle cells. DMD is characterized by progressive loss of muscle, respiratory insufficiency, and dilated cardiomyopathy. Existing therapeutic strategies are unable to restore full-length dystrophin due to the large size of the protein (427 kDa) and the diversity of unique mutations.

Nonsense mutations, in which a premature termination codon prevents translation of full-length dystrophin, are found in approximately 15% of patients with muscular dystrophy and are associated with more severe forms of the disorder. Suppressor tRNAs are tRNA molecules in which the anticodon has been altered to enable ribosomes to read through nonsense mutations and produce full-length, functional protein. Since there are only three premature termination codons (TGA, TAA and TAG), a limited number of suppressor tRNAs potentially allows for treatment of all DMD patients with nonsense mutations.

We have used the D2-mdx mouse model, which contains a nonsense mutation and recapitulates key aspects of DMD pathology in humans, to test whether a transgene encoding a suppressor tRNA delivered systemically using an Adeno-Associated Virus (AAV) vector can restore dystrophin protein and lost motor function. At 6 weeks post-dosing, we show that the muscles of treated animals express full-length dystrophin protein in a dose-dependent manner and that the rescued protein is organized in the stereotypical fashion of wild-type dystrophin protein. Additionally, we report that by 12 weeks post-dosing, there is significant restoration of motor function as demonstrated by an increase in latency time in the rotarod performance test and significantly increased forelimb and hindlimb grip strength. There is no evidence of adverse treatment effects as measured by behavioral or histologic changes in major organs or in blood chemistry.

To our knowledge, this study is the first demonstration of sustained restoration of full-length dystrophin accompanied by functional muscle improvement in an animal model of DMD using a practical therapeutic vector. In addition to being a potentially highly effective treatment for DMD patients with nonsense mutations, these results establish suppressor tRNAs as a viable therapeutic platform for a range of neuromuscular disorders and cardiomyopathies.

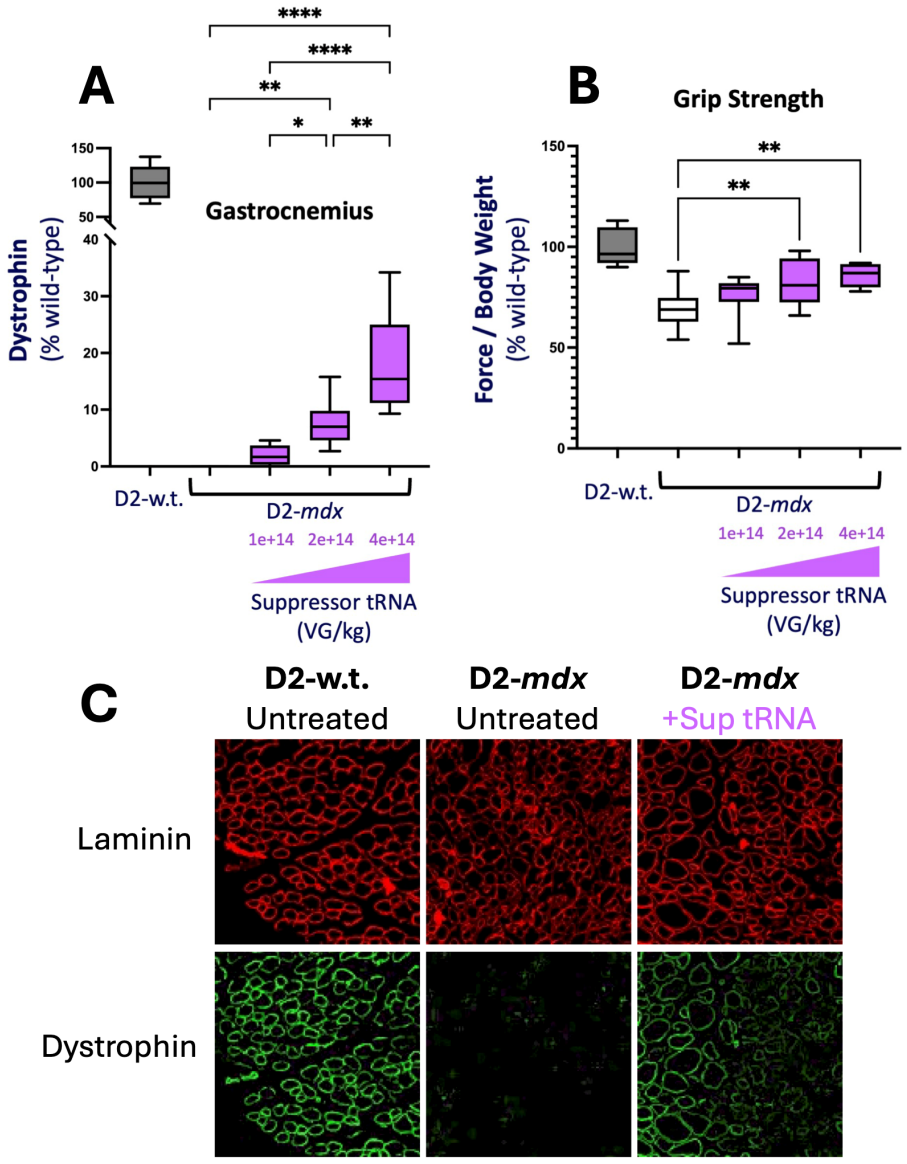

Figure 1. (A-B) Quantification of full-length Dystrophin as detected by western blot in gastrocnemius muscle **(A)** and grip strength **(B)** at 12 weeks post-injection (intravenous administration; indicated doses). **(C)** Immunohistochemistry for Laminin and Dystrophin in tibialis anterior muscle at 6 weeks post-injection (intramuscular administration; 1e+11 VG/muscle).

207 CRISPR-Cas9 Mediated Endogenous Utrophin Upregulation Improves Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is a progressive neuromuscular disorder caused by mutations in the *DMD* gene, leading to a loss of expression of the dystrophin protein. This induces inflammation, necrosis, fibrosis, and muscle wasting. There is currently no curative treatment for this devastating disease, which is lethal around the age of 20-30 years old. Several dystrophin-based therapies are currently under study such as exon-skipping, AAV-mediated delivery of mini/micro-dystrophin constructs or CRISPR-mediated editing strategies. However, these strategies propose to restore truncated forms of dystrophin, converting the phenotype to a Becker-like dystrophy, and might induce immune response to the newly expressed dystrophin. In addition, exon skipping and CRISPR correction are mutation-dependent, thus only subsets of patients could benefit from the treatment. An alternative therapeutic approach, potentially suitable to all DMD patients irrespective of their genetic defect, consists in upregulating utrophin (UTRN), a structural and functional paralogue of dystrophin, able to compensate for the dystrophin deficit. Several studies have shown that its overexpression ameliorates the dystrophic phenotype in mice and dogs with a lower risk of immune response. While a 1.5-fold increase of utrophin results in a therapeutic benefit, a 3-4-fold overexpression prevents the dystrophic pathology. Here, we developed a CRISPR-Cas9-mediated strategy to increase utrophin expression by relieving its repression. Previous work has shown that UTRN is post-transcriptionally downregulated by the Let-7c microRNA (miR) binding its 3' untranslated region (3'UTR). Using a Cas9/gRNA ribonucleoprotein complex we disrupted the binding site (BS) of this miR at the DNA level in human DMD and murine myoblasts to permanently upregulate utrophin. This induced a 3.5- and 3-fold increase of UTRN expression at the mRNA and protein levels, respectively. Results were confirmed in three-dimensional human DMD cultures, where Let-7c BS disruption resulted in over 2-fold UTRN upregulation and functional improvements of calcium intake and muscle contraction. In addition, we performed Guide-Seq analysis and didn't observe any major off-target editing for the selected gRNA. Finally, we evaluated this strategy in the mdx mouse model of Duchenne. Since some miRs are dysregulated in DMD, we first confirmed by qPCR that miR Let-7c expression is not affected in the tibialis anterior, diaphragm and heart of this model compared to the wild-type C57BL10J mice. We performed intravenous injection of two recombinant adeno-associated viruses type 9 (rAAV9s) encoding for Cas9 and gRNA. This resulted in levels of DNA editing in the tibialis anterior (13%), heart (21%) and diaphragm (5%) that were sufficient to upregulate UTRN expression by about 1.5-2-fold depending on the organs. Interestingly, this level of upregulation resulted in an amelioration of the muscle histopathological phenotype (centronucleation, necrosis, fibrosis). As genome editing efficiency remains limited, we are currently treating mdx mice with a more myotropic AAV, aiming to increase delivery and consequently, editing. Other gRNAs to increase UTRN expression - transcriptionally or post-transcriptionally- have also been designed and validated in human DMD myoblasts and are currently tested in 3D organoids. These findings provide the foundations for a universal gene editing therapeutic strategy for DMD.

208 Overexpressing Murine *Prg4* Isoforms with High-Capacity Adenoviral Vectors (HCAd) by Intra-Articular Injection Improves Articular Cartilage Preservation in a Murine Model of Post-Traumatic Osteoarthritis (PTOA)

Zelong Dou[1], Racel Cela[1], Philip Ng[1], Jiansen Yan[1], Ming-ming Jiang[2], Oscar Ruiz[2], Carolina Leynes[1], Camilla Majano[1], Matthew W Grol[3], Brian Dawson[4], Heidi Reesink[5], Nele Haelterman[1], Yangjin Bae[1], Brendan Lee[1]
[1]Baylor College of Medicine, Houston, TX, [2]Baylor College of Medicine, Houston, [3]Western University, London, [4]GQ Bio Therapeutics GmbH, Luckenwalde, Germany, [5]Cornell University, Ithaca, NY

Proteoglycan 4 (*Prg4*) acts as a chondroprotective agent within joint tissues, and its expression is altered in osteoarthritis (OA). This reduction makes intra-articular injections of exogenous PRG4 a promising treatment. Loss-of-function mutations in PRG4 in humans cause camptodactyly-arthropathy-coxa vara-pericarditis syndrome (OMIM #208250), which includes early onset OA. *Prg4* knockout mice also develop OA, consistent with its chondroprotective role. Our group previously demonstrated that using High-Capacity Adenovirus (HCAd) over expressing either *Prg4* or *IL-1Ra* via intra-articular (IA) injection preserved cartilage and delayed OA progression in both small (for both) and large (for *IL-1Ra*) preclinical models. These studies have paved the way for a current phase I clinical trial of HCAd-*IL-1Ra* gene therapy in OA patients (NCT04119687) and its recent designation as a Regenerative Medicine Advanced Therapy (RMAT) by the FDA.

However, the physiological roles of PRG4 isoforms across different tissues and their regulation under pathological conditions remain unclear, and different orientations of *Prg4* isoforms in HCAd vectors may affect *Prg4* transcription levels. Based on this and the role of hemopexin in limiting oxidative stress, binding of TIMPS, we hypothesize that the *Prg4* isoform containing the hemopexin-like domain may contribute to joint preservation.

The murine isoforms packaged into HCAd include a truncated C-terminal murine PRG4, primarily containing the hemopexin-like domain (*EF1-mPrg4-999*), and a longer PRG4 isoform that also comprises the full Mucin and Somatomedin B (SMB) domains (*EF1-mPrg4-3276*), both in -1 or -2 orientations. The orientation "-1" is used when the 5' to 3' orientation of inserted transgene is toward the ITR of HCAd, and orientation "-2" is used when 5' to 3' orientation of inserted transgene is directed away from the ITR. Meanwhile, HCAd0 (a control virus without transgenes), PBS, and the NFkB-responsive murine IL-1Ra HCAd were utilized as experimental negative and positive controls. Bilateral destabilization of the medial meniscal tibial ligament (DMM) surgery was performed to induce murine post-traumatic osteoarthritis (PTOA). Two weeks postoperatively, the above HCAds and PBS were administered via intra-articular injection of the knee joint. Twelve weeks postoperatively, we harvested both knee joints for 2D histological analysis, 3D phase contrast micro-CT analysis, and immunohistochemical staining using F4/80 and CD206 to differentiate the total and M2 macrophage populations.

Employing 3D phase contrast micro-CT scanning, we observed that *in vivo* administration of HCAd-*EF1-mPrg4-999-2* significantly attenuated cartilage volume loss during OA progression compared to HCAd0 and PBS control groups. Additionally, HCAd-*EF1-mPrg4-3276-1* administration notably preserved cartilage-covered bone surface compared to PBS control, achieving results comparable to HCAd-*mIL-1Ra* injection. We are evaluating cellular changes and immune cell infiltration using Safranin-O staining, H&E staining, and immunohistochemical analysis of F4/80 and CD206 to understand the therapeutic effects of these PRG4 isoforms on chondroprotection and inflammation.

In these studies, we demonstrated a novel chondroprotective effect of the hemopexin-like carboxy-terminal domain of PRG4 in the context of PTOA. The data suggest that different components of the PRG4 protein may contribute to diverse activities in mediating chondroprotection.

209 A Prenatal Gene Editing Approach to Congenital Musculoskeletal Disease with Systemically Delivered Lipid Nanoparticles

Introduction.
Congenital musculoskeletal disorders, including Duchenne muscular dystrophy (DMD), represent an opportunity for gene therapy. Lipid nanoparticles (LNP) represent a promising alternative to viral vectors for systemic administration, though achieving robust skeletal muscle delivery remains challenging. We aimed to evaluate both the muscle transduction potential of LNPs and the efficiency of CRISPR-Cas9 adenine base editing (ABE) at a therapeutic target for exon-skipping in the dystrophin gene, both in adult mice and *in utero.*

Methods.
CAG-Sun1/sfGFP (Sun1GFP) mice with floxed nuclear-localized green fluorescent protein (GFP) were injected with LNPs bearing different ionizable lipids (LNP1, LNP2) encapsulating Cre mRNA which drives nuclear GFP expression in successfully transduced cells. Mice received 1.5 mg/kg IV injections at gestational day 14 (E14) or 16 (E16) via the vitelline vein, or at 8 weeks of age via the retroorbital sinus. Quadriceps and diaphragm were harvested at 4 weeks of life (E14, E16) or 4 weeks post-injection (adults) and underwent nuclear extraction and fixation, followed by antibody staining for myonuclear (PCM1+) and muscle stem cell (PAX7+) markers. Fluorescence-activated nuclear sorting (FANS) quantified GFP+ fractions for each tissue and cell type. To assess *in vivo* base editing efficiency in skeletal muscle, adenine base editor mRNA and nucleoside-optimized guide RNA targeting the exon 45 splice acceptor site of the dystrophin gene were encapsulated within an LNP from prior Sun1GFP studies and injected into E14 and adult BALB/c mice at 2mg/kg or 3mg/kg and later harvested at similar time points. In addition to sequencing whole tissue DNA, muscle tissue underwent FANS protocol with nuclear sorting into myocyte nuclear fractions, followed by DNA recovery and sequencing to assess myocyte-specific base editing efficiency.

Results.
Efficient transduction of Sun1GFP myocytes and muscle stem cells were observed with *in utero* LNP injections, but not following adult injections. Up to 90% of quadricep myocytes and stem cell nuclei expressed GFP after E14 and E16 injections with both LNP formulations. In the diaphragm, myocyte transduction was similarly efficient; however, decreasing muscle stem cell transduction was seen from E14 to E16 (LNP1: 72% vs 56%; LNP2: 75% vs 43%). LNP2 was chosen for base editing studies. Next generation sequencing at the dystrophin exon 45 locus demonstrated efficient on-target adenine-to-guanine conversion in both E14 and adult livers. *In utero* LNP administration increased skeletal muscle editing compared to adult administration in the diaphragm and quadriceps. Importantly, significant on-target base editing was achieved specifically in myocyte nuclei in the diaphragm and quadricep after in utero LNP injections.

Conclusion.
In utero systemically administered LNPs can transduce skeletal myocytes and stem cells throughout the body, and base editing of the diaphragm and skeletal muscles via LNPs is more efficient when administered prenatally. Most importantly, however, as data suggest only a minority of dystrophin loci need to be corrected in skeletal muscle to be clinically therapeutic, we herein present data that suggest we can leverage systemically administered LNPs to deliver base editing constructs to skeletal and diaphragm myocytes in doses that may be sufficient to treat DMD, and potentially other congenital myopathies, prior to birth.

210 AAVrh74.tMCK.hBAG3 Gene Therapy Improves Phenotype in a Hereditary IBM Model, VCP-A232E Mouse

Burcak Ozes[1], Lingying Tong[2], Kyle Moss[3], Morgan Myers[3], Edward Son[3], Tatyana Vetter[3], Zarife Sahenk[3]
[1]Nationwide Childrens Hospital, Columbus, Ohio, [2]Nationwide Children's Hospital, Dublin, OH, [3]Nationwide Children's Hospital, Columbus, OH

Introduction:
Sporadic inclusion body myositis (sIBM) is the most common acquired myopathy in older adults. sIBM is characterized by chronic progressive weakness and its pathology involves an interplay between inflammatory and degenerative pathways. Histopathology indicates mitochondrial abnormalities and protein accumulation. Mutations in the valosin-containing protein (VCP) gene leads to a hereditary type of IBM (hIBM), in which sarcoplasmic and myonuclear inclusions with TDP-43 pathology are observed. Pathophysiological conditions in the cell cause the protein quality control system to depend on the autophagy-lysosome pathway (ALP) for degradation of accumulated misfolded proteins. BCL2-associated athanogene 3 (BAG3) protein enables aggresome formation and initiates the ALP.

Aim:
We aim to ameliorate disease process resulting from misfolded protein aggregation by upregulating the ALP. We

assessed our strategy of reducing the aggregate burden in the muscle by overexpressing the BAG3 in the VCP-A232E mouse, a model for hIBM.

Methods:
Seven male VCP mice received $3x10^{12}$ vg total dose of AAVrh74.tMCK.hBAG3 via tail vein injection at three months of age and eleven sex- and aged-matched VCP mice served as untreated (UT) controls. Mice were tested on rotarod and treadmill at the experimental endpoint, nine months post gene delivery. The other outcome measures conducted were quantitative muscle histopathology and morphometry assessing the amount of TDP-43 accumulation, as well as expression levels of autophagy markers.

Results:
BAG3 treatment resulted in functional improvements; 35% greater distance run on the treadmill (BAG3: 70.0 ± 4.4 vs UT: 51.7 ± 4.6 m, p=0.015) and 46% better performance in the rotarod (BAG3: 32.3 ± 2.5 s vs UT: 22.1 ± 2.1 s, p=0.007) at the endpoint compared to untreated mice. To assess the efficacy of AAV.hBAG3 gene therapy in treating abnormal mitochondrial content and distribution, we quantified abnormal muscle fibers in gastrocnemius (GAS) and tibialis anterior (TA) muscles, demonstrating that the BAG3 treatment lead to a significantly smaller number of abnormal fibers in both muscles (GAS, BAG3: 13.6 ± 2.6 vs UT: 29.4 ± 4.8 number/mm^2, p=0.034; TA, BAG3: 7.0 ± 2.1 vs UT: 20.0 ± 3.5 number/mm^2, p=0.010). Our quantifications in TA muscle samples also showed a significant decrease in the number of fibers with internal nuclei following BAG3 gene therapy. Muscle fiber analysis on SDH-stained samples revealed that BAG3 gene therapy in VCP mice caused a significant increase in the size of fast-twitch fibers in both muscles analyzed. We utilized immunofluorescence staining to assess the TDP-43 accumulation levels in VCP mice and we observed a significant decrease in the number of TDP-43-positive aggregates in the treated muscle samples (BAG3: 191.7 ± 20.6 vs UT: 261.0 ± 21.1 aggregate/mm^2, p=0.037). These observations were associated with significantly increased autophagy markers, p62 and LC3 on western blots of muscle samples from the BAG3 treated cohort, compared to UT counterparts.

Conclusion:
Systemic delivery of AAVrh74.tMCK.BAG3 at $3x10^{12}$ vg in VCP-A232E mouse model for hIBM resulted in significant improvements in functional, histopathological, and molecular analyses, compared to UT cohort. Our strategy of supporting ALP system by overexpressing BAG3, has potential therapeutic use for other myodegenerative conditions associated with abnormal protein aggregates.

211 Identifying Adeno-Associated Virus Serotypes that Transduce Fibro-Adipogenic Progenitors in Mouse Healthy and Fibrotic Skeletal Muscles *In Vivo*

Fady Guirguis[1]*, Veronique Bolduc[2], Astrid Brull[3], Huachun Liu[4], Jay Chiorini[5], Nerea Zabaleta[6], Luk Vandenberghe[7], Haiyan Zhou[8], Francesco Muntoni, Carsten Bonnemann[9]

**Corresponding Author*

The skeletal muscles extracellular matrix (ECM) serves multiple critical functions to maintain skeletal muscles' health. In most myopathies and dystrophies, the ECM undergoes maladaptive fibrotic changes due to the excessive production of dysfunctional ECM. These changes become major contributors to the pathogenesis and progression of various disorders affecting muscle. In addition, some muscular dystrophies are caused directly by pathogenic variants in the genes encoding skeletal muscles ECM proteins. One of those proteins is collagen VI, and pathogenic variants in its coding genes cause collagen VI-related dystrophies (COL6-RDs).

Fibro-adipogenic progenitors (FAPs) are one of the major cell types that produce ECM proteins in skeletal muscles. To date, no delivery vector has been shown to transduce skeletal muscles FAPs via systemic injection *in vivo*. This has markedly contributed to the current absence of effective gene therapies for many of the myopathies caused by ECM pathogenic variants and dysregulated ECM production.

Here, we screened 9 clinically relevant naturally occurring adeno-associated virus (AAV) serotypes to identify AAVs capable of transducing mouse skeletal muscles FAPs efficiently and selectively *in vivo*.

We intravenously (IV) injected 7-9-week-old Cre/FAPs reporter male mice (Ai14;PDGFRα^{EGFP}) with each serotype at 1.5x10^{12} vector genomes (VGs)/mouse (n=3/serotype). Tissues were collected 4 weeks post-injection, and the percentage of transduced cells was quantified using fluorescence-activated cell sorting.

We assessed the 9 AAVs' efficiencies at transducing FAPs and non-FAPs in skeletal muscles and the liver. We identified a serotype that was significantly more efficient at transducing FAPs in both tissues than most serotypes, while its transduction of non-FAPs was no different from the majority of the other serotypes. These results suggest this serotype has a selectively greater transduction efficiency towards FAPs in different tissues compared to other serotypes. Besides the top-performing serotype, we identified 3 moderate FAP-transducing serotypes that were significantly more efficient at transducing muscle FAPs than the remaining 5 poor-performing serotypes.

We are currently quantifying the number of VGs per diploid genome, further characterizing the serotypes' biodistribution, and identifying the AAV capsid motifs specific to the top-performing serotypes to inform rationally designing potentially more efficient and selective FAPs-targeting capsids. Additionally, we are in the process of assessing the efficiency of the top-performing serotypes at transducing FAPs in male and female fibrotic skeletal muscles of a COL6-RDs mouse model. Once confirmed in the COL6-RDs mouse model, the top-performing serotypes will be further validated in human *in vitro* cellular models.

Lipid Nanoparticles I

212 Discovery of peptides for targeted delivery of mRNA lipid nanoparticles to cystic fibrosis lung epithelia

Cystic fibrosis (CF) is a genetic disease affiliated with hyperconcentrated mucus that lines the epithelia of multiple organs. In the lungs, this mucosal abnormality is the main cause for morbidity and mortality for CF patients, leading researchers to focus their attention on genetic correction in the airways. Non-viral approaches to gene therapy have shown clinical promise; however, the thick mucus barrier found in CF afflicted lungs remains a significant challenge for cell uptake of the carrier and thus the therapeutic cargo. Given this obstacle, we were encouraged to develop a phage display selection method to identify a mucus and cell penetrating peptide that could overcome this delivery barrier and be used in the context of a non-viral delivery system (i.e., lipid nanoparticles) to deliver mRNA. In this work, we used primary human bronchial epithelial cells from CF patients cultured at air-liquid interface for our selection model. At the air-liquid interface, primary human bronchial epithelial cells produce mucus and differentiate into multiple cell types, making it clinically relevant. With this method, we discovered a lead candidate peptide and incorporated it into lipid nanoparticles to deliver mRNA to primary human bronchial epithelia *in vitro* and mouse lungs *in vivo*. Compared to lipid nanoparticles without our peptide, peptide-lipid nanoparticles demonstrated up to 7.8-fold and 3.4-fold higher reporter luciferase bioactivity *in vitro* and *in vivo*, respectively. Importantly, these peptides facilitated higher specific uptake of nanoparticles into lung epithelia relative to other nontarget cell types. Since nucleic acid delivery to primary human bronchial epithelia is a significant challenge, we are encouraged by these results and anticipate that our peptide could be used to successfully deliver cystic fibrosis gene therapies in future work.

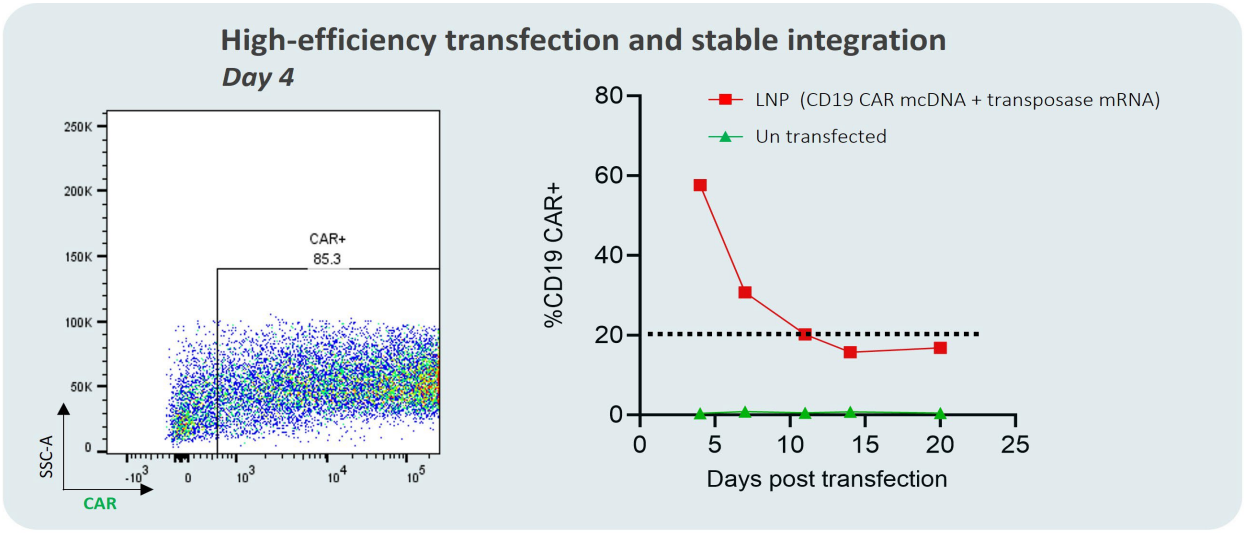
The engineering of immune cells to express Chimeric Antigen Receptors (CARs) has revolutionized cancer treatment, with ex vivo CAR-T therapies achieving significant clinical and commercial success. However, these therapies come with major limitations, including high costs, lengthy manufacturing processes, potential toxicity, and logistical challenges associated with patient-specific cell production. These constraints emphasize the need for next-generation approaches to improve accessibility and efficiency.

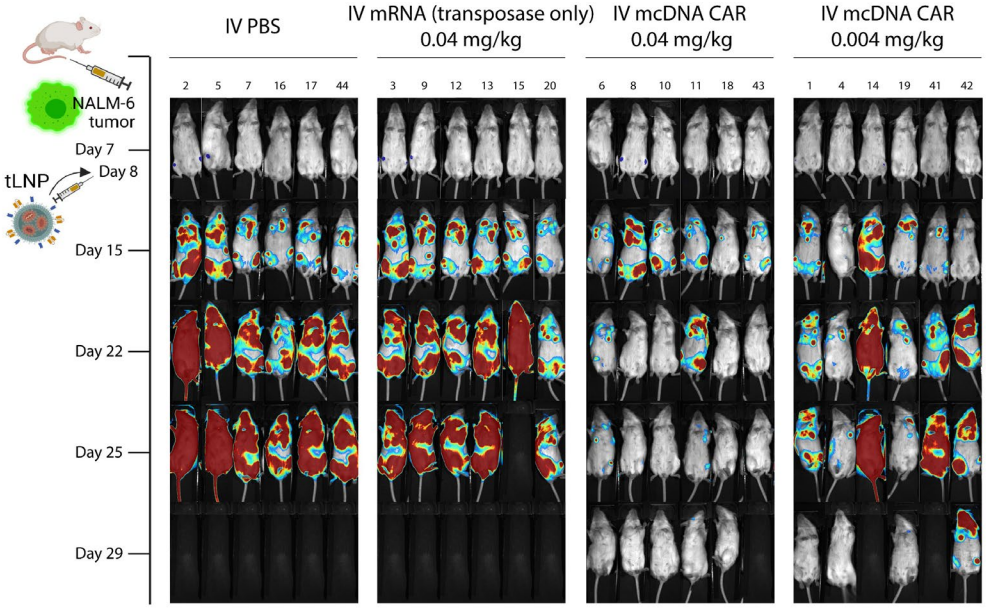
We present an innovative cell-targeted lipid nanoparticle (tLNP) platform designed to deliver both DNA and RNA directly to T cells, enabling in situ CAR-T cell generation (Fig. 1). This tLNP system consists of lipid nanoparticles carrying transposon DNA (encoding CAR), mRNA (encoding transposase), and targeting/activating protein

components. We demonstrate that this approach can activate resting primary T cells and facilitate stable CAR expression without requiring traditional ex vivo expansion or external activation steps.

Beyond in vitro modification, we show that this non-viral vector drives functional CAR-T cell generation in vivo. We would like to present and discuss our latest data demonstrating successful generation of CAR T in an NSG mouse model injected with a human B-cell leukemia cell line. We will discuss that a single dose of tLNP (carrying DNA/RNA) results in durable CAR-T cell generation, tumor control, and prolonged survival (Fig. 2).

By shifting CAR-T engineering from a labor-intensive, facility-dependent process to a streamlined, in vivo approach, this platform has the potential to overcome critical barriers in cell therapy, making CAR-T treatments more scalable, cost-effective, and widely accessible.





214 Lipid Nanoparticle-Mediated CRISPR-based Therapy Enables Mutation-Agnostic Gene Editing Solving for Autosomal Dominant Polycystic Kidney Disease

Poulami Chaudhuri[1], Neha Gaur[2], Harsha Rohira[3], Rakesh Kappagantu[3], Yugantak Raj Gupta[3], Gayathri Sembara[4], Naveen Kumar Dhondi[4], Rohini Kalvakuntla[1], Anirudh Nishtala[5]

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is a prevalent hereditary disorder caused by mutations in the *PKD1* (85%) or *PKD2* (13%) genes, which encode polycystin-1 and polycystin-2, respectively. This condition leads to the formation of fluid-filled renal cysts, often resulting in end-stage renal disease (ESRD). Restoring *PKD1/PKD2* expression in preclinical models has shown potential to attenuate and reverse cystogenesis. To address the broad mutation heterogeneity in *PKD1*, with over 800 pathogenic variants, we have developed a mutation-agnostic strategy for modulating certain regulatory elements that impact *PKD1* expression.

Helex's proprietary kidney-tropic lipid nanoparticle (LNP) platform addresses the delivery challenge for gene editing in kidney cells. Tail vein administration of LNPs in BALB/c mice demonstrated significant kidney tropism, confirmed via *in vivo* and *ex vivo* biodistribution studies. Using our proprietary ionizable lipid, the LNP achieved even biodistribution between the kidney and liver, reducing off-target liver accumulation by 100 times compared to commercial lipid-based formulations. Renal artery (RA) injection further enhanced kidney tropism, achieving ~50 times higher kidney accumulation than intravenous delivery and with minimal to nil off-target biodistribution in other organs.

In ADPKD patient-derived kidney cell lines, LNP-delivered CRISPR-Cas9 successfully edited the regulatory target, leading to a four-fold increase in *PKD1* mRNA levels. This was accompanied by increased polycystin-1 expression and modulation of downstream cystic pathways, including pCREB, PKA-C, and mTOR pathways confirmed by RT-PCR and western blotting. The proprietary LNP demonstrated a significantly improved safety profile compared to formulations using commercial lipids, supporting its suitability for therapeutic translation.

By integrating a kidney-tropic LNP platform with Helex's Epic-Cure™ drug design framework, this mutation-agnostic approach offers a transformative strategy for ADPKD. Beyond halting disease progression, it holds promise for reversing the disease phenotype, presenting a significant advancement over existing symptomatic treatments.

215 Rational Design and Preclinical Applications of Long Circulating Lipid Nanoparticles (lcLNPs) for Extra Hepatic Delivery of Nucleic Acids

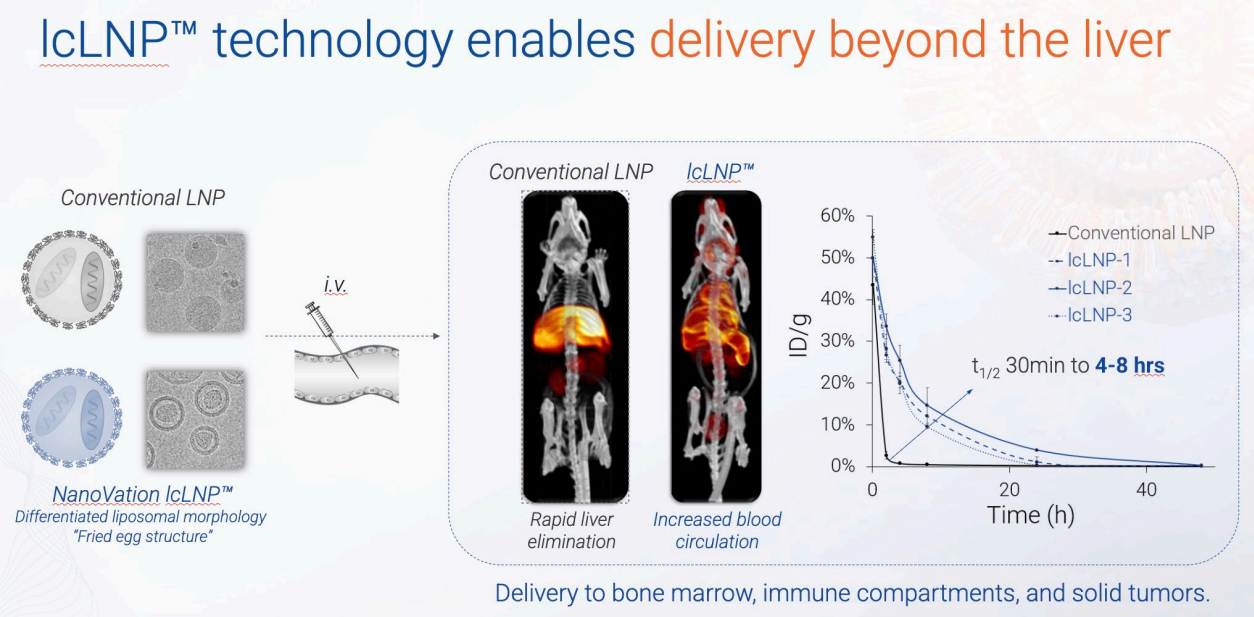
Historically, the potential for gene therapies has been limited due to the delivery. The most conventional approach includes the use of modified viruses that offer long lasting impact following single dose administration. However, they do suffer from safety issues, adaptive immune responses, lower packaging capacity and poor manufacturing scalability. Non-viral drug delivery systems, however, when designed appropriately can overcome these limitations and offer more access to gene therapies. Lipid nanoparticles have already enabled successful delivery and manipulation of targets in the liver as demonstrated by the first ever approved RNAi therapeutic, Onpattro. This composition comprising of ionizable lipids, phosphatidylcholine, cholesterol and PEG-lipid (50/10/38.5/1.5 mol%, respectively) was able to deliver the paylod (SiRNA) into the cytosol of hepatocytes. Onpattro was designed to accumulated rapidly in the liver following intravenous administration, which made the extrahepatic tissues inaccessible. Various solutions have been implemented to overcome rapid liver accumulation including PEGylation (persistent PEG-lipid), particle surface modification including ligands and charged lipids. However, they all face limitations in their clinical utility due to adaptive immune responses, acute immune stimulations and manufacturing complications.

Inspired by the development of long-circulating liposomes for small molecule therapeutics, we rationally designed a novel set of LNP formulations to deliver nucleic acids to extrahepatic tissues by extending the circulation half-life of the nanoparticles.Firstly, we demonstrated that formulations with elevated distearoylphosphatidylcholine (DSPC) displayed extended circulation profiles that was five-fold greater than benchmark LNPs, and they exhibited a substantially different morphology. Next, we were able to demonstrate that these unique and novel long circulating LNP systems (lcLNPs) can deliver multiple nucleic acid payloads including mRNA, SiRNA to target tissues of interest including abdominal skin. Furthermore, we demonstrated that optimizing the lcLNP compositions and ionizable lipids resulted in a 300-fold increase in mRNA expression in the abdominal skin when compared to conventional LNP compositions. We also saw a similar increase in mRNA expression in the long-term hematopoietic stem cells in the bone marrow, monocytes in circulation and splenic T-cells.

Our findings demonstrate that changing LNP compositions alone can modulate LNP tissue accumulation negating the need to add additional components to LNPs. This further supports the hypothesis that extrahepatic delivery can be achieved by extending circulation profiles of LNPs.



216 Enhancing Liver DNA Delivery with a Fully Non-Viral Multifunctional LNP Approach for In Vivo Transposon-Mediated Genomic Integration of Large DNA Cargo

Johannes Schwerk[1], Hua Wang[1], Mauricio Barajas-Mora[2], Nicholas Cam[2], James Yen[2], Lijun Huang[1], Gopi Nath Vemuri[1], Alicia Davis[1], Khalid Hajj[1], Sang Lee, Johnnatan Tamayo[2], Fernando Lopez Espinoza[2], Cindy Negron[1], Matthew Nitzahn[1], Arturo Barcenas[2], Mu Li[1], Bonnie Jacques[1], Michael Bennett[1], Joshua Rychak[1], Blair Madison[1]

Integrating DNA into a patient's genome holds great promise for treating genetic diseases by restoring function through gene addition. The Super piggyBac (SPB) DNA integration system can achieve genome integration of large cargo up to 200 kb without inducing double-strand DNA (dsDNA) breaks. A non-viral delivery platform capable of delivering transposon DNA and the transposase enzyme could enable repeat dosing for titratable gene addition.

To enable cellular delivery of dsDNA, we developed an LNP format incorporating an ionizable lipid and a novel non-lipid intracellular trafficking agent (ICTA). ICTAs are amphipathic organic compounds that enhance encapsulation and release of complex genetic payloads like pDNA. First-generation ICTAs improved delivery but led to aggregation and poor storage stability. A second-generation ICTA series was synthesized and screened in mice to elucidate structure-activity relationships for liver DNA delivery. Several ICTAs enabled LNPs with a 60-

130 nm size distribution (depending on ICTA and loading ratio), facilitating cellular uptake and passage through liver sinusoids. ICTAs provided a 10-fold increase in luciferase reporter transgene expression and improved delivery of phenylalanine hydroxylase and hFVIII transgenes by 3-5-fold in adult and juvenile mice. ICTA LNPs achieved therapeutically relevant protein levels, with PAH protein in >10% of hepatocytes and hFVIII exceeding 100% normal plasma levels, as determined by ELISA 6 days post-administration.

Uptake of DNA-carrying LNPs by innate immune cells can trigger pro-inflammatory cytokine secretion, activating cell death pathways in adjacent cells. We explored a strategy to neutralize inflammation and promote cell survival using transient expression of chimeric cytokine transmembrane receptors, where an intracellular pro-survival RTK domain was paired with an extracellular pro-inflammatory cytokine receptor. Adult mice given 1 mg/kg LNPs co-encapsulating transgene donor DNA and mRNA for these receptors showed up to a 60% reduction in serum MCP-1 at 4 hours and a 50% reduction in liver transaminases at 24 hours, compared to control mRNA LNPs. Transgene expression remained robust 6 days post-administration.

The ability to fine-tune transgene expression would enable patient-tailored treatment, crucial for clotting disorders. To achieve this, we tested an inducible iCasp9 “modulator switch” in our transposon, allowing the reduction of hFVIII levels via an inducer molecule. This modulator, linked via T2A in our FVIII transposon, was co-encapsulated with SPB mRNA in an LNP. Adult wild-type mice received a single intravenous LNP dose, achieving ~75% normal hFVIII levels by day 6. Subsequent IV doses of rimiducid (0.001–1.0 mg/kg) reduced hFVIII to between 31% and ~1% of normal, dose-dependently, with no hepatotoxicity.

The non-viral platform presented here may enable a safer, tunable, and durable solution for genetic medicines with broad applicability for rare and non-rare diseases.

217 Pharmacodynamic Activity, Pharmacokinetics and Tolerability of Lipid Nanoparticle Formulations of mRNA Following Repeated Intravenous Dosing in Monkeys

With the increasing adoption of lipid nanoparticle (LNP) technology in the development of nucleic acid-based therapeutics, particularly in the areas of gene editing and gene modulation, there is an increasing need for a detailed understanding of factors influencing LNP activity, pharmacokinetics (PK), and tolerability, to continue to rationally improve the therapeutic index of LNP systems and to support their development as therapeutics. To investigate these, we have evaluated the activity, plasma PK profiles and tolerability of three different LNP formulations in cynomolgus monkeys, using two different mRNA payloads. LNP were administered at 0.5 or 1.5 mg/kg by 1-hour intravenous (IV) infusions, once per month for three months. Pharmacodynamic activity was quantified by measuring levels of human IgG (ELISA) or alpha-galactosidase (LC-MS/MS) encoded by the encapsulated mRNAs; plasma PK profiles of ionizable lipid and PEG-lipid concentrations were measured by LC-MS/MS; and mRNA-LNP tolerability was assessed via standard clinical pathology endpoints, multiplex assays for cytokines (MSD), ELISA/EIA methods for complement and anti-PEG antibodies, and histopathology. Distinct pharmacodynamic activity profiles were observed in monkeys for the three different LNP compositions evaluated, based on differences in the ionizable lipids and payloads (mRNA), but the pattern of response did not change with repeat dosing. PK analysis of the three LNP revealed distinct plasma PK profiles and relatively large differences (~13-fold) in plasma exposure of the ionizable lipids; however, the PK profile and plasma exposure of the PEG-lipid was independent of the LNP and was the same for each LNP evaluated, consistent with rapid exchange out of the LNP in the circulation. PK profiles of the three LNP were unaffected by different payloads and repeated dosing. The substitution of a different mRNA into the same LNP composition resulted in overlapping PK profiles, and repeated monthly infusions did not alter plasma exposure. Changes in clinical pathology parameters, including increases in liver enzyme levels (ALT/AST), were observed to be dose-related and transient (peaking 48 hours after dosing). Differences in the magnitude of ALT changes were observed with different payloads, indicating a payload effect,

while peak ALT levels were consistent on each dosing occasion with repeated dosing of the same payload. Cytokine/chemokine levels were transient, generally peaking at 6 hours post-dose, and peak levels remained consistent with repeated dosing of the same payload. Despite the relatively large difference in plasma exposure between three LNP, the profile of histopathology findings and the target organs were the same: liver (vacuolation, single-cell necrosis and/or swelling of hepatocytes; mixed leukocyte infiltration), spleen (vacuolation and/or hypocellularity in red pulp; lymphoid depletion) and adrenal glands (lipid depletion in the cortex). Overall, these results provide a comprehensive characterization of the activity, PK and tolerability of different LNP in monkeys, following repeated monthly infusions. Each of the LNP were well tolerated, resulting in non-adverse, transient, predictable and reversible changes in clinical pathology (e.g., ALT/AST) parameters and histopathology findings, indicating that repeat dosing of mRNA-LNP is feasible and safe.

218 Modulation of Lipid Nanoparticle-Formulated Plasmid DNA Drives Innate Immune Activation Promoting Adaptive Immunity

Nucleic acid vaccines have grown in importance over the past several years, with the development of new approaches remaining a focus. We describe a lipid nanoparticle-formulated DNA (DNA-LNP) formulation which induces robust innate and adaptive immunity with similar serological potency to mRNA-LNPs and adjuvanted protein. Using an influenza virus hemagglutinin-encoding construct (HA), we show that these DNA-LNPs drive potent inflammation dependent on the cGAS-STING-TBK1 pathway but independent of TLR9. Priming with HA DNA-LNP demonstrated strong upregulation and activation in migratory DC (mDC) subpopulations, and these changes were STING-dependent. Transcriptomics elucidated activation and upregulation of pro-migration factors among multiple innate immune populations after priming with DNA-LNP. Relative to mRNA-LNPs or adjuvanted protein, HA DNA-LNP induced superior antigen-specific CD8+ T cell responses with memory responses persisting beyond one year. In rabbits immunized with HA DNA-LNP, we observed immune responses comparable or superior to mRNA-LNPs at the same dose. Using an additional pathogen model, SARS-CoV-2 spike-encoding DNA-LNPs elicited protective efficacy comparable to spike mRNA-LNPs. Our study identifies a platform-specific priming mechanism for DNA-LNPs divergent from mRNA-LNPs or adjuvanted protein, suggesting avenues for this approach in prophylactic and therapeutic vaccine development.

Novel Therapeutic Gene Editing Applications

219 Efficient Cas9 LNP Mediated Repair of a Pathogenic *TCAP* Mutation in Skeletal Muscle

Maine, Bar Harbor, ME, [6]University of Massachusetts Chan Medical School, [7]The Jackson Laboratory, Bar Harbor, [8]UT Southwestern Medical Center, Dallas, [9]UMass Chan Medical School, Worcester, Massachusetts

Pathogenic insertion and deletion (InDel) mutations that result in loss of protein expression account for the vast majority of debilitating neuromuscular diseases, such as Duchenne Muscular Dystrophy (DMD) and Limb Girdle Muscular Dystrophy (LGMD), for which few therapeutic options exist. Gene editing-based therapeutics hold promise for a cure for monogenic neuromuscular diseases by repairing the disease-associated mutations. Nuclease-based gene editing is among the simplest and most effective approaches to modify the genome of a target cell population in vivo. Delivery of Cas9 nuclease and a single guide RNA creates a double-strand break (DSB) at its target site, which is precisely or imprecisely repaired by the endogenous DNA damage repair machinery. In proliferating cells, the InDel distribution resulting from imprecise repair is predictable based on the local sequence context and can be dominated by a single allele (e.g. Non Homologous End Joining (NHEJ)-mediated 1 bp insertion or Microhomology-mediated end joining (MMEJ) deletion). These dominant repair outcomes can be leveraged to restore a disrupted reading frame within a gene caused by a pathogenic mutation. In addition, MMEJ-based deletions can correct pathogenic insertion mutations consisting of a short stretch of duplicated sequence (microduplication), but the efficiency of MMEJ-based DSB repair in post-mitotic skeletal muscle has not been extensively characterized.

We examined a nuclease-based strategy for therapeutic correction of an 8bp microduplication mutation in the skeletal muscle gene, TCAP. Biallelic loss of function mutations in TCAP result in LGMDR7. We performed in vivo editing by delivering Cas9 mRNA or ribonucleoprotein (RNP) complexes intramuscularly in an LGMDR7 mouse model containing the humanized TCAP 8 bp microduplication. We have previously shown that this microduplication mutation can be efficiently corrected via MMEJ repair in proliferating cells.[1] We employed a Selective ORgan Targeting (SORT) LNP formulation that facilitates the local delivery of Cas9 mRNA or RNP to skeletal muscle.[2] We compared Cas9 editing outcomes at two target sites for Cas9 mRNA or RNP when employing end modified or heavily modified sgRNAs. Our best LNP-Cas9 formulation achieved local editing rates >30%. In addition, LNP size impacted the distribution of editing throughout different muscle groups in the hindlimb for Tibialis Anterior (TA) injection. Cas9 editing restored expression and proper sarcomere localization of Telethonin (encoded by TCAP) heterogeneously throughout the injected TA. Interestingly, indel distributions at the target site differ between LGMDR7 patient-derived induced Myoblasts in vitro and mouse skeletal muscle in vivo, which can be attributed to differences in the active DNA repair pathways in post-mitotic cells. We also evaluated the temporal cytokine, humoral and cellular immune responses associated with LNP Cas9-mRNA and RNP delivery to understand their potential impact on editing outcomes and persistence. These studies revealed differences in the host response between the two different Cas9 effector modalities. Our findings yield important insights into in vivo editing outcomes, LNP distribution and immune response in skeletal muscle that will be beneficial for developing effective gene editing technologies for a variety of muscular dystrophies.

220 Brain-wide Genome Editing via STEP-RNPs for Treatment of Angelman Syndrome

Xiaona Lu[1], Ying xie[2], Youmei Bao[2], Jiang Yu[2], Zefeng Wang[2], Jiali Fan[2], Wendy Sheu[2], Gretchen Long[2], Zewei Tu[2], Binfan Chen[2], Zhouqi Meng[2], Ying-hong Ma[1], Caihong Qiu[1], Bony Kumar[1], Caroline Hendry[1], Jiangbin Zhou[2], Yong-hui Jiang[1]*
[1]Yale University School of Medicine, New Haven, CT, [2]Yale University, New Haven, CT
**Corresponding Author*

Brain-wide genome-editing remains a major hurdle for the treatment of neurogenetic disorders. Gene editing using CRISPR/Cas9 for neurogenetic disorders is challenged by difficulty in crossing blood-brain barrier, limited penetration, and narrow therapeutic windows. While modified adeno-associated virus (AAVs) overcome some of these barriers, their immunogenicity and higher risk of off-target effects due to the long-term presence of Cas9 protein, limited their translational value in human neurogenetic disorders. To address this, we developed an innovative We report a non-viral, non-nanoparticle, chemical modification-based method, called Stimuli-Responsive

Traceless Engineering Platform (STEP), which deliver conjugated Cas9 protein and sgRNA (RNP). STEP-RNP achieved effective delivery of CRISPR to neuronal cells in the brain, and the transient Cas9 protein substantially minimized the risk of off-target effect. We tested the STEP-RNP in vitro and in vivo for Angelman syndrome (AS), a neurodevelopmental disorder caused by the deficiency of neuron and maternal-specific *UBE3A* gene expression. The repressed expression of *UBE3A* in the paternal chromosome is mediated by the paternally expressed non-coding *UBE3A* antisense transcripts (*UBE3A-ATS*). Inactivation of *UBE3A-ATS* via antisense oligo (ASO) has shown positive clinical efficacy in ongoing phase 1/2 clinical trials in human AS. However, the transient effect of ASO that requires monthly repeating intrathecal delivery post a challenge as a standard clinical treatment. We designed STEP-RNP delivery system selectively inactivates *Ube3a-ATS* expression and potentially achieves permanent therapeutic effects via a single treatment. Using *Ube3a-YFP* reporter mice, we observed high gene editing efficiency (>75% targeting neurons) with widespread brain penetration. We administered STEP-RNP via intrathecal to newborn (P1-2) and adult AS (P21 or P42) *Ube3a*$^{m-/p+}$ mice. The treatment resulted in significant reduction of *Ube3a-ATS* and reactivation of *Ube3a* protein expression up to 40% of normal level across the cortex, hippocampus, and cerebellum. Accordingly, this treatment led to significant improvement in multiple behavioral domains, including locomotor function, anxiety-like behaviors, learning and memory, and also extended the latency for chemical induced myoclonic and tonic seizures in adult AS *Ube3a*$^{m-/p+}$ model. Importantly, we have not observed any acute toxicity and immunogenicity associated with STEP-RNP, neither detectable off-target events by comprehensive genomic profiling. Moreover, we have found the STEP-RNP effectively reactivate the *UBE3A* expression from the paternal chromosome in human 2D neurons and cortical organoids differentiated from AS patient iPSCs. In addition, we have shown the intravenous delivery also reach widespread penetration and efficient editing in brains. We are currently conduct FDA IND studies for Angelman syndrome using STEP-RNP supported by NIH Somatic Cell Genome Editing Consortium. Genome editing via STEP-RNP will have broad applications and the great potential to treat many neurogenetic disorders.

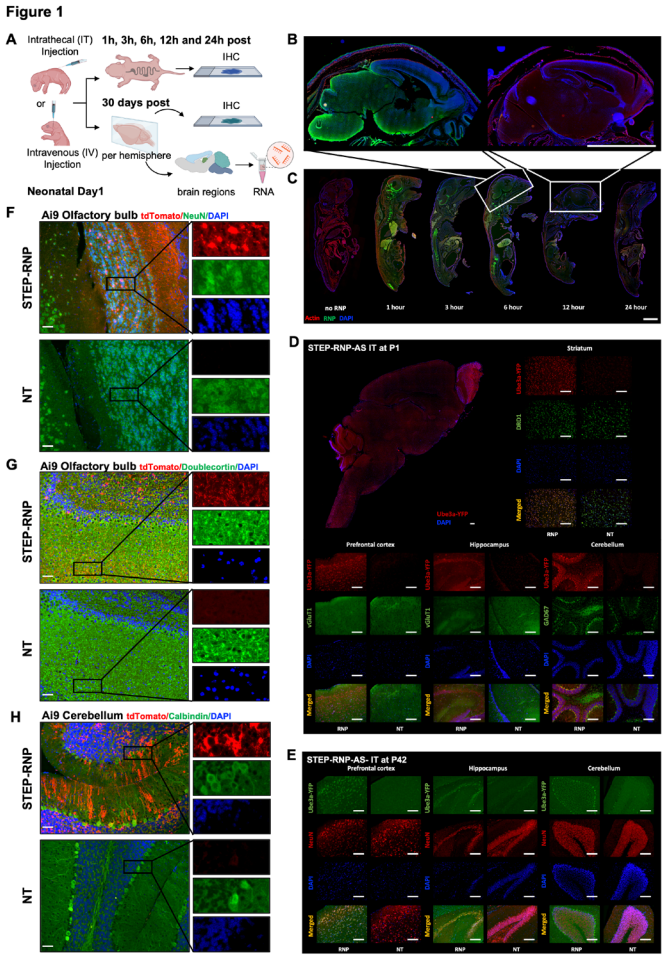

Fig 1. Biodistribution and cell type specificity of STEP-RNP
(A) Delivery of STEP-RNP via intrathecal (IT) and intravenous (IV) injection routes were assessed for whole body distribution at 1-, 3-, 6-, 12-, and 24-hours post-injection in pups (upper), and at 30 days post injection, brain of both neonates and adults were collected for further analysis.
(B-C) Representative images of STEP-RNP detection in the neonatal mouse brain (B) and whole body (C), over time following IT administration (10ug/ul, 10ul/mouse). STEP-RNP is detected by immunostaining on His-tag fused with Cas9. STEP-RNP is detectable in the brain 1 hour following administration, including Midbrain (single arrow), Hypothalamus (double arrow) and Pons Medulla (star) regions and is undetectable in the brain by 12 hours (n = 3 each time point, scale bar = 5 mm).
(D) Representative images of UBE3A-YFP expression in whole brain (upper left) and brain regions (insets) 30 days after IT injection (10ug/ul, 10ul/mouse) of STEP-RNP-AS (G5 + sgRNA33) into P1 neonatal *Ube3a*$^{m+/p-YFP}$ mice. UBE3A-YFP expression colocalizes with markers for multiple neuron types: dopaminergic neurons (DRD1), glutamatergic neurons (vGLUT1) and GABAergic neurons (GAD67), in the striatum, prefrontal cortex, hippocampus and cerebellum, respectively (n=5, scale bar = 150 μm).
(E) Representative images of UBE3A-YFP expression 30 days after IT administration (20ug/ul, 20ul/mouse) of STEP-RNP-AS (G221 + sgRNA33) into adult *Ube3a*$^{m+/p-YFP}$ (42 day old) mice. UBE3A-YFP expression colocalizes with NeuN+ neurons across the prefrontal cortex, hippocampus, and cerebellum (n=5, scale bar = 150 μm).
(F-H) Representative image of tdTomato expression colocalized with NeuN (F), Doublecortin (G) and Calbindin (H) in Ai9 mice 30 days after IT administration of STEP-RNP-sgRNA-AB (10ug/ul, 10ul/mouse) (n=5, scale bar = 50 μm).

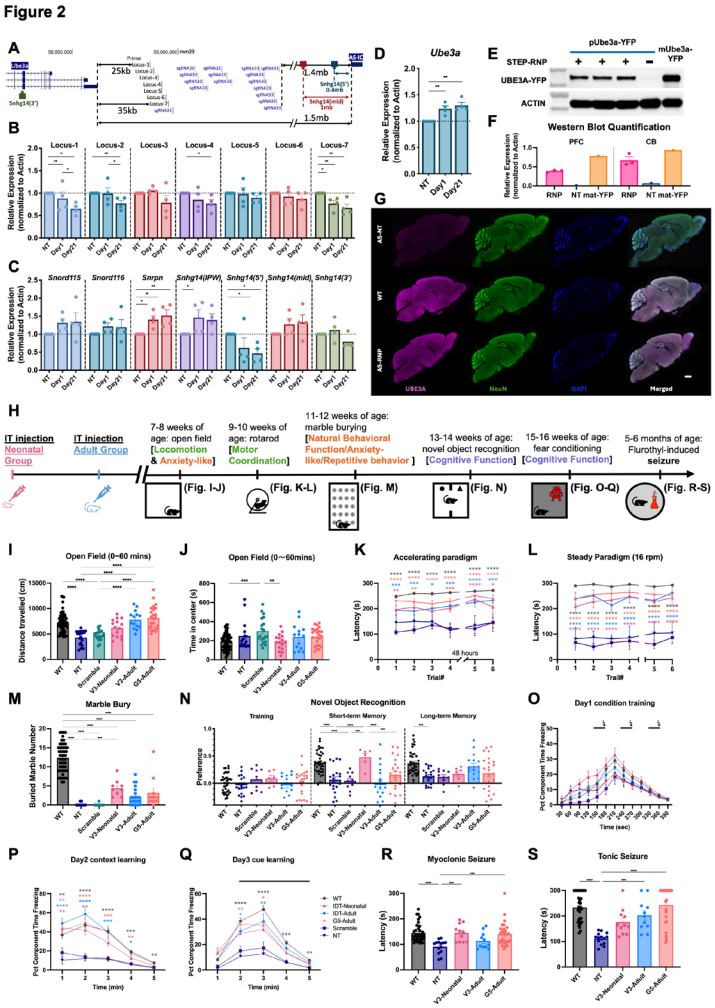

Fig 2. In vivo efficacy of STEP-RNP targeting Angelman syndrome (AS) mouse model

(A) Design of a series of primers targeting multiple loci of *Ube3a-ATS* (black), and multiple targeting loci of sgRNA33 (blue), and their location relative to *Ube3a* and Angelman Syndrome Imprinting Center (AS-IC).

(B) Relative expression of *Ube3a-ATS* in the mouse prefrontal cortex 30 days following STEP-RNP administration to postnatal day 1 and day 21 mice. qRT-PCR primers targeted multiple loci (locus 1-7) as shown in (A).

(C) Relative expression of genes surrounding *Ube3a-ATS* as assessed by qRT-PCR. Notably, there were no significant changes in the expression levels of *Snord115* and *Snord116* in the prefrontal cortex of mice treated with STEP-RNP when compared to untreated controls. A consistent decrease in the expression of *Snhg14* at the 5' end paralleled the observations in the qRT-PCR of *Ube3a-ATS* (n=4 for each group, *p<0.05; ** p<0.01).

(D) Relative reactivated expression of *Ube3a* assessed by qRT-PCR. The expression level of *Ube3a* in both postnatal day1 and day21 are significantly increased compared to untreated controls (n=4 for each group, *p<0.01; **p<0.001)

(E-F) Immunoblot analysis confirmed the reactivation of UBE3A protein 90 days after IT administration of STEP-RNP to P1 neonatal mice. Maternal UBE3A was used as a positive control. UBE3A from paternal chromosome is not detected without STEP-RNP. Paternal UBE3A was reactivated 49.53 ± 2.22% of maternal expression level in prefrontal cortex (PFC), and 71.83 ± 9.70% in cerebellum (CB) after STEP-RNP.

(G) Immunofluorescence showed that the effect of STEP-RNP gene editing was sustained for over 8 months after IT administration at P1-2. WT: Wild type; AS-NT: Angelman syndrome non-treated.

(H) Schematic diagram of behavioral analyses designed to evaluate the efficacy of STEP-RNP applied to AS (STEP-ANP-AS) mouse model (*Ube3a*$^{m-/p+}$). Neonatal (P1-2 day) (pink) and P21 and P42 days (adult) groups received a single injection of STEP-RNP before being subjected to all tests H – R. WT: Wild type; NT: no treatment.

(I) Open field test shows significant amelioration of locomotor function for AS mouse model groups treated with STEP-RNP-AS with either V3 Cas9 or G5 Cas9 compared to no-treatment (NT) and scrambled gRNA.

(J) Open field test shows significantly reduced time in center, a proxy for anxiety-like behavior, for neonates treated with STEP-RNP-AS compared to no-treatment (NT) and scrambled gRNA.

(K-L) Rotarod test shows significantly improved motor coordination performance under both accelerating (K) and steady speed (L) conditions in AS mouse model groups treated with STEP-RNP-AS compared to untreated and scrambled gRNA groups.

(M) Marble burying test shows partially increased marble recovery number in AS mouse model groups treated with STEP-RNP-AS compared to untreated and scrambled groups.

(N) Novel object recognition test shows significantly increased object preference in short term memory in AS mouse model groups treated with STEP-RNP-AS compared to untreated and scrambled groups, suggestive of improved short-term memory in these groups. Specifically, AS mice treated on day 1 have complete rescue for the recognition on the novel object in the short memory test. STEP-RNP treatment also improved the performance for long term memory in all groups.

(O-Q) Fear conditioning test shows significantly improvement of contextual learning and cue learning of AS mice treated with STEP-RNP-AS compared to untreated and scrambled groups at both ages.

(R-S) Flurothyl (bis-either) induced seizure test shows significantly increased latency and hence reduced susceptibility for both myoclonic seizure and tonic seizure in AS mouse model groups treated with STEP-RNP-AS compared to non-treated mice. In the myoclonic seizure test, both adult and neonatal AS mouse groups treated with STEP-RNP-AS show the full rescue of latency compared to the wild-type level. (*p<0.05, **p<0.01, ***p<0.001)

221 Development of *in Vivo* Genome Editing for the Treatment of Progressive Familial Intrahepatic Cholestasis Type 2

Chiara Simoni[1], Elena Barbon[2], Francesco Starinieri[3], Martino Alfredo Cappelluti[4], Elisabetta Manta[3], Camilla Negri[3], Mauro Biffi[3], Angelo Lombardo[5], Alessio Cantore[6]

[1]SR-TIGET, Milan, Milano, Italy, [2]SR-TIGET, Roma, C.F. e Partita I.V.A.: 04879781005, Italy, [3]SR-TIGET, Milan, Italy, [4]SR-TIGET, Milan, Lombardy, Italy, [5]San Raffaele - Telethon Institute for Gene Therapy (SR-Tiget), Milan, Italy, [6]SR-TIGET, Milan, Italy, Italy

Progressive familial intrahepatic cholestasis type 2 (PFIC2) is a monogenic inborn error of metabolism caused by the deficiency of the bile salt export pump (BSEP), transporter of bile acids (BA) across the canalicular membrane of hepatocytes, encoded by *ABCB11* gene. PFIC2 patients display jaundice, itching, and cholestasis and usually develop liver fibrosis and end-stage liver disease before adulthood. Current treatments include diet control and pharmacological or surgical interventions to decrease BA blood concentration. Most patients undergo liver transplantation as the only curative option. Early therapeutic intervention would be fundamental in diseases like PFIC2, presenting with early onset and rapid disease progression, to limit hepatic damage. Since BA levels and other stimuli tightly regulate *ABCB11* expression, we are developing a liver-directed CRISPR-Cas9 based-genome editing approach to integrate the corrective cDNA into the first intron of the *ABCB11* gene. This strategy may allow the stable correction of most disease-causing mutations, even in pediatric patients, while maintaining physiological gene regulation. We initially assessed lentiviral vectors (LV)-mediated liver gene addition in *Abcb11-/-* mice, a

PFIC2 model, to correlate therapeutic effects with the extent of liver transduction. We administered 2-week-old *Abcb11-/-* mice with LV encoding the murine BSEP transgene under the control of a hepatocyte-specific cassette. We observed that transgene mRNA levels of about 30% of the endogenous murine BSEP resulted in a significant decrease, up to normalization, of serum BA, bilirubin, and alkaline phosphatase (ALP) until 6 months of age in both males and females, indicating prevention of cholestatic damage. Towards genome editing, we selected the most efficient *Abcb11*-targeting guide RNA (gRNA) in hepatocyte cell lines. Moreover, we compared different mCherry-expressing donor DNAs designed to exploit homology-directed repair (HDR) or homology-independent targeted integration (HITI) strategies for site-specific integration. *In vitro*, we achieved the highest integration rate using the HDR-based donor DNA (up to 12%). *In vivo*, we tested the different mCherry-donor DNA configurations delivered via adeno-associated viral vectors (AAV) to 2-day or 2-week-old Cas9 transgenic mice. In the liver of mice of both ages, we observed a slightly higher integration rate (up to 16%), mCherry expression, and mCherry-positive liver area (up to 16%) exploiting HDR rather than HITI strategy. To move towards a translatable approach, we tested in 2-week-old wild-type (WT) mice the delivery of AAV-carrying HDR-based donor DNA followed by the administration of lipid nanoparticles (LNP) carrying Cas9 mRNA and gRNA at the same time, 48 hours later or 1 week later. We found that the coadministration of AAV and LNP results in the highest integration rate (up to 18%) and mCherry-positive liver area (up to 13%). The resulting mCherry expression was comparable to the BSEP expression obtained with the therapeutic LV gene transfer. We are currently testing the selected editing strategy in 2-week-old *Abcb11-/-* mice and evaluating therapeutic efficacy by measuring blood BA, bilirubin, and ALP. Overall, this study informs about the optimal strategy and timeframe of in vivo liver-directed genome editing and represents a first step towards site-specific durable gene correction of PFIC2.

222 *In vivo* site-specific T cell engineering allows complete remission of human leukemia in mice

Shlomo Moss[1], Inbal Reuveni Ofek[2], Miri Horovitz-Fried[3], Alessio Nahmad[4], Iris Dotan[5], Yifat Glucksam Galnoy[6], Daniel Nataf[6], Debora Bublik[6], Maayan Zaba[6], Peleg Rider[6], Adi Barzel[7]
[1]Tel Aviv University, Ra'anana, Israel, Israel, [2]Tel Aviv University, Petach Tiqva, HaMerkaz, Israel, [3]Tel Aviv University, Tel-Aviv, Tel-Aviv, Israel, [4]Samueli Integrative Cancer Pioneering Institute, Petah Tikva, HaMerkaz, [5]Tel Aviv University, Tel Aviv, Tel-Aviv, Israel, [6]Tel Aviv University, Tel Aviv, Israel, [7]Tel Aviv University, Tel Aviv, HaMerkaz, Israel

T cells engineered to express chimeric antigen receptors (CAR-T cells) show great promise in treating hematological malignancies. However, the *ex vivo* culturing and engineering of autologous T cells is cumbersome, time-consuming, and expensive. Here, we develop methods for the ***in vivo*** engineering of CAR-T cells, obviating pre-conditioning and reducing timelines and expenses without risking GVHD or graft rejection. We use adeno-associated viral vectors (AAV) coding for the CAR as well as for a nuclease targeting the CAR into the TCR alpha constant (TRAC) locus. Uniquely, our design allows co-encapsulation in a single AAV of the CAR gene, flanked by homology arms, together with a cassette coding for the "ARCUS" nuclease, an engineered derivative of the I-CreI homing endonuclease targeting the TRAC locus. Furthermore, to efficiently and specifically target cytotoxic T cells in vivo, we incorporate, in the capsid of our AAV, a designed ankyrin repeat protein (DARPin) targeting the human CD8 receptor. Importantly, we demonstrate both *ex vivo* and *in vivo* engineering of primary human T cells with our single AAV in mice xenotransplanted with human leukemia. In particular, subsequent to IP injection, *in vivo* engineered CAR T cells with the expected $CD8^+$, $CD3^-$, CAR^+ phenotype expand in the leukemia-bearing mice, reaching levels of up to ~12% of blood $CD8^+$ T cells. When applying IV injections, complete remission of the human leukemia was achieved in the xeno-transplanted mice. Site-specific *in vivo* engineering of CAR T cells may revolutionize the safety, efficacy, and scalability of cellular immunotherapies for hematological malignancies and beyond.

223 Preclinical Development of a CRISPR-Cas9-Based Therapeutic for the Treatment of Herpes Keratitis

Guoxiang Ruan[1], NADIA AMRANI[1], Kevin Luk[1], Pankaj Singh[2], Mason Shipley[3], Meltem Isik[1], Wenwen Huo[1], Donna Neumann[3], Jennifer Gordon[4]
[1]Excision BioTherapeutics, Watertown, MA, [2]University of Wisconsin-Madison, Madison, WI, [3]University of Wisconsin-Madison, [4]Excision Biotherapeutics, Inc., Watertown, MA

In this study, we explored a CRISPR-SaCas9-based therapeutic as a potential treatment for herpes keratitis, one of the leading global causes of blindness. Herpes keratitis is caused by infection with Herpes simplex virus 1 (HSV-1), one of the most common human viruses affecting approximately 3.7 billion individuals under the age of 50 (67%) worldwide. Upon infection, HSV-1 replicates at the site of entry before traveling via sensory neurons to establish lifelong latency in the trigeminal ganglia (TG) and other ganglia reservoirs. Reactivation from latency, often triggered by stress or immunosuppression, results in recurrent infections. These recurrences can manifest in many forms such as herpes keratitis, labialis (cold sores), encephalitis, or genital herpes. Despite the availability of therapies that alleviate symptoms and reduce recurrence, there is no approved cure or therapeutic vaccine to eliminate latent HSV-1 virus.

We employed CRISPR-SaCas9 to simultaneously target two essential HSV-1 genes, ICP0 and ICP27, leveraging a "dual cut" strategy to induce large deletions in the HSV-1 genome and prevent viral escape. Off-target analysis using GUIDE-seq and hybrid capture confirmed no off-target editing of the selected guide RNA pair, demonstrating the high specificity of the gRNAs. For in vivo proof-of-concept studies, we used a latent rabbit keratitis model, which closely mimics recurrent HSV-1 infection in humans. To evaluate promoter efficacy, we compared a minCMV promoter and a neuron-specific CaMKIIα0.4 promoter for driving SaCas9 expression. Intravenous administration of all-in-one AAV9 vectors containing either promoter achieved promising results. The AAV9-minCMV vector eliminated viral shedding in 83-100% of treated rabbit eyes and reduced HSV-1 DNA in the TG by 64-81%. The AAV9-CaMKIIα0.4 vector eliminated viral shedding in 90% of treated rabbit eyes and reduced HSV-1 DNA in the TG by 51%. Residual HSV-1 DNA in the TG showed insertions and deletions (Indel mutations) at the targeted HSV-1 sites and large genomic deletions of the HSV-1 genome, indicating effective disruption of the latent HSV-1 reservoir. Both promoters demonstrated robust SaCas9 expression in the TG at six weeks post-AAV9 administration, with the neuron-specific CaMKIIα0.4 promoter offering tissue-specific expression.

In summary, this preclinical rabbit study highlights the potential of a CRISPR-Cas9-based therapeutic to eradicate latent HSV-1 infection in patients with herpes keratitis. This gene-editing approach could also be extended to treat other HSV-1-related diseases. Furthermore, identification of conserved and robust gRNAs for both HSV-1 and HSV-2 may enable the development of a single therapeutic product for the treatment of all herpes-related diseases.

224 Enhancing HDR-Mediated *Pah* Transgene Insertions in a Murine Model of Phenylketonuria

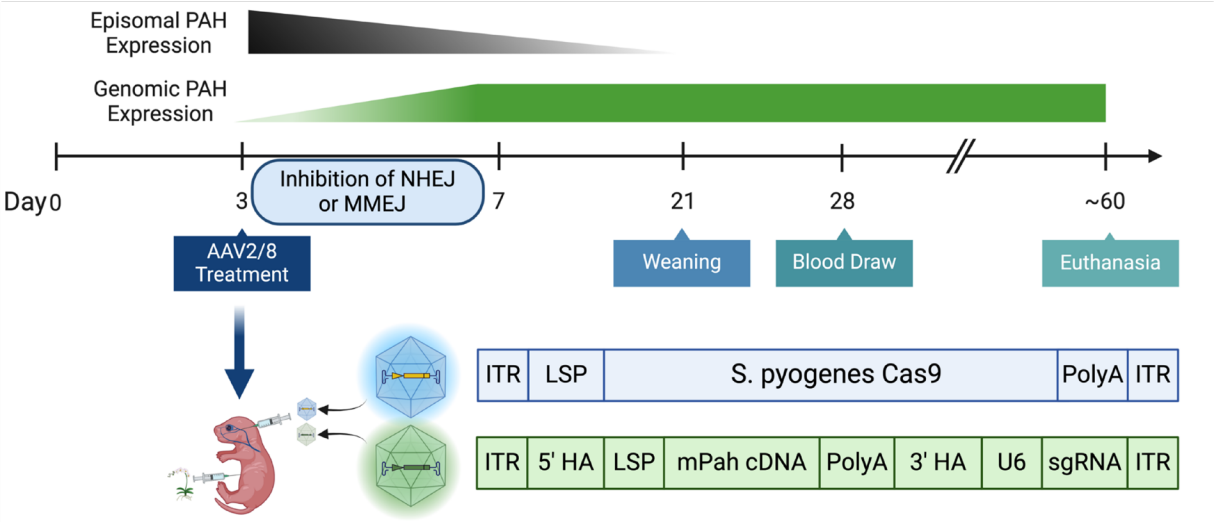
Michael Martinez[1], Daelyn Richards[2], Shelley Winn, Cary Harding[5]
[1]Oregon Health and Sciences University, Portland, OR, [2]WSU ESFCOM, Spokane, WA, [3]OHSU, Portland, OR, [4] Oregon Health & Science University, Portland, OR, [5]Oregon Health & Science University, Portland, OR

Introduction
A major challenge in resolving genetic diseases lies in the plethora of mutations that can each independently give rise to the same disorder. Over the past decade, significant progress has been made in developing gene correction and gene addition methods to treat these diseases. However, current gene addition techniques, which rely upon transient expression of viral episomes, offer only temporary relief in many diseases due to their limited stability in dividing cells. Alternatively, insertion a whole transgene using homology-directed repair (HDR) would provide permanent rescue of gene expression while being agnostic the specific genomic mutation. Previous work in our laboratory demonstrated significant reduction in serum phenylalanine concentrations in a murine model of phenylalanine hydroxylase (PAH) deficiency, a model of human phenylketonuria (PKU), following HDR-mediated gene correction. However, this response was only effective in neonatal mice that also received injections of vanillin,

an inhibitor of the non-homologous end joining pathway (NHEJ). We hypothesized that inhibition of DNA repair pathways that compete with homologous recombination (HR), such as NHEJ and microhomology-mediated end joining (MMEJ), would enhance the *in vivo* efficacy of large transgene insertions as well as gene corrections.

Results
PAH-deficient mice were treated with dual AAV2/8 vectors as neonates. One AAV vector expressed spCas9 and the other delivered a 2,379 bp *Pah* transgene repair template and expressed a guide RNA targeting exon 7 of the murine *Pah* gene (**Figure 1**). Simultaneous intraperitoneal administration of vanillin, an inhibitor of NHEJ, improved HDR insertion efficiency, reducing blood phenylalanine levels by 56.8%. Combining vanillin with novobiocin (NVB), an MMEJ inhibitor, in a treatment dubbed "Vanbiocin", further improved efficacy, with transgene insertions detected in 9.57% of hepatocyte alleles and blood Phenylalanine concentrations reduced on average by 70.6% to 631 µM. Vanbiocin treatment reversed hyperphenylalaninemia-associated hypopigmentation in affected mice and enabled dams to successfully rear their pups through weaning, overcoming the deficiencies of maternal PKU. Finally, oral administration of sapropterin dihydrochloride, a pharmacologic cofactor of PAH, reduced phenylalanine levels in Vanbiocin-treated mice to 396 µM, approaching 360 µM, the recommended treatment threshold for individuals with PKU.

Conclusion
Pharmacologic manipulation of DNA repair is a promising solution for enhancing HDR *in vivo*. Further refinement of this approach is required to provide a fully efficacious treatment for diseases such as PKU. However, the benefits of inserting a transgene into the genome would represent a generalizable treatment strategy that could be provided to a host of inherited errors of metabolism.

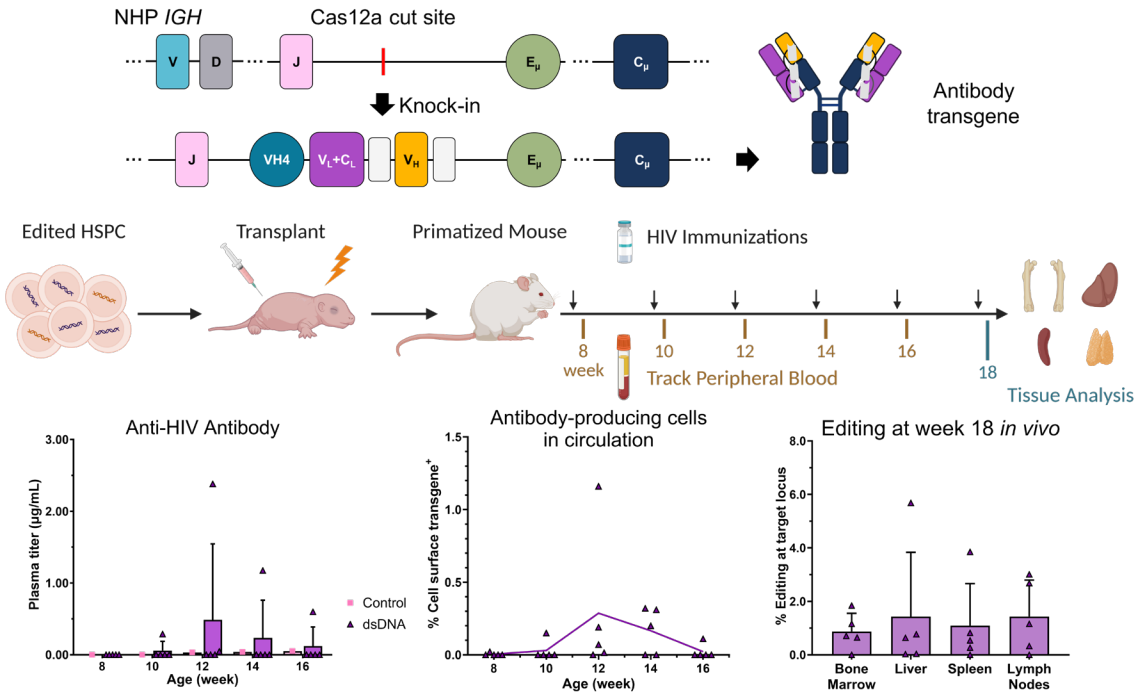


225 Editing Hematopoietic Stem and Progenitor Cells by Non-Viral Gene Knock-In Produces Anti-HIV Antibody *In Vivo*

Jack Castelli[1], Katrina Poljakov[1], Youngseo Jwa[2], Molly Cassidy[1], Matthew Gray[1], Jocelyn Sanchez Gaytan[3], Mark Enstrom[1], Jonathan Linton[1], Anthony Rongvaux[1], Justin Taylor[4], Jennifer Adair[5]
[1]Fred Hutchinson Cancer Center, Seattle, WA, [2]Seattle, WA, [3]Fred Hutchinson Cancer Center, Las Cruces, NM, [4]University of Virginia, Charlottesville, VA, [5]University of Massachusetts Chan Medical School, Worcester, MA

Non-viral gene editing offers a promising alternative to viral delivery for durable biologics production. Non-human primate (NHP) studies and human clinical trials have shown that adeno-associated virus encoding broadly neutralizing antibodies can protect against HIV, but result in limited, short-lived responses. The development of non-viral gene editing approaches in hematopoietic stem and progenitor cells (HSPC) holds promise for long-term antibody production. Here, we evaluate CRISPR/Cas9 and CRISPR/Cas12a for gene knock-in at the

immunoglobulin heavy chain locus in non-human primate HSPC as a preclinical model of HIV infection. Delivering the nuclease as a protein alongside a DNA template, we optimized editing with Cas12a demonstrating higher knock-in efficiency and fewer non-specific edits than Cas9 at this locus. We achieved up to 8.0% homology-directed repair events by electroporating Cas12a in the LCL 8664 NHP B cell line, with a larger fraction of productive insertions than Cas9 (85% vs 59%). We showed that delivery of large DNA templates (>2,250 base pairs) results in the durable expression of a reporter transgene from this locus in LCL 8664 cells. A double-stranded DNA template produced 2.6% transgene-positive cells, in comparison to 0.02% using a single-stranded oligodeoxynucleotide template. This approach was employed in primary CD34^{+} NHP HSPC, which were then transplanted into MISTRG mice. In this primatized mouse model, we observed engraftment, B cell differentiation, and reporter transgene expression, without any significant difference between electroporated and control conditions. Editing was detected *in vivo* at the target locus up to 16 weeks post-transplantation, with levels declining over time. To assess anti-HIV antibody expression, we developed a template encoding the broadly neutralizing antibody 10-1074 under the control a B cell-specific promoter, derived from a NHP variable heavy domain. After confirming recombinant antibody production *in vitro*, we transplanted MISTRG mice with NHP HSPC electroporated with Cas12a and this 10-1074 template. Beginning at 8 weeks of age, these mice were immunized with gp120 monomers. Anti-HIV antibodies were detected in peripheral blood circulation 4 weeks after immunization and declined thereafter. 20% of mice (n=1 of 5) developed titers of up to 2.4 µg/mL, similar to levels required to neutralize simian-HIV in NHP models. Surface expression of the antibody transgene was identified in all mice, although at low levels (≤1.2%). Mean editing frequency remained 1.5% in peripheral blood at week 16 post-transplantation; edited cells were also detected in the bone marrow, liver, spleen, and lymph nodes. NHP-CD19^{+} B cells were present in the lymph nodes and spleen, as well as NHP-CD34^{+} HSPC in the bone marrow. Our findings demonstrate that, following non-viral knock-in, HSPC remain capable of engraftment in an immunodeficient mouse model, where they can differentiate into immune cells producing biologically relevant levels of antibody from an endogenous locus. These data support proof of concept for this approach as a potential strategy for sustained biologics production in the treatment of chronic diseases such as HIV. Ongoing studies directly compare viral and non-viral editing using MISTRG6 mice, a strain with improved B cell differentiation and antibody production. Future work will assess efficacy in a NHP model of simian-HIV infection.



Manufacturing and Transduction for Viral Vectors

227 Suppressing APOBEC3 in Lentiviral Vector Producer Cells to Maximize Transgene Fidelity

Annika Mittelhauser[1], Kevyn Hart[2], Shivani Shivani Mohapatra[1], Roger Hollis[1], Donald Kohn[1]
[1] *University of California, Los Angeles, CA,* [2]*Los Angeles, CA*

Introduction:
Within the fields of gene and cell therapy, HIV-derived lentiviral vectors (LV) are an established method of delivering therapeutic transgenes into target cells. Overall, LVs have a strong efficacy and safety profile, but one downside is the frequent incorporation of mutations into the transgene. Mutations may be synonymous, but typically protein function is disrupted and the efficacy of the therapy reduced. Oncogenic gain-of-function mutations are also possible for certain proteins. Transgene mutations have long been attributed to the relatively low fidelity of reverse transcriptase (RT), but in LV-treated ADA SCID patient samples analyzed by our lab, most observed mutations were C→T. That is characteristic of the antiviral protein family apolipoprotein B mRNA editing enzyme catalytic polypeptide-like 3 (APOBEC3), which evolved to defend against retroviruses by hypermutating their genome. Wild-type (WT) HIV encodes Vif to defend against APOBEC3s, but during the development of LVs, Vif was removed. Therefore, it was hypothesized that eliminating or inhibiting APOBEC3s within HEK293T (293T) LV-producer cells would reduce mutations in the integrated LV transgene.

Methods:
To test this hypothesis, CRISPR/Cas9 was utilized to create an APOBEC3A→G knockout (KO) 293T cell line. EFS-ADA (adenosine deaminase) LVs were packaged in the APOBEC3A→G KO line and separately in WT 293Ts transfected with a Vif expression plasmid. Control LVs were packaged in WT 293Ts. The resultant LVs were transduced into CD34s, and the integrated transgenes were library prepped, enriched, and duplex sequenced. The sequencing provided high coverage and accuracy, as dual unique molecular identifiers facilitated the exclusion of duplicate reads and errors incorporated during PCR or sequencing. Importantly, since APOBEC3 proteins preferentially target lagging strand ssDNA, the C→T mutations appear as G→A upon sequencing of the leading strand.

Results:
Sequencing identified 95 mutations (91 G—>A) in EFS-ADA transgenes packaged in WT 293Ts. That number was reduced to 9 total mutations (8 G—>A) in transgenes packaged in the APOBEC3A→G KO line, representing a 90.5% reduction in total and a 91.2% reduction in G—>A mutations. Separately expressing Vif in WT 293Ts led to a 50.5% reduction in both total and G—>A mutations. Additionally, 89%, 75%, and 84% of all G→A mutations were associated with an APOBEC3 substrate signature in transgenes packaged in WT, APOBEC3A→G KO, and Vif-expressing 293Ts, respectively.

Conclusions and Future Directions:
The data provides strong evidence to support the hypothesis that the APOBEC3 family is the predominant cause of mutations within the LV transgene, not RT. Future directions will concern identifying when/where the APOBEC3 proteins deaminate the transgene within the production and transduction pathways, via sequencing of 293T cDNA mid-packaging and the LV genome pre-transduction. Similarly, it will be determined whether a full knockout of APOBEC3 (via additional KO of A3H) in producer 293Ts will maximally eradicate C→T mutations, or if Vif needs to be incorporated in the LV capsid to protect against APOBEC3s produced in the target cell. Overall, this work provides evidence that simple modification(s) to the packaging process of LVs can dramatically increase their fidelity, and by extension, their efficacy and safety profile for all gene and cell therapy applications.

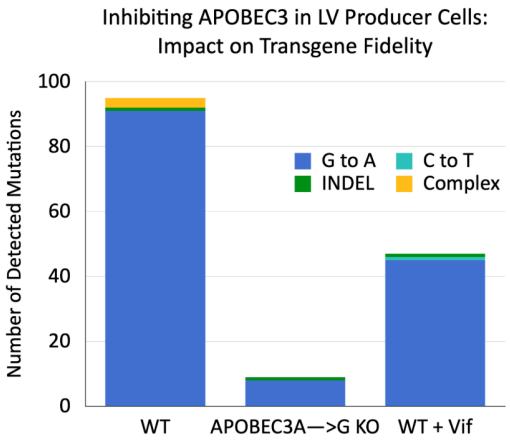


Figure 1: APOBEC3A→G KO or Inhibition Dramatically Reduces the Number of Mutations Within Integrated EFS-ADA Transgenes
EFS-ADA LVs were packaged under three different conditions: in WT 293Ts (WT), in APOBEC3A→G KO 293Ts, or in WT 293Ts expressing Vif (WT + Vif). The resultant LVs were transduced into CD34s and sequenced. The graph displays the number and type of all mutations identified in the EFS-ADA transgenes from each condition. APOBEC3s deaminate C→T, but the sequencing pipeline displays those mutations as G→A. INDEL = Insertion/Deletion.

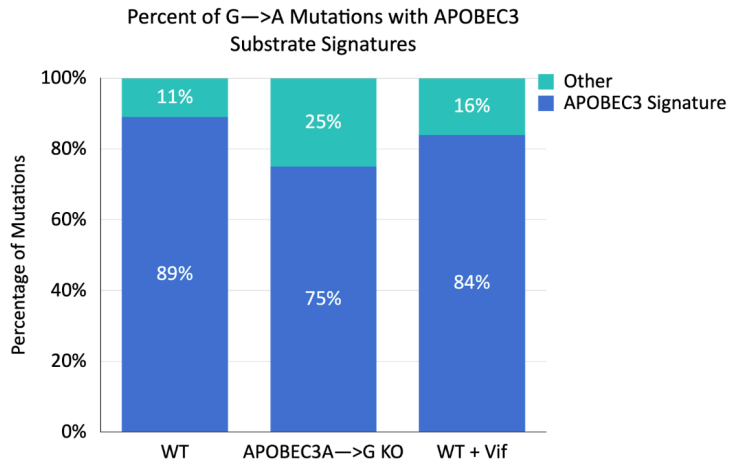

Figure 2: Majority of G→A Mutations Identified Within Integrated LV Transgenes are Associated with an APOBEC3 Substrate Signature
EFS-ADA LVs were packaged under three different conditions: in WT 293Ts (WT), in APOBEC3A→G KO 293Ts, or in WT 293Ts expressing Vif (WT + Vif). The resultant LVs were transduced into CD34s and sequenced. APOBEC3s deaminate C→T, but the sequencing pipeline displays those mutations as G→A. Thus, the graph displays the percentage of G→A mutations identified within each condition that are associated with an APOBEC3 substrate signature.

228 Engineering Lentiviruses for Enhanced Transduction of Primary Human T Cells

Devin Stranford[1], Hailey Edelstein[2], Mahdy Al Majed Yassine[1], Rana Kennedy[1], Raghav Gupta[1], Maureen Regan[1], Joshua Leonard[3], MATTEO STOPPATO*
[1]Syenex, Inc., Evanston, IL, [2]Syenex, Evanston, IL, [3]Northwestern University, Evanston, IL
**Corresponding Author*

In recent years, CAR T immunotherapies have proven curative for multiple cancers; however, high costs and manufacturing challenges have limited patient access to such treatments. To address these needs, Syenex is

developing enhanced viral gene delivery vectors to generate CAR T cells more efficiently, optimizing functional particle yield per production batch to significantly reduce per-patient dose costs. By screening libraries of envelope functionalization proteins and membrane display scaffolds, we developed SNX-T1, an additional plasmid component for lentiviral production systems that enhances transduction of activated primary human T cells by 10-fold over a standard VSV-G pseudotyped virus. SNX-T1 is compatible with a variety of lentiviral systems, including different producer cell types, different lentivirus generations, different fusogens, integration-deficient designs, and large transgene cargos. To further reduce manufacturing time and cost, we have expanded on this concept to create SNX-T2, a multi-plasmid mix that enables activation and transduction of resting T cells in mixed populations. This allows for the removal of external activation reagents and isolation steps in CAR T cell production, thereby shortening timelines for patient cell transduction. We have demonstrated efficient transduction of resting T cells in as little as one hour and greater than 99% T cell specificity in a PBMC population, an important step toward bedside CAR T engineering. Taken together, Syenex's suite of T cell engineering systems maximizes the output of viable therapeutic particles from each production run and/or shortens timeline processes, thereby lowering the overall cost per patient dose and improving accessibility of gene therapies. By screening libraries of designs, we have gained a deeper understanding of the rules of T cell-vesicle fusion, which are being applied to our in vivo delivery systems.

229 Purification and Chemical Shielding of Adenoviral Vectors for Gene Therapy, Vaccines, and Oncolytic Virotherapy

Mary Barry[1], Michael Barry[1]
[1]*Mayo Clinic, Rochester, MN*

In most *in vivo* applications, adenovirus (Ad) vectors are more potent than other viral or non-vector systems. However, Ads suffer from strong innate and adaptive immune responses that start by the binding of host proteins to the surfaces of their virions in a serotype-specific fashion. For example, Ad serotypes can be bound by natural antibodies or neutralizing antibodies that can trigger complement activation, innate immune responses, and their destruction by macrophages and Kupffer cells. This problem of host protein binding to Ad virions was made more apparently by observations of vaccine-induced thrombotic thrombocytopenia (VITT) in Ad COVID-19 vaccines. It has been proposed that different blood protein, platelet factor 4 (PF4), also binds Ad virions. This binding and the patterned display of PF4 on the virus surface is thought to induce antibodies against PF4 to induce VITT. One approach to reduce these bindings and to increase safety is the chemically "shield" the viruses with polymers like polyethylene glycol (PEG). PEGylation protects Ad from pre-existing and new neutralizing antibody and T cell responses. Relevant to VITT and other clotting side effects, we showed that 5 kDa linear NHS-PEGylation reduces binding to and activation of platelets and endothelial cells, blocked platelet loss, and reduced D-dimer levels after IV injections. While NHS-PEG is protective, it randomly covalently conjugates all of the lysines on the surface of Ad and reduces receptor binding and vaccine efficacy. To avoid this inactivation, we have inserted a single cysteine or 4 cysteines into the 7 the hexons of Ad to target PEGylation to one specific site on the virus using maleimide-PEG. This avoids inactivating the Ad's fiber receptor binding protein and maintained Ad potency. We will describe here the process for adenovirus vector purification and how NHS and maleimide PEGylation is applied during purification to better shield Ad for its various applications.

230 AnelloBricks: Development of a Scalable, Low-Cost, In-Vitro Assembled Anellovirus-Derived Platform for Gene Therapy Applications

Erik Hansen[1]*, Nidhi Mukund Acharekar[1], **Yue Zhang**[1], Andrew Keezer[1], Lynn Zeheb[1], Rajendra Boggavarapu[1], Hyun Jung Jun[1], Konstantin Konstantinov[1], Geoffrey Parsons[1], Timsi Rao[1], Kurt Swanson[1]
[1]*Ring Therapeutics, Cambridge, MA*

Anelloviruses, a family of small, non-enveloped, single-stranded DNA (ssDNA) viruses ubiquitously present in humans, represent a promising yet underexplored platform for gene therapy. Their unique biology, including their persistent yet asymptomatic and immune silent nature, positions them as ideal candidates for potentially safe and efficient gene delivery. Here we report the development of a cell-free, in-vitro assembled genetic medicines platform offering a modular approach with potential to treat a broad range of diseases across diverse therapeutic modalities.

This novel platform is composed principally of two components: recombinant capsid proteins and nucleic acid payloads (e.g. DNA, RNA), offering payload diversity while also simplifying production to conventional and readily scalable systems. In vitro assembly is initiated by the interaction of recombinant anelloviral capsid proteins with the nucleic acid payloads in a cell-free reaction system. The process is driven by the specific binding of the nucleic acids to the capsid proteins. Assembly proceeds through highly cooperative addition of payload bound to capsid proteins, guided by electrostatic and structural complementarity, to form a fully mature icosahedral Anellovector. This modular system allows for precise control over the stoichiometry and composition of the assembled vector, with the potential for reproducible manufacturing and efficient encapsidation of therapeutic nucleic acids.

We demonstrate successful packaging of ssDNA payload encoding GFP, efficient transduction in vitro, and in rodents. These findings highlight the potential of anellovirus-derived vectors as a novel gene therapy platform for a wide range of diseases, offering potential advantages in manufacturing scalability and cost compared to existing viral vector systems.

231 A Massively Parallel Reporter Assay for Evaluating Lentiviral Transfer Plasmid Design

Joseph Collins[1], Jeremy Gam[1], Brianna Jayanthi[1], Ben Gordon[1], Evan Cofer[1], Jaclyn Thompson[1]
[1]*Asimov, Boston, MA*

Lentiviral plasmids play a pivotal role in cell and gene therapies, but due to the intricacies of their genetic design, it is challenging to predict how different combinations of components influence their behavior. In principle, massively parallel reporter assays (MPRAs) can enable high-throughput evaluation of designs, however MPRAs have not yet been used, to our knowledge, to survey the impact of lentiviral transfer plasmid design on viral genome packaging and infectious titer. To address this, we developed an MPRA approach based on our commercially-available semi-stable lentivirus packaging system and used it to interrogate a library of nearly 5,000 lentiviral transfer plasmid designs. The assay evaluated the impact of design on lentiviral life cycle at two stages: RNA-seq was used to assess viral genome packaging and targeted genomic DNA-seq was used to assess infectious titer of a HEK293 cell line. We analyzed the resulting MPRA data with a novel two-stage hierarchical Bayesian regression model in order to simultaneously remove sequencing artifacts and quantify contributions from individual genetic parts. To do this, the model employed a zero-inflated negative binomial distribution to account for technical dropout and overdispersion. The resulting model encompasses both viral genome packaging and infectious titer while precisely identifying the impact of each plasmid design.

To validate our approach, we individually characterized 10 modeled designs that spanned a broad dynamic range of viral genome packaging and infectious titer. Viral genome packaging was assessed using RT-qPCR, and infectious titer was assessed using ddPCR. Spearman's rho between model activity estimates and observed MPRA activity for the single plasmid designs were 0.66 for viral genome packaging and 0.71 for infectious titer, supporting the validity of our screening approach and model. Across all designs, the hierarchical Bayesian regression model demonstrated high generalizability and highly accurate estimates for part contributions, capturing the vast majority of the variance (five-fold cross-validation mean Pearson's r of 0.96 and 0.94 between observed and posterior estimates of viral genome packaging and infectious titer, respectively, for a single representative gene of interest).

Our high-throughput evaluation of plasmid designs at multiple stages of the lentiviral life cycle provides new understanding of how specific design elements influence the overall system. For instance, we found that the commonly used woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) and the SV40 origin of replication both had minimal impact on infectious titer. However, in the case of WPRE we discovered that the element actually decreased viral genome packaging while simultaneously enhancing viral delivery. As another example, our final model required no interaction terms. This indicates that the genetic parts we tested contributed independently to titer, and suggests a means for streamlined MPRA-based exploration of vast combinatorial design spaces. Overall, these results demonstrate that pooled assays can generate quantitative insights for lentiviral plasmid design and enable precise modeling of the impact of design on titer.

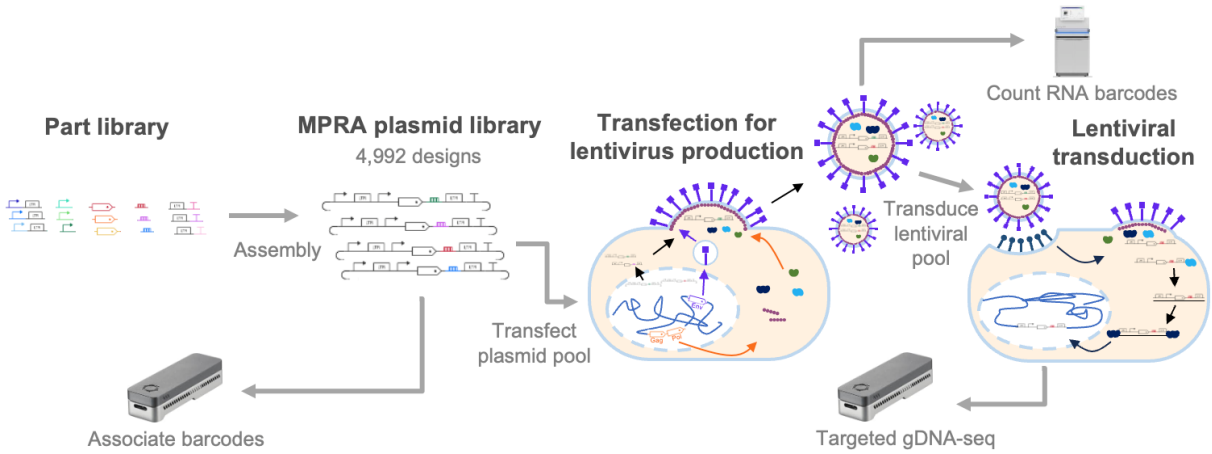

Figure 1: Overview of the lentiviral transfer plasmid MPRA workflow. A plasmid library containing 4,992 designs was introduced into a semi-stable packaging cell line to generate a lentiviral pool. This library was sequenced using RNA-seq to assess viral genome packaging and was also used to transduce a HEK293 cell line. Targeted gDNA-seq on the transduced cells was employed to assess infectious titer of the lentiviral pool.

232 Non-Integrative and Long-Lived Expression of Chimeric Antigen Receptor with Self- and Trans-Amplifying RNA

Jonathan Gunn[1], Matthew Kim[1], Keerthana Ananda[1], Edith Lopez[1], Barbara Sade-Perez[1], Jesus Beltran[2], Ester Kwon[1]*, Dan Kaufman[3]*

Introduction:
Although CAR-T cell therapies have transformed the treatment of B cell lymphoma and multiple myeloma, *ex vivo* cell engineering is costly and time-consuming. *In vivo* gene therapies offer a resource-efficient alternative but can result in off-target genomic integration. Transient mRNA-based therapies mitigate this risk but may require frequent re-dosing due to the rapid turnover of mRNA. Recent studies show that synthetic circular RNA is a promising solution to attain long-term expression; however, translation of the transgene can be inefficient and thus require greater, though less frequent, dosing to achieve the same efficacy as that of linear mRNA.

This study aims to improve both transgene expression and RNA longevity by employing self- and trans-amplifying RNAs (saRNA and taRNA). The saRNA in this study replicates transgene RNA using the Venezuelan equine encephalitis virus (VEEV) RNA-dependent RNA polymerase, or replicase, which recognizes VEEV conserved secondary structures in the UTRs. The taRNA construct includes minimal 5' and 3' UTRs for RNA replication but lacks the ~8 kb VEEV replicase, leading to more efficient expression of transgene. As little as a single saRNA copy can propagate, leading to sustained CAR expression in both parent and daughter cells. saRNA is particularly well-suited to T and NK cell transfection, which exhibit low basal translational activity and would therefore benefit from exogenous amplification of transgene-coding RNA.

Methods:
An anti-human CD19 CAR construct was cloned into a canonical linear mRNA backbone with an α-globin 5′ UTR and AES-mtRNR1 3′ UTR. A bicistronic anti-hCD19 CAR-T2A-BFP cassette was incorporated into an saRNA backbone encoding the VEEV replicase. The taRNA construct was designed with an mNeonGreen reporter downstream of the anti-hCD19 CAR-T2A sequence and contains minimal VEEV-derived UTRs required for replication. CleanCap AU and a 100% 5-methylcytidine substitution were incorporated into the *in vitro*-transcribed RNA.

Functionality of ta- and saRNA were initially validated in HEK293T cells. Then, PBMC-derived human T cells were electroporated with linear mRNA, saRNA, taRNA, or saRNA + taRNA combinations encoding anti-hCD19 CAR.

Results:
In HEK293T cells, saRNA encoding anti-hCD19 CAR demonstrated improved protein expression, with 6.5% of cells expressing CAR 24 hours following transfection using wild-type replicase and 20% CAR-positive cells using hyper-replicase. Moreover, the combination of saRNA and taRNA maintained expression of CAR-positive cells and increased CAR levels 2-3-fold above that of taRNA alone, as measured by mean fluorescence intensity (Figure 1).

In primary human T cells, electroporation with combined saRNA and taRNA constructs demonstrated greater and more sustained expression of mNeonGreen reporter compared to that of conventional mRNA—expression was maintained for 96+ hours, as shown in Figure 2. In ongoing experiments, we are assaying the cytotoxicity of T and NK cells electroporated with CAR by saRNA-taRNA against CD19+ tumor cells.

Conclusion:
This study demonstrates the ability of saRNA and taRNA to sustain robust CAR expression in T cells. These findings highlight the potential for non-integrative, long-lived RNA-based therapies tailored to immune cells. Future efforts will focus on optimizing this platform for T and NK cells to enable *in vivo* delivery via lipid nanoparticles.

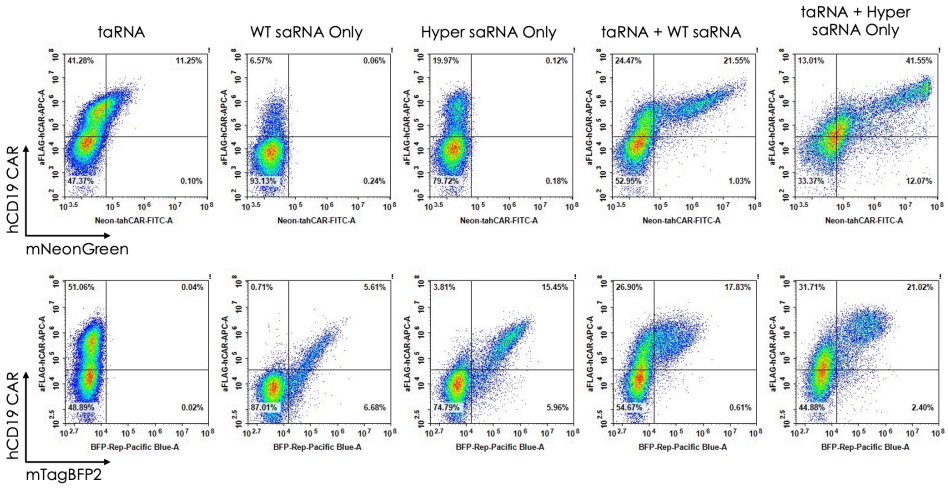

Figure 1. Flow cytometry 24 hours post-lipofection of HEK293T cells with taRNA alone, saRNA alone, or both ta- and saRNA. HEK293T cells were seeded at 30,000 cells/well in a 96-well plate one day before RNA transfection with Lipofectamine MessengerMax. The cells were transfected with 100 ng of taRNA, 100 ng of saRNA, or 100 ng of saRNA + 100 ng of taRNA. mNeonGreen and mTagBFP2 were the fluorescent reporters for taRNA and saRNA, respectively. The hyper-replicase demonstrated superior RNA replication to that of the wild-type replicase, resulting in higher levels of CAR and more cells expressing CAR in both the saRNA only and saRNA + taRNA conditions.

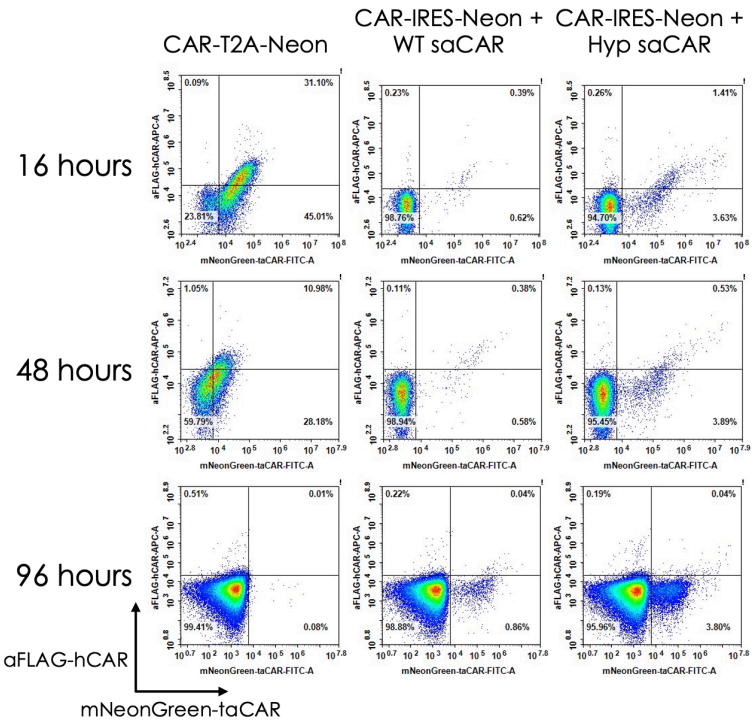

Figure 2. Flow cytometry analysis of RNA-electroporated primary human T cells. T cells, 7 days after removal of CD3/28 beads, were electroporated with 15 µg of linear mRNA encoding CAR-T2A-mNeonGreen, or with a combination of 5 µg taRNA (CAR-IRES-mNeonGreen) and 10 µg saRNA (WT or hyper saCAR). Results demonstrate that after 96 hours, the linear mRNA encoding CAR-T2A-mNeonGreen lost expression altogether, while both the conditions with sa- and taRNA maintained mNeonGreen expression. As T cells continued to expand at 48 and 96 hours, the mNeonGreen signal remained steady in cells transfected with the sa- and taRNA combination unlike that with cells transfected with linear CAR-T2A-Neon, indicating that RNA or protein was transferred to daughter cells and enabled longer-lasting expression.

AAV Vector Manufacturing: Experimental Design & Analytics

233 Quantification of Empty and Full Adeno-associated viral Capsids using Chip-Based Molecular Diagnostics

Introduction:
In the past decade, gene therapy has enabled a transformative shift in the treatment of genetic disorders. Of the options currently on the market, AAVs have gained popularity as the vehicle of choice for gene therapeutic delivery. The past decade has witnessed an accelerated approval pipeline of gene therapies by the FDA, as well as a rapid expansion of AAV therapy production. Despite these exciting developments, the biomanufacturing industry supporting process analytical technology (PAT) for AAV, specifically on differentiating full vs empty capsids, continues to lag. More importantly, ongoing research studies have revealed that administering a patient with an AAV dose that has partially filled or empty capsids has the risk of triggering immune responses and may compete for binding sites, resulting in reduced transduction.

Methods:
In this work, we developed a two-chip-based molecular diagnostic assay for at-line AAV quantification: the D4 (Dispense, Dissolve, Dissolve, and Detect) immunoassay for capsid titer and the CRISPR-AAV Evaluation (CRAAVE) assay for genome titer. The D4 assay utilizes fluorescently labeled detection antibodies (dAb) and capture antibodies (cAb) printed on a non-fouling polymer-coated glass slide. The dAb is printed onto soluble substrate so that it dissolves into the sample matrix upon sample addition and forms an immunocomplex at the cAb spots for fluorescent signal generation. The CRAAVE assay employs CRISPR-Cas12a for amplification-free genome detection. The CRAAVE assay utilizes the CRISPR/Cas12a system to recognize the AAV genome and subsequently cleave the F-Q reporters, where fluorescence from the cleaved reporters is correlated to genome titer. The assay composition is fully optimized in its lyophilized form on a miniature chip.

Results:
Through our two-chip assay, we achieved an empty-to-full capsid ratio within 30 minutes. Our D4 assay is multiplex friendly as the construction consists of multiple cAb zones specific for each serotype and AAX antibody fragment as our broadly nonspecific dAb. Additionally, the D4 assay has an impressive LOD of 6.5× 10^7 capsids/mL. The CRAAVE assay demonstrated high sensitivity, detecting AAV titers as low as 7 × 10^7 vg/mL with excellent precision (error <3%).

Conclusion:
We successfully developed a lab-on-a-chip solution that can provide the empty-to-full capsid ratio following a simplified, robust, and rapid protocol. Both the CRAAVE assay for genome titration and the D4 assay for capsid titer returned results comparable to ddPCR and ELISA but significantly reduced the user time and cost. The D4 assay and CRAAVE assay have been tested on AAV2, AAV5, and AAV6 serotypes and show great potential for adaption onto other AAV serotypes.

234 Leveraging Charge Detection Mass Spectrometry to Overcome Key Characterization Challenges in Recombinant Adeno-Associated Viruses

Anisha Haris[1], Rebecca D'Esposito[2], David Bruton[3], Keith Richardson[4], Jakub Ujma[5], Chris Wheeldon[6], Alistair Schofield[5], David Eatough[5], Michael Danby[5], Kevin Giles[7]
[1]Waters Corporation, Cheshire, Cheshire, United Kingdom, [2]Waters Corporation, Milford, MA, [3]Waters Corporation, Manchester, United Kingdom, [4]Waters Corporation, UNITED KINGDOM, [5]Waters Corporation, Wilmslow, United Kingdom, [6]Waters Corporation, Wilmslow, Cheshire, United Kingdom, [7]Waters Corporation

Recombinant adeno-associated viruses (rAAVs) are widely known as promising therapeutic modalities to treat a wide variety of genetic diseases. As AAV-based gene therapy progresses, there is an increasing need for advanced analytical tools to better characterize these therapeutics and streamline their production. Utilizing rAAVs for gene therapy requires evaluating and characterizing their critical quality attributes, which can significantly impact the safety and efficacy of the final product. Charge detection mass spectrometry (CDMS), using an electrostatic linear ion trap (ELIT), is a cutting-edge technique for ultra-high mass analysis. It simultaneously measures the mass-to-charge ratio (m/z) and charge (z) of individual ions, enabling calculation of their mass. CDMS is highly effective in characterizing rAAVs and their product-related impurities, which often present significant challenges for current methodologies and conventional mass spectrometry.

AAV empty and full capsid standards of various serotypes (AAV1, AAV2, AAV5, AAV6, AAV8 and AAV9) were buffer exchanged into 200mM ammonium acetate solution with 0.01 % Pluronic F-68 (Gibco) using Micro Bio-Spin columns (Bio-Rad). Ions were generated in positive ion mode using nanoelectrospray ionisation and mass analysis was performed using a prototype CDMS instrument. Signal processing and data visualization were performed using software developed in-house. Ions were trapped for 100 ms, and total acquisitions times were between 5 and 20 minutes. Detected time-domain signals were Fourier transformed; the measured frequency and the magnitude correspond to an individual ion's m/z and z respectively, enabling direct calculation of mass values. Data for individual ions were histogrammed to generate m/z, charge and mass spectra as well as 2-dimensional heat-maps.

An AAV serotype panel analysis was conducted, and the measured average masses were in good agreement with the theoretically expected mass values of the empty (3.8 MDa) and full capsids (4.5 – 5.5 MDa). This investigation also revealed distinct differences in the charge distributions of the various AAV serotypes, possibly due to the differences in viral protein content within the capsid structure. Additionally, for the full AAV capsid samples, empty particles were detected in AAV1, 2, 5, 8, and 9 with partial/intermediate particles detected in AAV1, 5, 6, and 9. These data highlight the ability of CDMS to readily distinguish between empty, full, and the partially full/intermediate capsids. A higher percentage of empty particles, around 12%, were detected in the full capsid samples of AAV5 and AAV8, which were manufactured in 2016. In contrast, the empty particle percentage in AAV1 and AAV9 samples, manufactured in 2020, was half of that or lower. For one of the samples, upon longer term storage at 4 °C, aggregates were detected at double the mass of the empty capsid (~ 8 MDa). This indicates that storage conditions of AAVs significantly impact their stability, which can ultimately affect the potency of the therapeutic product. The data presented here demonstrates that CDMS can effectively support the extended characterization of capsid population profiles, including capsid content determination based on AAV peak area ratios in the mass histogram. This advanced technique ensures accurate and comprehensive analysis, enhancing the overall quality control of gene therapy products.

235 Production of adeno-associated viral vectors by a novel human derived cell line HAT and comprehensive characterization of purified vectors

[Introduction]
Currently, the production of AAV vectors is mainly carried out using the transfection method with HEK293 cells or the baculovirus expression system. One of the major challenges in production is to obtain the AAV drug substance with a high full particle percentage, and there are two approaches to achieving this. One is to improve the full particle percentage during upstream process, and the other is to remove particles other than full particles by improving the purification method in downstream process. Meanwhile, how differences in manufacturing methods affect quality attributes are unclear, and the relationship between quality characteristics and efficacy and safety is still not fully understood. In this presentation, we will report on the manufacturability of AAV vectors using the novel human derived suspension cell line HAT and the quality characteristics of the manufactured AAV vectors.

[Methods]
In this study, we tested productivity by HAT cells of AAV vectors with serotypes, AAV2, AAV5, AAV6, AAV8 and AAV9, with GFP as the GOI. After producing AAV vectors using HAT cells with the triple transfection method, the titer and full-to-empty particle ratio (F/E ratio, F/(E+F)) was measured after the cell lysis followed by affinity chromatography, and then AAV vectors were prepared with more than 90% EF ratio through our small-scale purification platform. AAV vectors were also produced using the triple transfection method with HEK293 cells, AAV vectors with more than 90% EF ratio were prepared. Twelve quality attributes of each AAV vector produced

using the two cell lines were comprehensively determined and compared. We further studied AAV2, AAV5, and AAV9, with GFP as the GOI for detailed analysis. The production efficiency of AAV using HAT cells in flask was compared with those using bioreactor.

[Results and Discussion]
For all five serotypes, HAT cells produced AAV vectors with higher F/E ratio than those of HEK293 cells. Surprisingly, F/E ratio of AAV9 vector in cell lysis followed by affinity purification was more than 70% in the case of HAT cells, demonstrating high potential of HAT cells for the production of AAV vectors. Highly purified AAV vectors produced in HAT cells and HEK293 cells showed equivalence in all quality attributes except VP ratio. Bioreactor-based culture showed similar manufacturability to flask culture.

[Conclusion]
Based on these results, HAT is a novel human suspension cell line suitable for the production of AAV vectors with quality attributes equivalent to those from HEK cells, and now that we have confirmed its manufacturability in bioreactor, we plan to verify its usefulness for clinical trials and commercial production as well as for actual use.

236 Building efficient AAV testing platform: Prioritizing critical quality attributes with risk ranking-based scoring

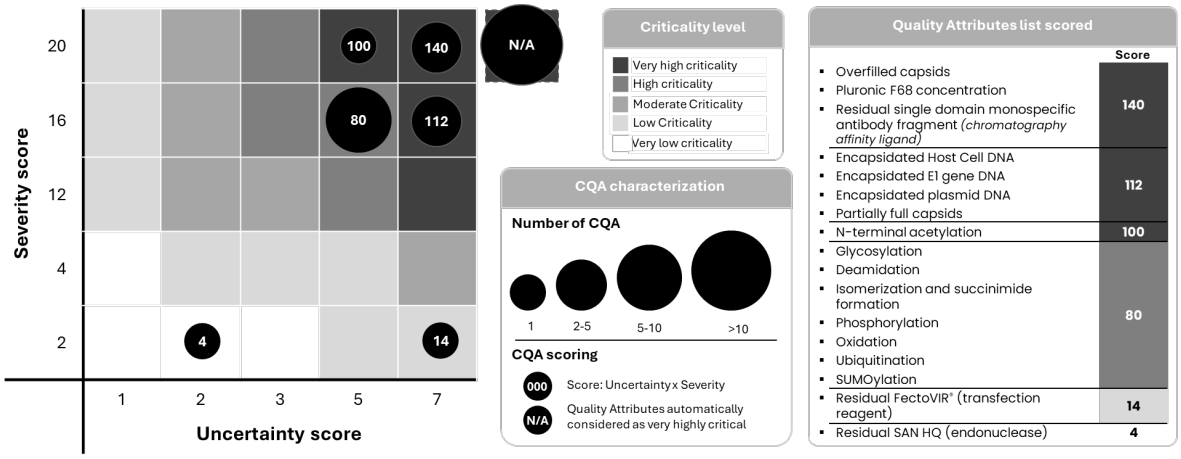
Emilie Gateau[1], Camille Lemaigre[2], Céline Tellier[3], Tiago Albano[4], Vasily Medvedev[4], Hanna Lesch[5]
[1]Exothera, Jumet, Walloonia, Belgium, [2]Exothera, Jumet, Hainaut, Belgium, [3]CREACT Consulting, Namur, Namur, Belgium, [4]Exothera, Jumet, Belgium, [5]Exothera Jumet, Beligium

Developing adeno-associated virus (AAV) gene therapies requires a robust and scalable manufacturing process ensuring consistent quality, safety, and efficacy. A critical component is the establishment of a Chemistry, Manufacturing, and Controls (CMC) strategy that addresses the complexities of viral vector production. Using Quality by Design (QbD) methodology support early identification, and control of critical process parameters and quality attributes (CQAs) throughout the product lifecycle. By proactively integrating QbD principles, manufacturers can mitigate risks and meet regulatory requirements supporting the successful development, approval, and commercialization of AAV-based gene therapies.

We adopted three different methodologies based on data availability, CQA's nature and complexity. The first methodology, risk ranking and filtering, applies when access to clinical data is limited. The second one, preliminary hazard analysis, is used when (pre-)clinical data are available. The third assess process-related impurities based on the calculation of an impurity safety factor.

For the AAV ExoREADY™ platform at current developmental phase, the first tool was used to assess the criticality of the quality attributes. The criticality score is determined based on severity (efficacy, PK/PD, immunogenicity, safety) and uncertainty scores, leading to the ranking of 32 highly critical CQAs (see Figure 1). Based on compendial and regulatory expectations, 24 CQAs were identified as obligatory CQAs. Critical quality attributes for AAV gene therapy include capsid and genome identity, integrity, and purity, ensuring the correct structure and function of the viral vector. Additional factors such as empty capsids, vector aggregates, residual host cell components (proteins, DNA, E1 gene, plasmids), titers (capsid, vector genome, infectious particles), genetic insert expression, biological activity, and absence of contaminants (adventitious viruses, mycoplasma) are essential for safety and efficacy.

This methodology helped prioritize analytical development and confirm the manufacturing process's ability to produce high-quality AAV. A robust control strategy ensures investigational drugs are safe and effective for clinical applications. Additionally, the ExoREADY™ platform provides an optimized, pre-developed framework for efficient, cost-effective gene therapy production. With at least 134 AAV products in clinical trials in 2022 and 9 already FDA/EMA-approved as of 2022, staying aligned with evolving scientific understanding of AAV is crucial. Continuous CQA scoring guiding review, analytical portfolio expansion, and process improvements will ensure the platform adapts to new insights, clinical data, and industry advancements.



237 Enhanced AAV Capture Using Membrane Chromatography and Optimized Mid-Stream Processing

Enhanced AAV Capture Using Membrane Chromatography and Optimized Mid-Stream Processing
Membrane chromatography offers an innovative solution for the capture of adeno-associated viruses (AAV), addressing bottlenecks associated with traditional resin-based technologies, offering significantly improved productivity and reduced processing time by increased throughput and high dynamic binding capacity.

This work demonstrates the advantages of using strong cation exchange Natrix® CH membrane chromatography in an AAV2 and AAV9 non-affinity capture process following an optimized mid-stream approach for simple and robust processing. The process is shown to be a viable, cost-effective, and flexible alternative that meets the need for a serotype-independent capture solutions. By optimizing critical mid-stream steps, this new process enables fast processing at up to 8 MV/min while maintaining high dynamic binding capacities (>1E14 vp/mL) and low pressures during the capture phase. Importantly, these strategies ensure that both genome titer and AAV infectivity are retained throughout the purification process.

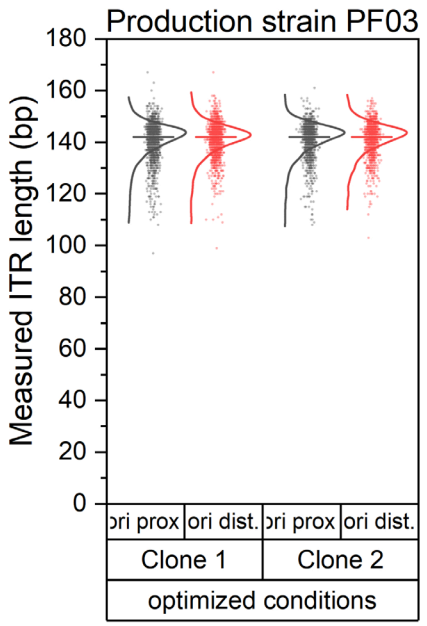
238 Stable maintenance of full-length ITRs in AAV transfer plasmids

Ram Shankar[1], Marco Radukic[2], Dinh To Le[3], Susanne Golm[3], Nina Schäffer[4], Martin Schleef[5], Kristian Müller[3]
[1]PlasmidFactory GmbH, Bielefeld, Nordrhein-Westfalen, Germany, [2]Bielefeld University, 33615 Bielefeld, Germany, [3]Bielefeld University, Bielefeld, Germany, [4]PlasmidFactory GmbH, Bielefeld, Germany, [5]PlasmidFactory GmbH & Co KG, Bielefeld, Germany

The inverted terminal repeats (ITRs) of adeno-associated virus (AAV) are a critical feature for the rescue of the AAV genome from the transfer plasmid containing the transgene and for efficient rAAV genome packaging into capsids. Full-length ITRs are effective in producing full capsids and homogeneous payloads. However, these largely palindromic sequences are prone to secondary structure formation and often tend to acquire deletions during bacterial propagation of transfer plasmids. Such plasmid populations containing truncated ITRs seriously undermine plasmid homogeneity and cause shortcomings in AAV yield and genomic purity.

In this study, we show that, by turning to optimized fermentation conditions such as cultivation temperature and by choosing the right bacterial strain containing mutations in genes responsible for genome organization, *E. coli* was denied the conditions that would potentially lead to ITR sequence deletions. These experiments were complemented by a robust analytical tool to measure ITR lengths in a plasmid population using next generation sequencing (NGS). Additionally, ITR length variants were characterized using capillary gel electrophoresis, which was found to be a complementary, rapid in-process control method. Furthermore, we replicated these results in a bioreactor cultivation and produced an AAV transfer plasmid containing full-length wild type ITRs. Taking this development a step further, we recently produced the first AAV transfer minicircle containing full-length ITRs and devoid of bacterial backbone sequences. The minicircle resulted in high yields of vectors in initial transfection experiments in HEK-293 cells.

We thus demonstrate our ability to obtain ITR sequences in their full length (wild type length), maintain them in that state during plasmid production and effectively track them by a robust analytical method. These findings open new possibilities for AAV manufacturers to increase their vector yield and quality.



239 Shedding Light on AAV Manufacturing: Application of Raman Spectroscopy for Real-Time Process Monitoring

Olaide Ibiyemi[1], Jennie Gullick[2], Samantha Higgins[2], Stefanie Frank[3], Stephen Goldrick[3]
[1]University College London, LONDON, Greater London, United Kingdom, [2]Cytiva, Portsmouth, United Kingdom, [3]University College London, London, United Kingdom

Introduction:
The success of adeno-associated virus (AAV) gene therapies has driven the demand for scalable, reliable, and reproducible manufacturing processes to meet clinical needs. However, AAV production by transient transfection is complex and presents significant challenges. The efficacy and consistency of the process is influenced by multivariate interactions between raw materials, process conditions and transfection parameters. Achieving reproducible processes with high product quality requires precise control of the dynamic biological system. Real-time monitoring of process variables can help improve process understanding to facilitate informed decisions for improved yields and batch-to-batch consistency.

Traditional analytical methods rely on offline sampling, which is time-consuming and lacks the ability for real-time measurements. Process Analytical Technologies (PAT) address this limitation by providing in-situ measurements for enhanced monitoring and control. Raman spectroscopy is a non-invasive analytical technique that can be used for this. It is based on the inelastic scattering of monochromatic light and enables measurements of a sample's composition from a single spectral measurement. Here, we apply Raman spectroscopy to the monitoring of key parameters including viable cell density (VCD), glucose, lactate and ammonia concentrations during AAV production.

Method:
Raman spectroscopy was applied to a 3L transiently transfected AAV2 production process in HEK293F cells (Figure 1). Spectra were recorded every 12.5 minutes using a 785 nm Raman analyser (Endress+Hauser), while offline samples were collected twice daily to measure VCD using the ViCell Blu (Beckman Coulter) and to determine glucose, lactate, and ammonia concentrations using the BioProfile FLEX (Nova Biomedical). Due to the large and highly dimensional datasets generated, multivariate data analytics tools are required for data interpretation. Partial Least Squares (PLS) regression was used to develop models correlating Raman spectra with offline measurements. The predictive performance of these models was evaluated using the coefficient of determination (R^2) which quantifies how closely the model predictions match the measured values. An R^2 value closer to 1 indicates strong predictive performance and a good fit between predicted and measured data.

Results and Conclusions:
The PLS models demonstrate strong predictive performance with R^2 values exceeding 0.7 on unseen data. The VCD model achieved an R^2 of 0.77 for cell densities ranging from 0.3 to $2.5x10^6$ cells/ml. As transfection is often based on VCD, this model could be used to optimize viral titre and productivity. Glucose and lactate models showed high accuracy, both with R^2 values of 0.99, strongly aligning with the offline data. The ammonia model achieved an R^2 of 0.93, demonstrating reliable predictions.

These results highlight the potential of Raman spectroscopy to enhance process understanding and control in AAV manufacturing while reducing the reliance on offline sampling. By providing real-time insights into culture dynamics, it can enable more effective monitoring, improved process control, and support the development of optimized feeding strategies. This approach can contribute to greater consistency and improved product quality in AAV production.

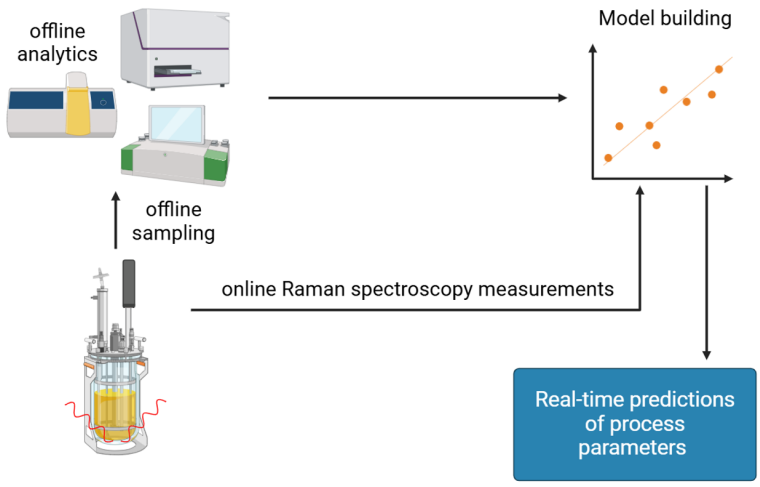


Figure 1. Methodology for online Raman spectroscopy analysis of process variables in AAV2 production in 3L bioreactors.

Vaccines and Immunotherapy for Cancer

240 Programmable Adeno-Associated Virally Delivered Lifelong In Vivo T Cell Engagement Provides a Novel Framework for Prevention and Treatment of Metastatic Cancer

Timothy Cripe[1], Mark Currier[2], Pin-Yi Wang[3], Chun-Yu Chen[4], Andrea Glaspell[5], Allen Reha[6], Debashree Das[7], Danielle Hanlon[7], Allan Kaspar[7], Samit Varma[7], Brian Kaspar[7], Jacob Scott[8], Brian Hutzen[4]
[1]Nationwide Children's Hospital, Columbus, Ohio, [2]Nationwide Children's Hospital, [3]The Research Institute at Nationwide Children's Hospital, Columbus, OH, [4]The Research Institute at Nationwide Children's Hospital, Columbus, OH, [5]Nationwide Children's Hospital, Columbus, OH, [6]Vironexis Biotherapeutics, Millstone Township, NJ, [7]Vironexis Biotherapeutics, Inc., San Diego, CA, [8]Cleveland Clinic, Cleveland, OH

Cancer remains the most common cause of death due to disease in children and the second leading cause of death due to disease in adults, behind heart disease. Deaths in patients with solid tumors mostly result from the development of metastases, as exemplified by neuroblastoma in children and breast and gastrointestinal cancers in adults. Metastases are thought to arise from circulating tumor cells, in what could be thought of as the “leukemic compartment” of solid tumors. Furthermore, metastatic relapses that often occur years after treatment is finished result from reactivation of quiescent, disseminated cancer cells that escape prior therapies. Preventing the initial dissemination and the subsequent reawakening of these cells will thus require a treatment that is systemically and consistently active over years. We reasoned that circulating tumor cells, or those early in the metastatic process or in isolated deposits, exist outside of their immunosuppressive microenvironment and may thus be vulnerable to immunotherapy. We propose that long-term, persistent cytotoxic pressure directed at validated tumor associated antigens can be achieved using gene therapy and be effective in preventing the development of metastases. To test our hypothesis, we created two adeno-associated virus (AAV) constructs expressing a secreted bispecific T cell engager (termed "TransJoin") targeted to either the disialogangioside GD2, highly upregulated on neuroblastoma, or HER2, a well-known cancer driver upregulated on breast, gastric and other cancers. Using the purified bispecific proteins, we found dose-dependent cytotoxicity of cancer cell lines cocultured with human peripheral blood mononuclear cells (hPBMCs) that was proportional to cell surface target density, with no detectable killing in cells with low cell surface target density. In immunodeficient (NSGS) and immunocompetent (Balb/c and C57BL6) mice, we achieved consistent steady-state serum levels of the transgene product for >1 year following a single AAV administration, compared with the 2-hour half-life of the protein. To evaluate anti-metastasis efficacy, we tested

these vectors in models of luciferase-tagged GD2+ neuroblastoma or HER2+ breast and gastric cancers, enabling us to measure and track metastases by bioluminescent imaging over time. Following administration of a bolus of intravenous human cancer cells into immunodeficient mice peripherally humanized with intravenous blood mononuclear cells from normal human donors, systemic injection of the relevant AAV construct prevented >99% metastases in each model compared with animals given a control virus. The effect was seen even if we waited a week to allow establishment of metastases. Utilization of a murine host doubly knocked out for HLA class I and II (DKO) reduced the development of graft-vs-host disease seen in NSGS mice and enabled us to observe protection against metastasis >140 days after tumor cell injection. We are currently testing the HER2 construct in formal toxicology and IND-enabling antitumor efficacy studies. Overall, our data suggest that expression of protein-based immunotherapeutics via an AAV platform represents a novel adjuvant therapy for the treatment and prevention of cancer metastasis and recurrence.

241 Employing Pre-Existing Immunity Against Pathogens for Enhanced Cancer Immunotherapy via mRNA Vaccines

Jian-Dong Huang[1], Renhao Li[2], Xiang Gao[3]
[1]The University of Hong Kong, Pokfulam, Central and Western, Hong Kong, [2]The University of Hong Kong, Pokfulam, Hong Kong, [3]Durham, NC

Introduction
We explored a novel cancer immunotherapy strategy that suppresses tumor growth and extends the lifespan of tumor-bearing mice. This strategy introduces pathogen antigens into tumors via mRNA-lipid nanoparticles, leveraging pre-existing immunity to enhance therapeutic efficacy.

Objectives
Our goal was to assess whether mRNA-based vaccines could tag tumor cells with pathogen antigens and mobilize pre-existing immune responses to eliminate cancer cells. Specifically, we tested if prior immunization with the BNT162b2 COVID-19 vaccine would enhance the anti-tumor response against tumors tagged with the same protein.

Methods
The study used multiple tumor models in mice. Mice previously immunized with the BNT162b2 encoding the SARS-CoV-2 spike protein received intratumoral injections of the same vaccine. We measured tumor growth suppression, lifespan extension, mobilization of memory immunity, reprogramming of the tumor microenvironment, and tumor antigen-specific T-cell responses. Statistical analyses determined the significance of the results.

Results
Intratumoral injections of BNT162b2 in previously immunized mice tagged tumor cells with the mRNA-expressed spike protein. This rapidly mobilized pre-existing memory immunity against SARS-CoV-2, leading to the elimination of cancer cells displaying the spike protein and reprogramming of the TME by attracting immune cells. Partial elimination of tumor cells in a normalized TME triggered extensive tumor antigen-specific T-cell responses through antigen spreading, resulting in potent systemic tumor-targeting immune responses. Combining BNT162b2 treatment with anti-PD-L1 therapy yielded a substantial therapeutic impact, even in "cold tumors" typically less responsive to treatment.

Conclusion
Leveraging pre-existing immunity against pathogen antigens via mRNA-based vaccines, such as BNT162b2, significantly enhances cancer immunotherapy efficacy. Given widespread memory immunity against various pathogens from prior infections or vaccinations, this approach could rapidly transition into clinical use. mRNA vaccines against other pathogens, such as HBV, Common Human Coronaviruses, and influenza virus, hold great potential for treating different cancers and overcoming drug resistance, providing a promising alternative for cancer patients.

242 mRNA-LNP Vaccine Providing Antigen and Co-Stimulation in the Tumor Microenvironment (CART-Vac) Enhances CAR-T Cell Function

Shoji Saito[1], Ikumi Nakashima[2], Eiichi Akahoshi[3], Mitsuko Sugano-Ishihara[3], Shigeki Yagyu[4], Yozo Nakazawa[5]
[1]Shinshu University, Matsumoto, Nagano, Japan, [2]Shinshu University School of Medicine, Nagano Pref., Japan, [3]Toshiba Corporation, Kawasaki, Japan, [4]Shinshu University, Kyoto, SA, Japan, [5]Shinshu University School of Medicine, Matsumoto, Japan

Introduction
The immunosuppressive tumor microenvironment (TME) in solid tumors induces T cell exhaustion, compromising the expansion and functionality of CAR-T cells. Preserving the stemness of CAR-T cells within the TME is crucial for sustaining long-term efficacy. Previously, we established a CAR-T cell manufacturing process that preserves stemness by co-culturing CAR-T cells with antigen-presenting PBMCs overexpressing target antigens (TA) and co-stimulatory molecules (CSMs). This approach highlighted the importance of physiological T cell stimulation through antigen presentation and co-stimulation in maintaining CAR-T cell memory function. We hypothesized that inducing TA and CSM overexpression within the TME could similarly enhance CAR-T cell expansion and improve anti-tumor activity in an immunosuppressive environment. To validate this, we examined CAR-T cell functionality in the context of genetically modified sarcoma cells engineered to overexpress TA and CSMs. Furthermore, we assessed the synergistic effects of intratumoral administration of an mRNA lipid nanoparticle (LNP) vaccine encoding TA and CSMs (CART-Vac) to investigate its potential in boosting CAR-T cell efficacy against solid tumors.

Methods
To generate genetically modified tumor cells, the EPHB4-positive sarcoma cell line Rh30 was transduced with truncated EPHB4, CD80, and CD137L, creating Rh30-TACS cells. EPHB4 CAR-T cells were developed using *piggyBac* transposon-mediated gene modification, as previously described. CART-Vac was produced by synthesizing mRNA encoding truncated EPHB4, CD80, and CD137L, which was then encapsulated in LNPs with specific tropism for Rh30 cells. We evaluated the *in vitro* and *in vivo* anti-tumor efficacy of these CAR-T cells, focusing on their expansion and activity within the TME against Rh30-TACS cells. Additionally, we assessed the synergistic anti-tumor effects of combining CART-Vac with EPHB4 CAR-T cell therapy via intratumoral administration.

Results
Flow cytometry confirmed that Rh30 cells expressed EPHB4 but lacked CD80 and CD137L, whereas Rh30-TACS cells overexpressed all three. EPHB4 CAR-T cells exhibited enhanced cytotoxicity, robust proliferation, and increased secretion of pro-inflammatory cytokines against Rh30-TACS compared to Rh30 cells *in vitro*. *In vivo*, EPHB4 CAR-T cells achieved superior tumor control in Rh30-TACS-bearing mice, with increased T cell proliferation and infiltration into tumor tissues, compared to Rh30-bearing mice. CART-Vac successfully transfected Rh30 cells, inducing overexpression of EPHB4, CD80, and CD137L, with peak expression observed 24 hours post-treatment. Pretreatment of Rh30 cells with CART-Vac enhanced the in vitro anti-tumor functionality of EPHB4 CAR-T cells, promoting robust CAR-T cell expansion. In Rh30-bearing mice, CART-Vac pretreatment efficiently induced tumor-localized expression of EPHB4, CD80, and CD137L. Furthermore, the combination of intratumoral CART-Vac and systemic EPHB4 CAR-T cell therapy significantly enhanced tumor growth suppression and CAR-T cell expansion *in vivo*.

Conclusion
LNP-based CART-Vac effectively induces tumor-localized expression of TA and CSMs, significantly enhancing CAR-T cell efficacy. This combinatorial strategy holds promise for overcoming TME-associated challenges and improving CAR-T therapy outcomes in solid tumors.

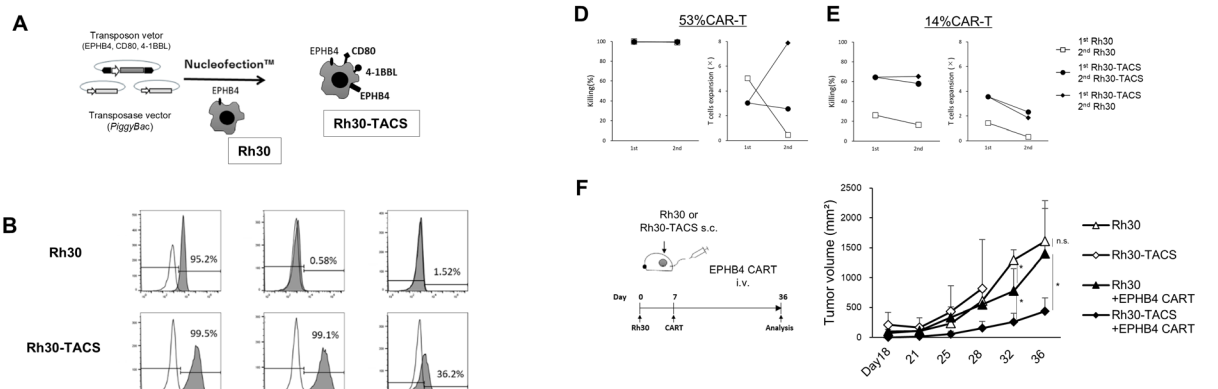

Figure 1. Overexpression of TAA and co-stimulatory molecules enhanced the efficacy of EPHB4 CARTs

(A) Schema of genetically modified Rh30 cells with stably expressing TA and CSMs (Rh30-TACS).
(B) EPHB4, CD80, and 4-1BBL expression in Rh30 or Rh30-TACS cells by flowcytometry.
(C) EPHB4, CD80, and 4-1BBL expressions in Rh30 or Rh30-TACS tumors by immunohistochemistry.
(D) Overexpression of TA and CSMs significantly enhanced the anti-tumor effects of EPHB4 CART cells *in vitro*. EPHB4 CAR-T cells with CAR expression of 53% were used.
(E) Similar serial co-culture experiment results as (D) but using CARTs with CAR expression of 14% were used.

243 Cancer Immunotherapy Using AIRE Conditioning of the Tumour Epitopeome

Jose Pulido[1], Alex Chen[2], Benjamin Kendall[3], Jason Tonne[4], Muriel Metko[3], Jill Thompson[5], Thanich Sangsuwannukul[4], Maria Chiriboga[6], Rosa Diaz[3], Mason Webb[3], Amanda Huff[2], Madelyn Moore[3], Matthew Schuelke[2], Sheeba Irshad[7], Elizabeth Appleton[8], Alan Melcher[9], **Richard Vile[4]**
[1]Wills Eye Hospital, Bryn Mawr, PA, [2]Mayo Clinic, Rochester, [3]Mayo Clinic Minnesota, [4]Mayo Clinic, Rochester, MN, [5]Mayo Clinic Minnesota, Rochester, MN, [6]Mayo Clinic, Rochester, Rochester, MN, [7]King's College London, London, United Kingdom, [8]The Institute of Cancer Research, London, United Kingdom, [9]The Institute of Cancer Research, London, England, United Kingdom

T cell immune tolerance is established in part through the activity of the Auto-immune Regulator (AIRE) transcription factor in the medullary Thymic Epithelial Cells (mTEC) of the thymus by expressing a broad profile of SELF peripheral tissue-specific antigens for presentation to naïve T cells to promote activation/deletion of potentially autoreactive T cells. Here, we hypothesized that AIRE expression in tumors may mimic its role in mTEC - but with the opposite purpose of setting a steady-state profile of SELF epitopes against which no functional T cell reactivities exist thus cloaking the tumor from T cell attack. We show that changes in AIRE expression in tumor cells altered their profile of SELFNESS by changing the balance of AIRE-regulated epitopes occupying MHC Class I molecules. AIRE-induced altered SELFNESS significantly enhanced adoptive T cell therapy and stimulated heteroclitic $CD8^+$ T cell-mediated rejection of tumors through dendritic cell-mediated vaccination or *in vivo* delivery of AIRE-expressing vectors. Anti-tumor therapy was supported by AIRE-mediated generation of helper $CD4^+$ T cell epitopes and enhanced by immune checkpoint blockade. Our data are significant in that they demonstrate that changes in AIRE steady state levels re-sets the SELFNESS of cancer cells and converts a highly tolerized T cell compartment into a heteroclitic tumor-reactive T cell population. Exploiting AIRE as a master switch to manipulate tumor SELFNESS removes the need to identify specific TAA as targets for generation of *de novo* $CD8^+$ and helper $CD4^+$ T cell responses which can clear tumors and can be supported by additional immunotherapy interventions.

244 Unlocking Durable Anti-Tumor Immunity: Oncolytic Virotherapy as a Solution to Tumor Vaccine Shortcomings

William Jia, Virogin Biotech Canada Ltd., Richmond, BC

Tumor vaccines have shown clinical promise in certain cancers, yet their efficacy is limited by two major challenges: (1) the immune-suppressive tumor microenvironment (TME), and (2) limitation of only targeting antigen-positive tumor cells, which can result in the overgrowth of antigen-negative cells and eventual relapse.

To address these barriers, we explored a combination approach using mRNA tumor vaccines and oncolytic virotherapy in HPV and HER2 mouse tumor models. Our results indicate that while mRNA vaccines effectively eliminate antigen-positive tumors and inhibit their initial growth, tumors rapidly develop resistance, allowing them to escape the vaccine's effects.

However, introducing oncolytic virotherapy after mRNA vaccination—whether the virus expressed HPV or HER2 antigens or not—significantly extended the durability of anti-tumor responses in both models. The oncolytic virus, through its lytic infection, facilitated broad and dynamic tumor antigen presentation, lysing tumor cells and releasing a wide variety of tumor-associated antigens. This process not only increased the antigenic diversity within the tumor but also reprogrammed the TME, converting it from an immune-suppressive to an immune-supportive environment.

The combination of mRNA vaccination with oncolytic virotherapy generated a robust local immune response, driven by enhanced antigen presentation from viral infection. Additionally, the reprogrammed TME allowed the systemically established anti-tumor immunity from the mRNA vaccine to infiltrate and act within the tumor, overcoming previous immune barriers. We also observed the development of systemic antigen-specific T cells, which provided resistance to subsequent tumor challenges, indicating strong immune memory.

These findings underscore the unique role of oncolytic virotherapy as an intratumoral “boost” agent, capable of broadening tumor antigen exposure through tumor cell lysis while reconditioning the TME to amplify the effects of the systemic tumor vaccine. When combined in a prime-boost regimen, mRNA vaccines and oncolytic virotherapy synergize to create a robust, durable anti-tumor response that acts both locally and systemically to protect against recurrence.

In conclusion, our study demonstrates that combining mRNA tumor vaccines with oncolytic virotherapy is a powerful strategy to enhance tumor antigen presentation, reshape the TME, and overcome immune evasion, offering a promising approach for achieving durable anti-tumor immunity.

245 A Dual-Stimulatory Receptor Provides T-Cell Activation-Dependent Costimulation to Augment Native and Transgenic TCR-Based T-Cell Therapies

Mansi Narula[1], Johannes Englisch[1], Azlann Arnett[1], Maksim Mamonkin[2], Norihiro Watanabe[2]*
[1]Baylor College of Medicine, Houston, TX, [2]Baylor College of Medicine, Houston, Texas
**Corresponding Author*

TCR-based cell therapies produce highly sensitive tumor targeting. Unlike CAR-based receptors, a TCR complex lacks inherent ancillary costimulatory (Signal 2) and elicits reduced cytokine (Signal 3) signals required for functional T-cell persistence in vivo. Physiologically, these signals are provided in sync with Signal 1 and are contingent on TCR stimulation. In contrast, most current strategies to provide such signals to T cells include incorporating an additional antigen receptor (e.g. a costimulatory CAR) or integrating constitutive signals (e.g. cytokine modification) which function independently of the main antigen receptor. Therefore, we developed a synthetic Dual-Stimulatory Receptor (DSR) which provides both Signals 2 and 3 in response to the TCR activation (Signal 1).

An optimized DSR consists of a 4-1BB ligand (4-1BBL) extracellular domain linked to the cMPL (thrombopoietin receptor) intracellular domain. The 4-1BBL in the DSR interacts with the endogenous 4-1BB which is transiently upregulated upon TCR stimulation, thus inducing native 4-1BB co-stimulation (Signal 2) and downstream NF-kB signaling. Additionally, this engagement initiates cMPL signaling from the DSR leading to STAT3 and STAT5 phosphorylation in activated T cells, providing a cytokine-like Signal 3. In the absence of TCR stimulation, 4-1BB is downregulated and the DSR signaling is switched off, preventing constitutive activation. Indeed, T cells engineered with DSR (n=7) persisted over 8 rounds of repeated CD3 stimulation *in vitro* while unmodified T cells fail to expand beyond 3 rounds. Control T cells modified with *wild-type* 4-1BBL or truncated DSR lacking the cMPL endodomain also ceased expanding after 4 rounds of stimulation. The DSR+ T-cell fraction was enriched over time during repeated antigen stimulation demonstrating the phenotypic advantage that promotes T-cell expansion and persistence. Of note, DSR+ T cells did not expand upon cessation of CD3 stimulation demonstrating signal 1-dependent DSR-mediated T cell expansion.

We assessed the benefit of DSR in preclinical models of hematological malignancies: Acute Myeloid Leukemia (AML) targeted by CD123 T-cell engagers (TCEs)-secreting T cells and B-cell leukemia targeted by survivin/HLA-A2-specific transgenic TCR. The anti-tumor activity and cell persistence of TCE-secreting T cells (TCE-T) against an aggressive CD123+ Molm-13 AML cell line was dramatically enhanced by DSR modification in a short-term *in vitro* assay (>155-fold higher T-cell expansion than unmodified TCE-T on Day 9 of coculture) and long-term *in vivo* (Median Survival, TCE-T: 24 days vs DSR+TCE-T: >90 days). DSR-modified T cells persisted in mice long-term and mounted a secondary anti-tumor response upon re-challenge on day 35 after the initial challenge. Similarly, DSR armed CD8 T cells expressing a survivin-specific TCR expand and persist in vivo improving tumor clearance in an ongoing BV173 B-cell leukemia xenograft model (53-fold less tumor burden and 18-fold higher T-cell expansion over control on Day 21 post T-cell infusion as measured by in vivo bioluminescence signal). Overall, these results support using the DSR to boost TCR-based T cell therapies of cancer.

246 APC-Targeted LNP Enables Systemic Delivery of Neoantigen mRNA Vaccines and Enhanced Antigen-Specific T Cell Responses

Jingwei Sun[1], Xi Zhu[2], Zhao Xu[3], Ke Liu[3], Chenxi Hou[4], Hong Chen[4], Jiaming Ren[4], Zhenjiang Liu[3], **Pin Wang[5]**, Yarong Liu[3]
[1]Grit Biotechnology, Shanghai, Shanghai, China, [2]Shanghai Vitalgen Biopharma, Shanghai, Shanghai, China, [3]Grit Biotechnology, Shanghai, China, [4]Shanghai Vitalgen Biopharma, Shanghai, China, [5]University of Southern California, Los Angeles, CA

mRNA cancer vaccines have demonstrated promising clinical efficacy in patients with solid tumors. Currently, the primary clinical delivery methods for mRNA cancer vaccines are intramuscular (i.m.) injection using classic lipid nanoparticle (LNP) formulations and intravenous (i.v.) administration of lipoplex (LPX) that target antigen-presenting cells (APCs). However, even with i.m. delivery, classic LNP formulations can cause significant liver expression, raising concerns about liver toxicity, especially with repeated dosing. APC-targeted delivery of tumor antigen mRNA can enhance antigen-specific T cell responses while minimizing off-target toxicity. The permanently charged cationic lipids in LPX is associated with heightened toxicity, thereby limiting their tolerable dosage and clinical efficacy. In this study, we identified and developed a novel APC-targeted LNP (APC-LNP) formulation through the Dakini™ platform. Through an extensive screening of diverse ionizable lipid structures, lipid compositions and formulations, evaluated on human peripheral blood mononuclear cells (hPBMCs) and mouse models, we optimized a formulation that efficiently targets APCs across multiple organs with minimal off-target transfection in liver and lung parenchymal cells after i.v. injection, potentially enabling safe systemic administration. We compared the APC-LNP's ability to induce antigen-specific T cell responses with clinically used LPX and classic LNP formulation using the classic OVA-OT-I model. The effective dose for inducing OT-I-specific T cells with OVA-APC-LNP was ten times lower than with OVA-LPX via i.v. injection. Moreover, i.v. injection of OVA-APC-LNP resulted in significantly higher OT-I T cell induction compared to i.m. administration with classic LNP. The therapeutic efficacy of neoantigen vaccine was evaluated in a lung metastases model with CT26 tumor cells being intravenously inoculated. Twenty neoantigens, predicted using our AI-based neoantigen discovery platform NEOvigator™, were delivered via APC-LNP, achieving complete tumor suppression. In the aggressive and poorly immunogenic B16-F10 tumor model, the neoantigen vaccine showed significant tumor suppression. ELISpot analysis of neoantigen-specific responses in the spleen revealed a 52.6% response rate for predicted neoantigens. These results led to the development of our neoantigen cancer vaccine pipeline, GT601. The manufacture process for GT601 aligns with the standard for mRNA-LNP vaccine production. Preclinical toxicology studies across multiple species confirmed its favorable tolerability. GT601 is currently undergoing clinical evaluation in an investigator-initiated trial in China.

Organoids and iPSC Disease Modeling for Drug Discovery

247 Engineering Functionally Mature iPSC-derived Hepatocytes through Mapping Transcription Factor Regulatory Mechanisms

Helen Streff[1], Charles Gersbach[1], Mackenzie Parmenter[2], Samuel Reisman[1], Chloe McGeehan[1]
[1]Duke University, Durham, NC, [2]Factor Bioscience Inc., Cambridge, MA

The growing interest in differentiating induced pluripotent stem cells (iPSCs) into hepatocytes (iHeps) is driven by the shortage of liver donors for transplantations and the scarcity of primary human hepatocytes (PHHs) for toxicology studies. Thus far, iHeps have recapitulated many functions of primary hepatocytes enabling their usage in humanized transgene-free Il2rg-/-/Rag2-/-/Fah-/- (TIRF) mouse models and in vitro modelling assays. However, current protocols yield iHeps with immature gene expression and epigenetic signatures. In fact, we observed that primary hepatocytes have >75-fold and >7-fold higher expression of mature hepatocyte markers ALB and SERPINA1, respectively, compared with iHeps generated by conventional protocols. Additionally, our multi-omic single-cell ATAC-seq and RNA-seq analysis of iHeps demonstrates that only a subset of the cell population gains expression of mature hepatic markers. Deficiencies in maturity lead to limitations in the usage of iHeps as a cell

therapy and in disease modelling. Transcription factors (TFs) have pioneering roles in coordinating gene expression networks during liver development, and the inability of current protocols to recapitulate correct TF expression throughout the differentiation protocol likely contributes to the functional deficiencies of iHeps. To address these limitations, we employed TFome-wide open reading frame (ORF) overexpression and CRISPRko screens to identify factors that promote iHep maturity. Two iPSC lines were lentivirally transduced with libraries of either ORFs or guide RNAs and differentiated to iHeps. Subsequently, cells were immunostained for albumin and subjected to fluorescence-activated cell sorting (FACS) to isolate cells based on albumin levels. This process generated a list of 45 TFs putatively implicated in driving mature liver phenotypes when overexpressed, including TFs with known roles in liver development such as HNF4A, FOXA2, and NR5A2. Interestingly, several TFs had no previously established role in liver development or hepatocyte differentiation, suggesting the advantage of an unbiased screen in discovering novel regulators of in vitro cell fate. Validation experiments by RNA-seq corroborated the screen and confirmed the ability of most hits to upregulate the expression of maturation markers, including upregulation of ALB and SERPINA1 over 30- and 100-fold compared with negative controls, respectively. Further, scRNAseq demonstrated that the TF perturbations push the cells towards a more homogenously mature population. Functional experiments show that hit TFs produced iHeps with increased secretion of the liver-specific proteins albumin, angiotensin, fibrinogen, apolipoprotein A2, alpha-1-acid glycoprotein 1 and serpina1, and a morphology more closely resembling PHHs. To identify TFs that have both synergistic and complementary maturation effects, top validated hits were studied in combination. Three TFs (PPARG, NR5A2, and KLF7 (PNK)) uniquely led to augmented hepatic transcriptomic profiles when overexpressed together relative to each TF alone. PNK-iHeps enable long-term, functionally mature phenotypes in vitro. Ongoing work includes studying the gene regulatory networks through ATAC-seq and RNA-seq that enable the PNK factors to have a superior role in driving the maturation of iHeps and the potential for PNK-iHeps to be useful therapeutically in a humanized TIRF mouse model.

248 Phenotypic Characterization and AAV-Mediated Therapeutic Delivery in *C9ORF72* ALS iPSC-Derived Motor Neurons

Katherine Whiteman[1], Gregory Cajka[2], Yonghong Chen[1], Jean Ann Maguire[2], Deborah French[2], Ophir Shalem[2], Esteban Mazzoni[3], Beverly Davidson[1], Defne Amado[4]
[1]Children's Hospital of Philadelphia, Philadelphia, PA, [2]Children's Hospital of Philadelphia, Philadelphia, [3]Children's Hospital of Philadelphia, New York, [4]University of Pennsylvania, Philadelphia, PA

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by progressive paralysis and premature death. Hexanucleotide repeat expansions in the C9ORF72 gene are the leading genetic cause of ALS accounting for approximately 40% of familial cases. At the cellular level, 97% of ALS cases exhibit nuclear loss and cytoplasmic aggregation of the RNA-binding protein TDP-43, which is known to interact with ATXN2 in stress granules. Previously, we demonstrated that microRNA-mediated knockdown of Atxn2 (miAtxn2) improves mean survival by 54% in a Tdp-43 overexpressing mouse model of ALS (Amado et al. 2024). However, efficacy data in human cells is needed to support translation to clinic. Here, we identify disease-relevant phenotypes in C9ORF72 ALS patient iPSC-derived motor neurons (iPSC-MNs) and test the ability of our novel MN-targeting AAV, PM-AAV9, to transduce them and effectively deliver miATXN2. Doxycycline-inducible iPSC lower motor neurons were generated from an ALS patient with a hexanucleotide repeat expansion in the C9ORF72 gene and a healthy sibling control. C9ORF72 LMNs exhibited increased stress granule burden, elevated cell death, and reduced neurite length at DIV45. Delivery of eGFP by PM-AAV9 resulted in 90% transduction of LMNs at MOIs four logs lower than the published literature. PM-AAV9-miATXN2 reduced ATXN2 mRNA in a dose dependent manner up to 83% at an MOI of 5x105. Importantly total TDP-43 mRNA levels were not altered. A larger cohort of C9orf72-ALS patient cell lines and their isogenic control lines are being used in further validation studies wherein the expanded repeat in C9ORF72 (Meijboom et al. 2022) is deleted via CRISPR/Cas9 . This platform will enable further testing of miATXN2 and other ALS therapeutics in a human-relevant model.

249 Understanding Schizophrenia-Associated Loci Using iPSC-Derived Neurons and CRISPR Screening

Marisa Hamilton[1], Alexander Nelson[2], Julia Riley[1], Sophie Dornbaum[1], Aaron Coley[1], Ruhi Rai[1], Alejandro Barrera[1], Andrew Allen[1], Patrick Sullivan[3], Charles Gersbach[1], Gregory Crawford[1]
[1]Duke University, Durham, NC, [2]Duke University, Durham, [3]UNC, Chapel Hill, NC

Schizophrenia (SCZ) is a chronic neurological disorder with a lifetime risk of 1% and is associated with increased morbidity and mortality rates. Given that genetic differences play a large role in SCZ risk, further understanding the genetic underpinnings of SCZ holds potential for advancing effective therapeutics for SCZ patients. A recent GWAS identified >22,000 variants in 287 distinct loci where common variation is associated with SCZ risk. However, SCZ GWA is not able to directly identify target genes nor demonstrate causality for common non-coding variants. High-throughput CRISPR screens have enabled researchers to dissect disease-associated loci, shedding light on the cis-regulatory elements (cCREs) and non-coding variants that modulate gene expression in a locus. Identifying active CREs and linking variants that map within these CREs to their target genes using CRISPR screens will refine our understanding of the non-coding regions of the genome that underly SCZ risk.

We utilize a scalable fluorescent-based readout of gene expression, HCR-FlowFISH, which enables us to epigenetically silence hundreds of cCREs with CRISPRi and measure the downstream effects on gene expression all within a single experiment. We have focused on expression of SCZ genes that have been identified by case/control whole exome sequencing (WES) and map within GWA regions. We have conducted CRISPRi + HCR-FlowFISH screens in iPSCs and iPSC-derived neurons (iNs) to identify active CREs and target genes in three WES-prioritized SCZ-associated loci. We have identified 78 genetic elements across three SCZ GWA loci that significantly alter expression of WES-identified SCZ genes when perturbed in iPSCs and/or iNs. These CREs include non-coding enhancers/silencers as well as promoters of genes and lncRNAs. Future prime editing screens of these loci will further aid in the prioritization of disease-relevant genetic variants that underly SCZ risk through modulation of SCZ genes. Findings from this work will improve our understanding of the genetics of SCZ and will lay the foundations for improved disease risk prediction and therapeutics for SCZ patients.

250 From Gene to Therapy: Unraveling WWOX and Its Role in Neurological Diseases

RAMI AQEILAN, Hebrew University of Jerusalem, Jerusalem, Jerusalem, Israel

Gene products of common fragile sites (CFSs) have been well-documented in cancer. In recent years, emerging evidence links these products, such as WW domain-containing oxidoreductase (WWOX), with neurological diseases, including epilepsy, multiple sclerosis (MS), and Alzheimer's disease. Patients harboring pathogenic germline bi-allelic *WWOX* variants have been described with rare devastating autosomal recessive spinocerebellar ataxia 12 (SCAR12) and WWOX-related epileptic encephalopathy (WOREE syndrome). Individuals with these syndromes present with a highly heterogeneous clinical spectrum, the most common being severe epileptic encephalopathy, profound global developmental delay, and premature lethality. Using mouse genetics, we modeled WWOX loss of function and revealed that specific neuronal *Wwox* ablation leads to brain hyperexcitability, intractable epilepsy, ataxia, profound hypomyelination, and postnatal lethality. Moreover, we recently established brain organoids from CRISPR-engineered human embryonic stem cells (hESCs) and patient-derived induced pluripotent stem cells (iPSCs). We discovered dramatic cellular and molecular CNS abnormalities using these human cell systems, including neural population changes, cortical differentiation malfunctions, and Wnt-signaling and DNA damage response impairments. Prompted by these results, we next designed and provided a proof-of-concept that ectopic WWOX expression, using an adeno-associated viral vector (AAV9) harboring human *WWOX* cDNA and driven by the human neuronal Synapsin I promoter (*AAV9-SynI-WWOX*) could rescue WOREE syndrome phenotypes. Our findings underscore the utility of modeling childhood epileptic encephalopathies using genetically engineered mouse models and brain organoids and their use as a unique platform to test possible therapeutic intervention strategies.

251 A fully human pluripotent stem cell-derived blood-brain barrier model validates the therapeutic potential of neurotropic adeno-associated viruses

Vania Broccoli[1], Angelo Iannielli[2], Serena Giannelli[1], Mirko Luoni[3], Sharon Muggeo[4], Martina Greco[5], Elisa Enzi[6], Josep Canals[7], Raffaele Iorio[8]
[1]Ospedale San Raffaele, Milan, Milano, Italy, [2]CNR-Institute of Neuroscience, Milan, Italy, [3]San Raffaele Scientific Institute, Busto Arsizio, Varese, Italy, [4]Ospedale San Raffaele, Milano, Italy, [5]Vita-Salute San Raffaele University, Milano, Monza e Brianza, Italy, [6]University of Milano Bicocca, Milano, Italy, [7]University of Barcelona, Barcelona, Spain, [8]Ospedale Policlinico Gemelli, Roma, Italy

The blood-brain barrier (BBB) is a highly functionalized vascular interface which regulates the exchange of substances between the neural parenchyma and its periphery. BBB leakage, leading to its uncontrolled permeability, is increasingly recognized to facilitate the onset of neuropathologies and aggravate their clinical progression. In vitro models of the BBB have rapidly evolved into elaborated structures that mimic its spatial architecture and multicellular nature. However, their cellular components are currently highly heterogeneous in origin and maturation state. Here, we have developed novel procedures to establish reproducible and scalable sources of endothelial, mural and astroglial cells generating a fully human pluripotent stem cell (hPSC)-derived BBB model, termed thBBBA. hPSC-derived BBB cell types are readily assembled into thBBBAs that develop mature functional properties with high barrier impermeability. Mature thBBBAs can also be generated by frozen hPSC-derived cell samples, providing a simple and scalable off-the-shelf system for general use. thBBBAs are an invaluable system for evaluating the clinical potential of novel engineered AAV neurotropic capsids, previously selected in animal models or in vitro systems. In fact, we were able to rank a group of novel engineered AAV capsids for their ability to cross the thBBBA. Moreover, we established a thBBBA with the stable expression of the murine Ly6a, which encodes for the PHP.eB receptor in BBB endothelial cells. This Ly6a-thBBBA is the first and most convenient system for the direct comparison of BBB crossing capabilities between NHP-specific AAVs and the benchmark mouse-selective PHP.eB capsid. Additionally, thBBBAs were instrumental in identifying the critical pathological role of an IL-6 autocrine source in disrupting thBBBA integrity, increasing its permeability to NMDAR antibodies from autoimmune encephalitis patients, and revealing the therapeutic effects of tocilizumab in this disease.

252 Advancing Cardiovascular Drug discovery with iPSC-Derived 3D Cardiac Microtissues in High-Throughput Screening

Benoit Samson-Couterie[1], Benjamin Johnson[2], Katerina Pitsa[3], Tessa de Korte[2], **Mariana Argenziano**[4], Christine Mummery[5], Richard Davis, Shushant Jain[6]*
[1]Ncardia Services, LEIDEN, Netherlands, [2]Leiden University Medical Center, LEIDEN, Netherlands, [3]Ncardia, LEIDEN, Utrecht, Netherlands, [4]Ncardia, Leiden, Zuid-Holland, Netherlands, [5]Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands, [6]Ncardia, Leiden, Netherlands, Netherlands
**Corresponding Author*

Human induced pluripotent stem cell (hiPSC)-derived models are revolutionizing drug discovery by providing human-relevant cell types for more accurate preclinical evaluations, especially for cardiovascular diseases and drug-induced cardiotoxicity. 3D cardiac microtissues (cMTs), which replicate the architecture and function of the human heart, offer improved drug screening for both efficacy and safety compared to traditional models. These models, developed from patient-derived iPSCs, increase the relevance and predictability of cardiovascular drug testing, allowing for more reliable preclinical data.

The study used Ncardia's iPSC-derived Ncyte® vCardiomyocytes, along with other patient specific iPSC-derived cardiomyocytes. Cardiomyocytes were co-cultured with Ncyte® and other iPSC-derived cardiac fibroblasts, and endothelial cells to form 3D cMTs. These cMTs were integrated into high-throughput screening (HTS) platforms, enabling large-scale drug screening. Automated formation of the microtissues was achieved with the TECAN Fluent robot, ensuring consistency in size and morphology. Calcium transient recordings were used to assess drug effects, while statistical analyses like one-way ANOVA evaluated the impact of various compounds on cardiac function and biomarkers such as NT-proBNP release.

As hiPSC-CMs in cMTs exhibit improved structure and metabolism compared to when in monocultures, we investigated whether cMTs could also enhance the predictivity of hiPSC-CM responses to therapeutics. In cMTs, the positive inotropes compounds increased both the beat rate and Ca2+ peak amplitude, while in 2D multi-cell type cultures, these compounds only induced positive chronotropic responses without affecting the amplitude or kinetics Automating the procedure revealed highly reproducible drug responsiveness and predictive accuracy in a reference compound screening highlighting their potential for high-throughput cardiac safety assessments.

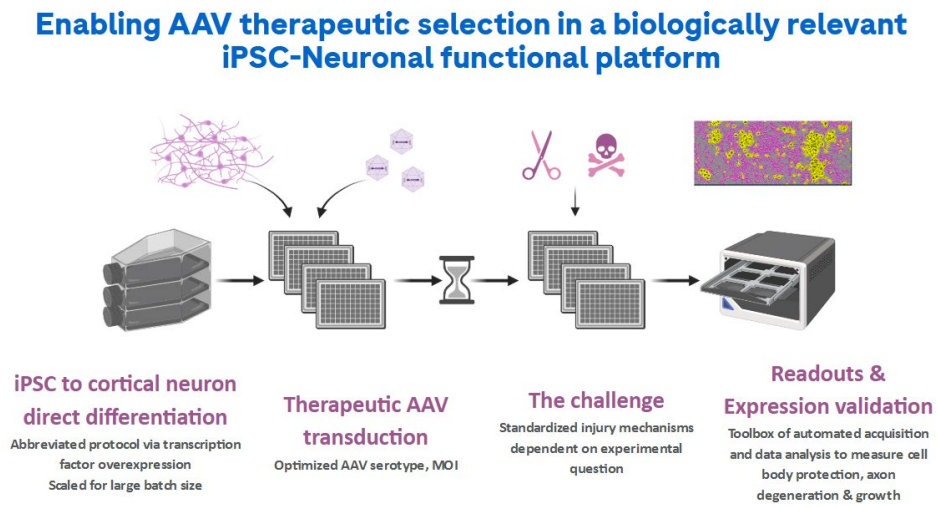
In modelling catecholaminergic polymorphic ventricular tachycardia (CPVT), arrhythmias were observed that could be rescued by flecainide, validating their use in drug testing. Screening using the Specs Repurposing library resulted in an ~4.6% hit rate. The study also demonstrated the cMTs sensitivity to changes in cardiac function, including a concentration-dependent increase in NT-proBNP release and varying responses in ischemia-reperfusion studies.

This study highlights the effectiveness of hiPSC-derived 3D cMTs in advancing cardiovascular drug discovery. Their low variability, high predictability, and ability to model disease conditions, like CPVT, make them powerful tools for drug screening and disease modelling. The results highlight their potential to bridge the gap between in vitro and in vivo systems, improving the accuracy of preclinical evaluations and accelerating the development of novel cardiovascular therapies.

253 *In Vitro* Assays to Study Neuroprotection and Axon Regeneration in Human Neurons Differentiated from Neurogenin-2 Engineered Induced Pluripotent Stem Cells

Gaia Ruggeri, Genentech, Inc, South San Francisco, CA

Drug discovery in neurodegenerative diseases is one of the most challenging therapeutic areas due to the lack of suitable models. Developing physiologically relevant in vitro neuroprotection and axon regeneration models is crucial for elucidating the mechanisms underlying neurodegeneration and designing effective therapeutic interventions. Neuroprotection focuses on maintaining the health of surviving neurons after injury, while regeneration seeks to repair or replace damaged neurons and synapses. Relevant *in vitro* experimental models of neuronal damage are necessary to evaluate any treatment's effectiveness. The discovery of induced pluripotent stem cells (iPSCs) has revolutionized the modeling of human diseases, significantly boosting the confidence of *in vitro* neurological disease models. We have developed in vitro assays using some common insults to model and study neuroprotection/axon regeneration, including chemical toxicity and mechanical damage in Neurogenin-2 engineered iPSC-derived human neurons (iNeurons). Integrating automated imaging and artificial intelligence (AI) analysis methods to measure axon degeneration/regeneration showed robust neuroprotection and regeneration *in vitro,* with little hands-on time. These models could help us accelerate therapeutic candidate validation and selection for neurodegenerative diseases.



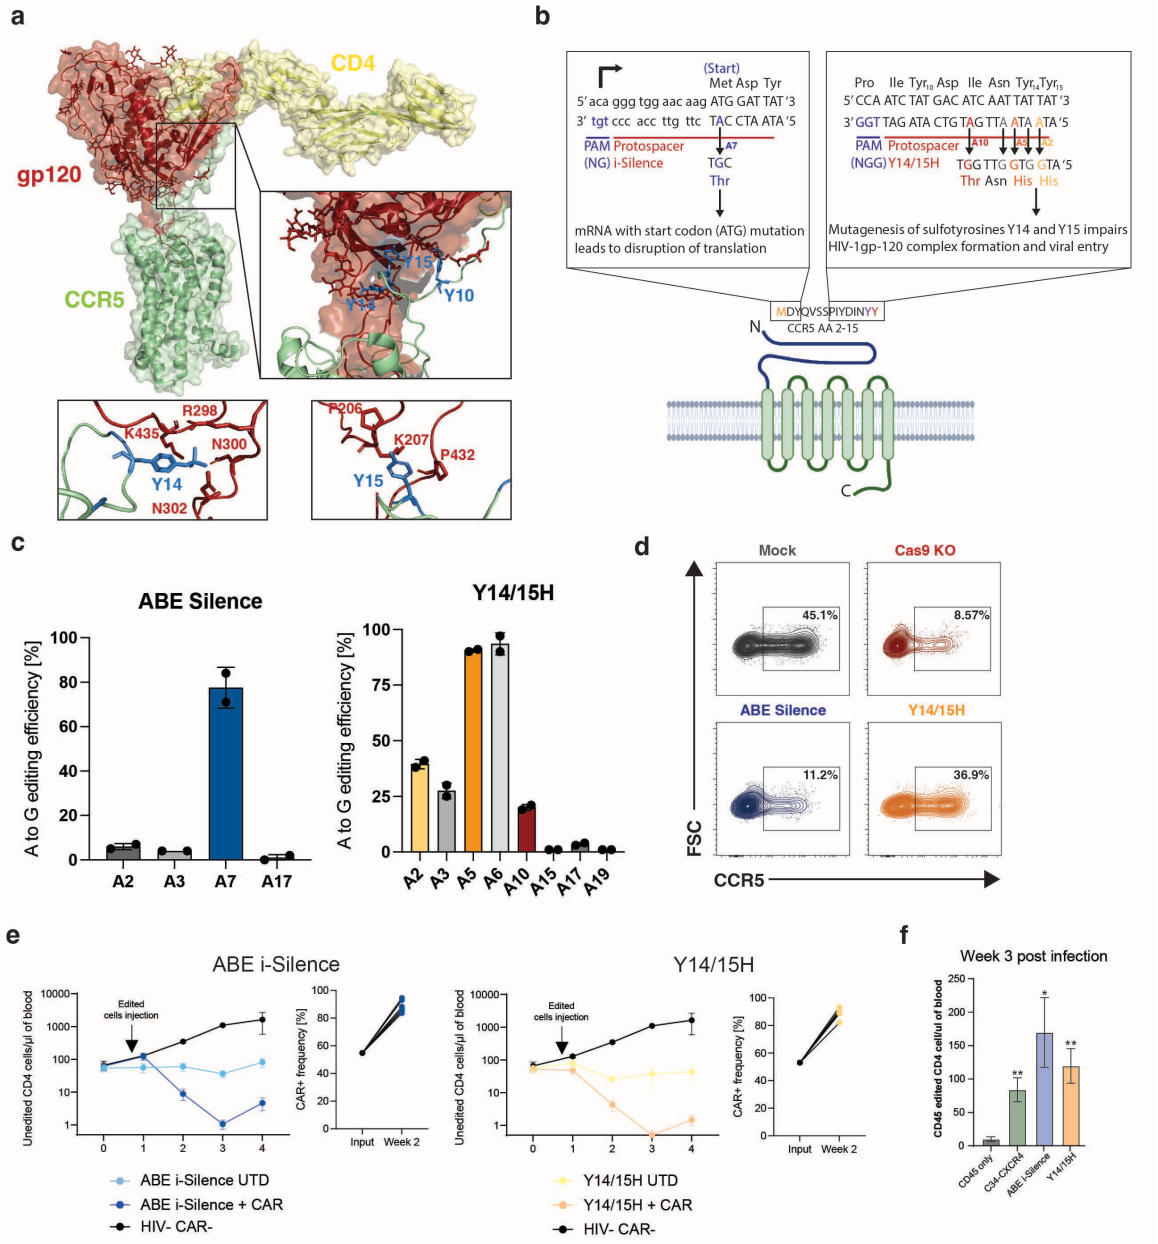
CAR T Innovations in Autoimmune and Infectious Disease and Allergy

254 Selection for an HIV-Resistant Immune System by Multiplex Base-Edited CD45 CAR-T Cell Therapy

Nils Wellhausen[1], Yuqi Zhou[2], Michael Bowman[1], Olga Shestova[3], Abhimanyu Gowda[4], Nils Engel[5], Carl June[1], Robert Bowman[5], James Riley[6], Saar Gill[1]
[1]University of Pennsylvania, Philadelphia, PA, [2]Philadelphia, PA, [3]University of Pennsylvania, [4]Oxford University, Oxford, United Kingdom, [5]University of Pennsylvania, Philadelphia, [6]The University of Pennsylvania, Philadelphia, PA

Introduction
Eradicating cellular reservoirs of human immunodeficiency virus (HIV) in patients on antiretroviral therapy (ART) is critical to curing HIV, since integrated provirus remains in CD4+ cells even in patients without detectable viral load on anti-retroviral therapy (ART). There are rare but compelling reports of HIV cures in patients who underwent allogeneic hematopoietic stem cell transplantation (alloHSCT) from CCR5Δ32/Δ32 donors, wherein myeloablative chemotherapy and donor alloreactive T cells completely eradicated the recipient's immunohematopoietic system and allowed it to be replaced by donor-derived hematopoiesis lacking the HIV co-receptor CCR5. While applying this strategy systematically as a treatment option is not feasible due to the paucity of HLA-matched CCR5Δ32/Δ32 donors and the high-risk nature of alloHSCT, these reports highlight that immunologic depletion of HIV reservoirs in combination with an HIV-resistant HSCT can achieve HIV eradication. To exert potent yet broad immune pressure against the cellular components of the viral reservoir we harnessed an HIV- and fratricide-resistant CAR-T cell therapy against the pan-leukocyte antigen CD45.

Results
Fratricide resistance of the anti-CD45 immunotherapy is achieved by epitope editing CD45 using an adenine base editing (ABE) as we recently described [PMID: 37651540]. At the same time, HIV-resistance is accomplished by either base editing the CCR5 start codon to silence CCR5 expression or mutating tyrosine residues (Y14 and Y15) in the N-terminal domain of CCR5 that are known to bind HIV gp120. Base editing CCR5 in primary human CD4 T cells is highly efficient with ~84% A to G editing at the CCR5 start codon, successfully silencing CCR5 protein expression. Similarly, a single gRNA achieved ~90% editing for A5 (Y14H) and ~38% for A2 (Y15H), accomplishing mutagenesis of the sulfotyrosine binding residues for HIV gp120 docking while preserving CCR5 expression. To test whether CCR5 base-edited cells (CCR5BE) are resistant to HIV infection, we infected CCR5BE or unedited CD4 T cells with the CCR5-tropic HIV stain BaL. Both groups of CCR5BE CD4 T cells showed reduced susceptibility to HIV BaL infection both in vitro and in vivo, whereas unedited control cells were readily infected. Resistance to HIV infection translated to a ~4-fold higher preservation of peripheral blood T cell numbers and a ~10-fold lower vRNA copy number in mice that received CCR5BE T cells compared to unedited T cells. Furthermore, we observed a strong enrichment of CCR5 edited cells from ~60% to >99% upon HIV infection, suggesting that CCR5BE T cells are protected from infection-induced cell death. To generate CD45 CAR-T cells that are resistant to fratricide and HIV infection, on-target base editing must co-occur biallelically at both the CCR5 loci and the CD45 epitope with high efficiency. Using single-cell DNA sequencing, we show that biallelic, multiplex base editing is efficient in primary human T cells with co-occurence of biallelic editing of ~75% (CCR5 start codon + CD45 and ~85% (CCR5 Y14/15 + CD45) respectively. Lastly, we demonstrate that multiplex base editing CD45 with CCR5 generates fratricide-and HIV-resistant CART45 cells that can eliminate HIV-infected CD4 T cells in mice while preventing the spreading of HIV particles from infected CD4 T cells to the CD4 positive CAR-T cells, thus facilitating their persistence compared to CD45-only edited CAR-T cells.



(a)Overall structure of the CD4-gp120-CCR5 complex (PDB:6MET); adapted from Shaik et. al43. (b) Adenine base editing strategies that are hypothesized to confer HIV-resistance to R5-tropic viruses. Left panel: gRNA that results in deletion of CCR5 expression by mutating CCR5 start codon using an NG-ABE8e (ABE Silence). Right panel: gRNA that mutates sulfotyrosine residues Y14 and Y15 which have been shown to impair viral entry when mutated. (c) Editing efficiency for ABE-mediated gene silencing and Y14/15H N-terminal mutagenesis in human T cells by targeted amplicon sequencing followed by analysis with EditR. Graphs depict all adenosine nucleotides within the 20 nucleotide protospacer regions with position one being the most PAM-distal nucleotide of the protospacer (n=2 biological replicates). Data are represented as mean ± SD (d) CCR5 protein expression measured by flow cytometry demonstrates that ABE-mediated CCR5 silencing can achieve comparable loss of protein expression compared to Cas9 nuclease mediated knockout. In contrast, Y14/15H mutation does not result in loss of protein expression despite high editing efficiencies. (e) Left panel: Number of unedited human CD4 T cells (infected target cells) in peripheral blood after the injection with CAR-transduced or untransduced epitope edited cells in comparison with mice that received neither HIV nor CAR injection. HIV- CAR- group was intentionally duplicated in each graph to facilitate visual comparisons at scale. Data are represented as mean ± SEM. Right panel: Percentage of CAR+ cell in human T cells before injection and 2 weeks post CAR T cell injection. (f) Number of CD45 edited human CD4 T cells (effector cells) in peripheral blood 3 weeks after HIV infection. (n= 6 mice per group)

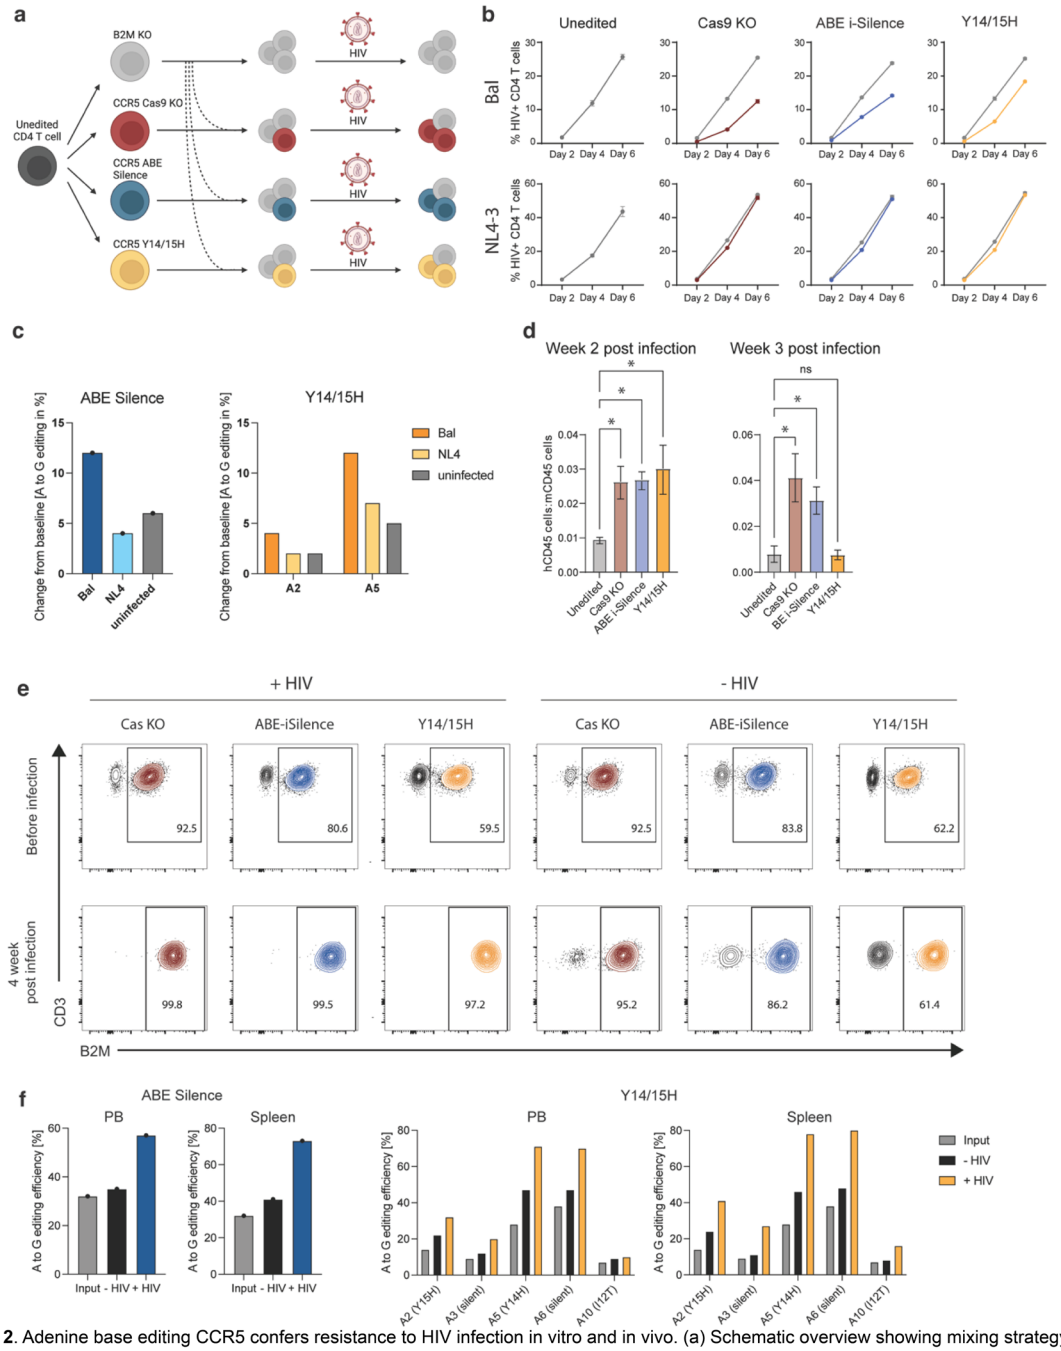


Figure 2. Adenine base editing CCR5 confers resistance to HIV infection in vitro and in vivo. (a) Schematic overview showing mixing strategy in both in vitro and in vivo experiments using beta-2-microglobuling negative cells as a surrogate for CCR5 unedited cells. CD4 T cells were edited at the targeted CCR5 locus and mixed with B2M KO CD4 T cells at 1:1 ratio and infected with HIV Bal (CCR5 tropic) or HIV NL4-3(CXCR4 tropic). (b) HIV infection was measured through intracellular FACs staining of HIV Gag core antigen every other day (n=3 technical replicates). Data are represented as mean ± SEM. (c) Quantification of on-target editing efficiencies by targeted amplicon sequencing 8 days after cells have been infected with either HIV BaL or HIV NL4-3. Left panel shows editing at A6 (on-target for CCR5 ABE silence) and right panel shows editing at A2 (Y15H) and A5 (A14H). (d) Two- and three-weeks post HIV infection, the ratio between human CD45+ cells and mouse CD45+ cells in mouse peripheral blood were analyzed. (n= 5-7 mice per group, *p<0.05, unpaired t-test). Data are represented as mean ± SEM. (e) The frequency of CCR5 edited cells (B2M+) in peripheral blood was measured through FACs staining of B2M before HIV infection and 4 weeks after HIV infection. (f) After 4 weeks, mice from each group (n=5-7 mice per group) were pooled and human CD45+ cells were sorted from spleen and peripheral blood (MACS) followed by targeted amplicon sequencing of human CCR5.

255 Multivalent CAR T cell therapy targeting membrane distal epitopes restricts HIV escape kinetics and enhances control of HIV replication in humanized mice

Human Immunodeficiency virus 1 (HIV-1) primarily infects $CD4^+$ T cells establishing a chronic infection and leading to severe immunodeficiency. Although antiretroviral therapy can suppress HIV replication, it is not curative and requires lifelong treatment. Chimeric antigen receptor (CAR) T cell therapy offers a promising method to enhance the natural T cell response against HIV infection. Using broadly neutralizing antibodies (bNAbs) that target relatively conserved regions of the HIV envelope (Env) as the CAR ectodomain may further improve immunotherapy efficacy against a broad range of HIV isolates.

We generated a panel of 19 bNAb-based CAR T cells targeting six well-characterized regions of the HIV Env: V1/V2 apex, V3 glycan, CD4 binding site, gp120-gp41 interface, silent face, and MPER. CAR functionality was assessed *in vitro* through killing and suppression assays. Notably, CARs targeting distal epitopes (V1/V2 apex, V3 glycan, CD4 binding site) exhibited higher killing potency and cytolytic potential, suggesting that the accessibility of the epitope plays a key role in determining CAR effectiveness. Antigen sensitivity was also evaluated using time-course intracellular cytokine staining (ICS) after stimulation with low- and high-Env expressing cells. Notably, the V3 glycan-specific CARs demonstrated the highest antigen sensitivity. Furthermore, different Env trimer-based binding assays indicated that the V3 glycan-targeting CARs showed the highest avidity.

To evaluate the *in vivo* efficacy, we treated HIV-infected humanized mice with CAR monotherapy. Deep sequencing of the HIV *env* gene revealed the emergence of escape mutations at defined bNAb contact sites, highlighting the need for targeting multiple epitopes to limit viral escape. Mapping of escape mutations helped identify potent CAR product combinations with orthogonal escape patterns. Combination CAR therapy - consisting of 3 monospecific CARs - restricted HIV escape kinetics and resulted in a significant and durable reduction in plasma viremia in humanized mice. We next developed tri-valent CAR products, simultaneously expressing the 3 most potent bNAb-CARs. These multivalent CAR products showed an *in vivo* expansion advantage over mono- or double-specific products, suggesting greater antigen sensitivity. Notably, some mice in the cohort exhibited complete control of plasma viremia, while even non-controllers had significant protection from memory $CD4^+$ T cell depletion.

In conclusion, our findings demonstrate the potential of bNAb-based CAR T cells for HIV immunotherapy. We identified bNAb CAR classes with superior potency and elucidated the mechanisms driving their effectiveness. Targeting multiple conserved epitopes on HIV Env can limit viral escape and lead to durable control of viremia. The development of multivalent CAR products, simultaneously expressing the most potent bNAb CARs, represents a promising strategy for advancing HIV cure efforts.

256 CAR19 Engineered Regulatory T Cells, a Novel Approach for Immune Reset in B and T Cell Mediated Autoimmune Disorders

Raffaele Scientific Institute, MIlan, Milano, Italy, [11]Seattle Children's Research Institute, [12]GentiBio, [13]GentiBio, Cambridge, [14]University of Washington, Seattle, WA, [15]Università Vita Salute San Raffaele, Milan, Italy

Conventional CD19 CAR T therapy has demonstrated promising efficacy in SLE by resetting the immune system via robust B cell depletion. However, long-term remission in these patient populations may require changes to additional pathogenic immune cell activities, including the suppression of autoreactive T cells. Besides safety issues associated with cytokine release syndrome (CRS), high manufacturing costs of autologous cell therapy limit the accessibility of conventional CAR T therapy. To address these limitations, here we report on allogeneic CD19 CAR engineered regulatory T cells (CAR19 EngTregs) that combine the best features of both CAR Ts and Tregs with potential for improved immune reset, improved safety, and reduced manufacturing cost. We show that CAR19 EngTregs maintain the clinically validated mechanism of B cell depletion like CAR Ts while also directly suppressing the T cell arm of the immune system, distinct from CAR Ts. In addition, compared to CAR Ts, CAR19 EngTregs display significantly reduced production of inflammatory cytokines associated with cytokine release syndrome and ICANS.

We first engineered CAR19 EngTregs using a technology platform that addresses key challenges facing Treg cell therapeutic success including phenotypic instability, environmental IL-2 scarcity, and lack of tissue specificity through modifications designed to enable (1) stable FOXP3 expression, (2) CAR19 for B-cell targeting and (3) a chemically inducible signaling complex (CISC) that provides a rapamycin driven IL-2 like signal to promote engraftment, activity, and stability in the IL-2 scarce environment of autoimmune disease, while also enabling enrichment with rapamycin to high purity during cell production.

CAR19 EngTregs produced with the above platform demonstrated a stable Treg phenotype (FoxP3, CD25, CTLA-4 and ICOS) and upon CAR stimulation, upregulation of classic activation markers (CD69) and Treg specific markers (TNFR2, LAP and GARP). In vitro proinflammatory cytokine secretion (INFg, TNFa, IL6) was low, especially compared to CAR T cells. Interestingly, CAR19 EngTregs mediated robust cytotoxicity against both the Nalm-6 B cell line and primary B cells while expressing lower cytolytic enzymes (Perforin, Granzyme A, and Granzyme B) compared to CAR T. CAR19 EngTregs prevented B cell proliferation and differentiation into plasmablasts and plasma cells while abrogating immunoglobulin production. Importantly, CAR19 EngTregs also mediated CD19-driven T cell suppression demonstrating modulation of both B cell and T cell compartments.

Allogeneic CAR19 EngTregs dosed in a humanized pristane model in adult NSG mice, depleted both B cells and T cells in vivo, while eliciting lower serum inflammatory cytokines and lower immunoglobulin titers compared to CAR T or the anti-CD19 monoclonal antibody, ineblizumab. Histopathology demonstrated CAR19 EngTregs reduced inflammatory lesions in tissue more deeply vs comparator treatments. These data support CAR19 EngTregs as a uniquely differentiated therapy for B cell driven autoimmune diseases that target both B and T cell arms of the immune system demonstrating a superior efficacy and safety profile compared to CAR T.

257 Chimeric Antigen Receptor T Cells Targeting the IgE B Cell Receptor Specifically Eliminate Human IgE Producing B cells

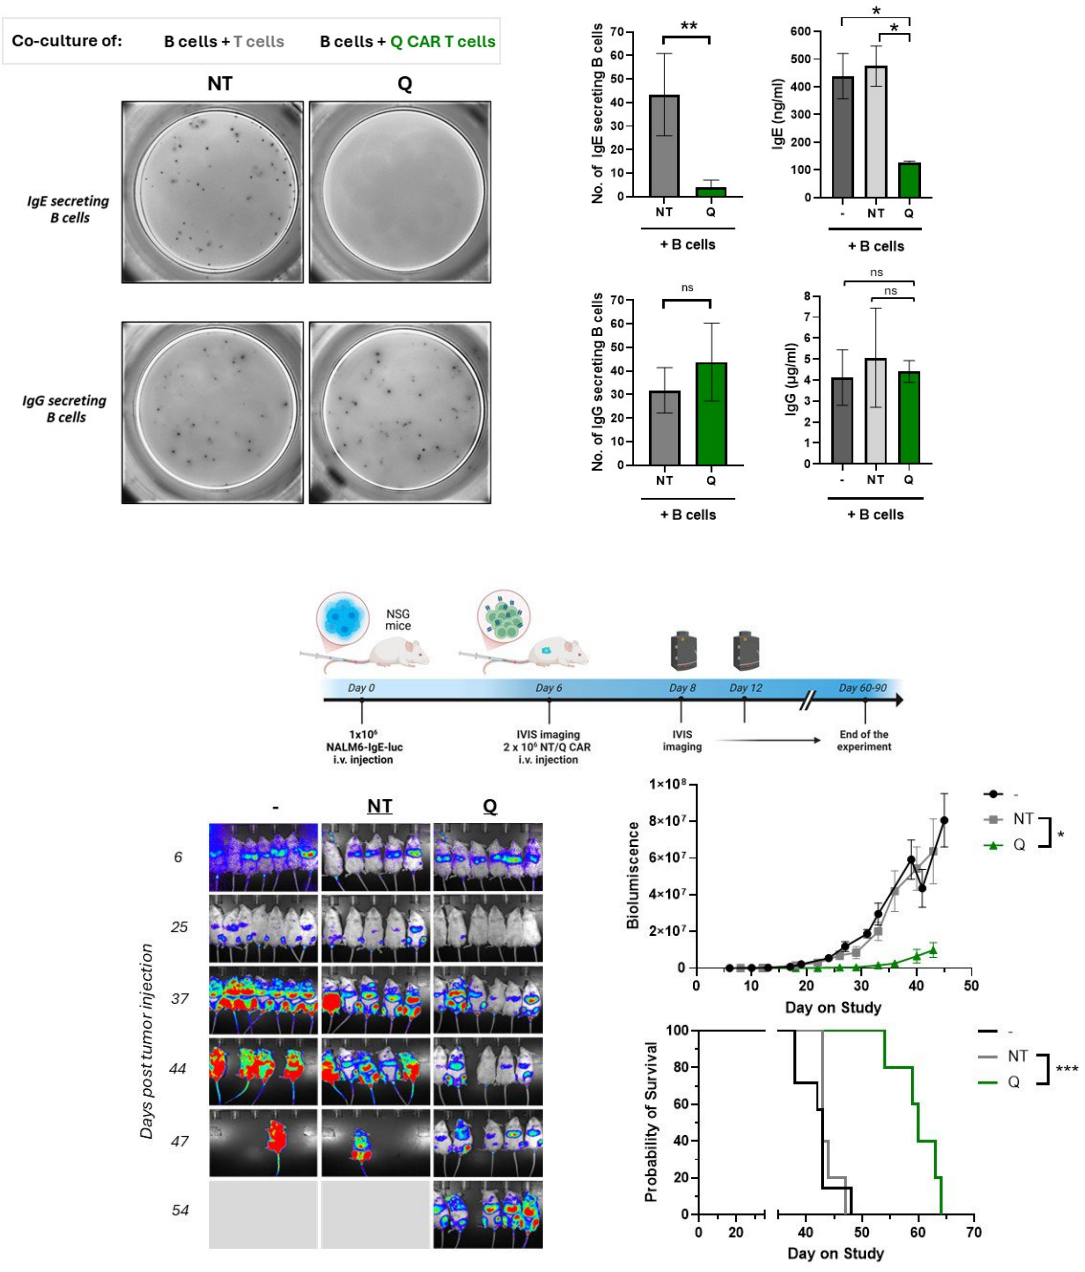
The prevalence of IgE-mediated allergic disorders has risen markedly in industrialized societies, posing significant clinical and socioeconomic challenges. These disorders are characterized by hypersensitivity reactions that range from acute, life-threatening anaphylaxis to chronic conditions such as allergic asthma and autoimmune chronic urticaria. Despite advances in therapeutic strategies, existing treatments—including pharmacological agents, monoclonal antibodies, and immunotherapy—remain limited in their capacity to provide definitive cures. Here, we

present a novel chimeric antigen receptor (CAR)-T cell therapy targeting M1', a unique extracellular domain of the IgE B-cell receptor (BCR). This domain, absent from free IgE, offers an unparalleled opportunity for selective targeting of IgE-producing cells. Our "Q CAR" construct, derived from the monoclonal antibody Quilizumab, demonstrated robust cytotoxicity against primary human IgE-secreting cells and significantly reduced IgE production in vitro. In an in vivo NSG mouse model, Q CAR-T cells inhibited the growth of IgE-expressing tumors and extended survival. By circumventing the limitations of prior CAR designs that target free IgE as well—this strategy provides a novel framework for the development of cellular therapies for allergic diseases. Our findings pave the way for further investigation in transgenic allergy models, with the ultimate goal of clinical translation to offer curative solutions for IgE-mediated disorders.

Q-CAR T cells, targeting IgE-BCR, specifically eliminate IgE-secreting B cells



258 A Two-Infusion Regimen with a Novel In Vivo Non-Viral Chimeric Antigen Receptor (CAR) Achieves up to 90% CD8+ T Cell Engineering and Tissue Depletion of Target Cells in Non-Human Primates (NHPs)

Introduction: A major objective in the field of autoimmunity is to advance novel therapies capable of achieving durable drug-free responses by resetting the immune system, without prolonged or residual on- or off-target toxicities. This requires memory and autoreactive B cell depletion in tissues, followed by repopulation with newly formed B cells comprising a naïve phenotype. To that aim, we developed a novel platform technology (CellSeekerTM) comprising proprietary ionizable lipid-based LNPs, functionalized to effectively target CD8+ T cells in vivo to deliver encapsulated mRNA payloads to transiently generate CAR T cells (Fig. 1). This platform does not require lymphodepletion conditioning and is tunable in dose level and frequency to achieve the necessary exposure. Previously, we demonstrated that an intensive dosing regimen (3 infusions, Q72hr) with >0.3 mg/kg of anti-CD20 CAR mRNA in CD8-LNPs, resulted in global B cell depletion in blood and lymphoid organs of NHPs (Fig 2). To facilitate the clinical translation of this technology, we evaluated the potency and mechanism of action of a streamlined 2-infusion cycle aiming to achieve B cell depletion sufficient for immune reset, with minimum drug exposure. Methods: We generated two similar tLNP formulations comprising a highly biodegradable ionizable lipid, that were decorated with humanized anti-CD8 monoclonal antibody: i) CPTX2309 containing mRNA encoding for an all human anti-human CD19 CAR and ii) CPTX2309(S) containing mRNA encoding for a murine anti-human CD20 CAR. These formulations showed comparable human T cell engineering rate and pharmacological effect against human primary B cells in vitro; however, only CPTX2309(S) was cross reactive against NHP B cells. Cynomolgus monkeys were intravenously administered one (n=2/group) or two (Q72hr) doses (n=3/group) of CPTX2309(S) (1-2 mg/kg) without pre-medication, or with PBS as a control. Both single-dose animals were euthanized on day 3, while one animal per 2-dose group was euthanized on day 10 and the other two on day 43. A comprehensive PK/PD analysis in blood and tissues by flow cytometry for CAR expression, immune cell phenotypes, activation markers (ICOS and PD-1), and cell enumeration were performed. Immunohistochemistry for B cell and microenvironment characterization, and MSD analysis for cytokines and other markers in blood, were also performed. Results: Two infusions of CPTX2309(S), 3 days apart, resulted in rapid and deep B cell depletion in in blood evident within 24 hrs post 1st dose, paralleled by global depletion of B cells in tissues including bone marrow, spleen and lymph nodes measured on day 10 (Fig 3). A single dose of 2mg/kg appeared less effective than 2 lower-dose infusions (1mg/kg, or 1.5mg/kg, or step up dosing with 1mg/kg followed by 2mg/kg) in achieving global B cell depletion. In the effective 2-dose regimen, B cells began to recover within 3 weeks, predominantly with naïve B cells, in 5/6 animals, maintaining this profile skewed toward naïve B cells and not reaching the pre-treatment levels of total or memory B cells during the 6-week observation period (Fig 3B). Flow cytometric analysis demonstrated rapid engineering of CD8+ T cells with increased CAR expression upon 2nd infusion, reaching up to 90% of CD8+ T cells (Fig 4A). There was no detectable engineering of B cells and minimal CAR expression by CD4+ T cells. CAR was transiently expressed by CD8+ NK cells and myeloid cells. CAR expressi

Background:
HIV-1 and related viruses (SIV, SHIV) infect CD4+ cells in humans and nonhuman primates (NHPs), respectively. Although antiretroviral therapy (ART) suppresses virus replication, cessation of ART leads to viral rebound. Our recent data suggest that the persisting HIV-1 reservoir may be immunologically silent, necessitating anti-HIV immunotherapies that do not require viral antigen expression. Here we developed an anti-CD4 chimeric antigen receptor (CAR) approach to transiently ablate the CD4 compartment, including latently-infected cells. Our novel anti-CD4 CARs were evaluated ex vivo for relative expression, specificity for autologous CD4+ target cells, and potency/duration of cytotoxicity. The most effective CAR was selected for an ongoing in vivo study (n=3) in SHIV-infected, ART-suppressed NHPs. Our in vivo study will inform the safety and feasibility of anti-CD4 CAR T-cells as a curative therapy for people living with HIV.

Methods:
Six anti-CD4 CAR transgenes, featuring two scFv orientations (VH-VL or VL-VH) and three spacer domains (short, medium, or long), were cloned and packaged into lentiviral vectors for transduction into rhesus macaque CD8+ T-cells. CAR T-cell proliferation was assessed with and without co-cultured autologous CD4+ T-cells in single-round antigen stimulation and long-term repeat stimulation assays (RSA). After identifying the most potent and specific CAR ex vivo, CAR T-cells were infused into SHIV-infected, ART-suppressed rhesus macaques via the intravenous route. The kinetics and magnitude of CAR expression and CD4 depletion were quantified in blood and tissues using flow cytometry, immunohistochemistry, and PCR-based assays. CAR vectors co-expressed truncated EGFR (EGFRt) to label CAR+ cells. In our NHP study, we used the anti-EGFR antibody Cetuximab to assess EGFRt as a "CAR-OFF" safety switch.

Results:
All 6 anti-CD4 CARs were functional ex vivo; CARs with VH-VL scFvs and short/medium spacer lengths had the highest CAR expression, with up to 90% expression in CD8+ T-cells after antigen stimulation. CAR expression increased 1.3-3-fold after stimulation with autologous CD4+ cells. Each anti-CD4 CAR molecule rapidly eliminated CD4+ targets (Figure 1) and proliferated specifically in response to antigen ex vivo. Early NHP data in peripheral blood indicate robust expansion of CAR T-cells and complete CD4 depletion. Cetuximab effectively depleted CAR T-cells to <2% in peripheral blood (Figure 2).

Conclusion:
NHPs are an ideal in vivo model to validate both the safety and efficacy of novel CAR T-cell therapies. We found that NHP anti-CD4 CAR T-cells exhibited potent function ex vivo and in vivo. Our CARs did not display significant fratricide, likely due to the use of double-purified CD8+ T-cells and exclusion of CD4+ T-cells during manufacturing. Cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS) were observed in the first CAR-treated animal. To our knowledge, we are the first to validate Cetuximab as a CAR safety switch in NHPs, opening new doors to further optimize regulated CAR function in the NHP model. Currently, we are quantifying the impact of anti-CD4 CAR T-cells in our model of HIV latency. We predict that efficient CD4 depletion may be associated with curative endpoints.

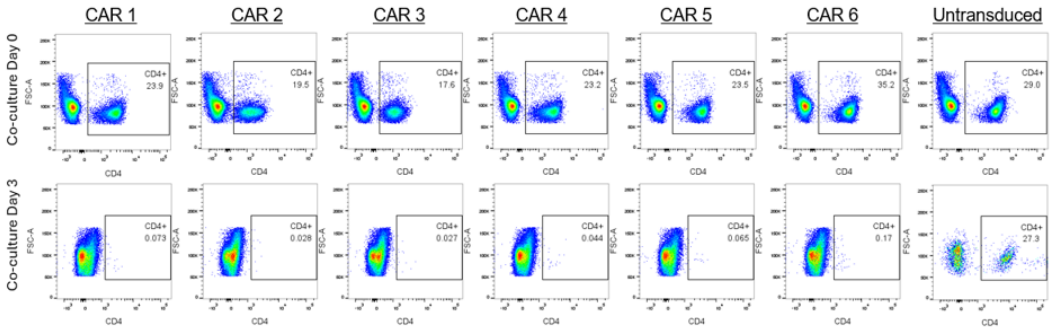

Figure 1. Anti-CD4 CAR T-Cells Kill CD4+ Targets ex vivo. Candidate anti-CD4 CARs 1-6 were expressed in primary rhesus macaque CD8+ T-cells, followed by co-culture with autologous CD4+ cells at a 5:1 effector-to-target ratio. The number of CD4+ targets was quantified immediately after mixing (Day 0, top row) and following 3 days of co-culture (Day 3, bottom row). Mock: negative control in which CD8+ T-cells were not modified with an anti-CD4 CAR vector.

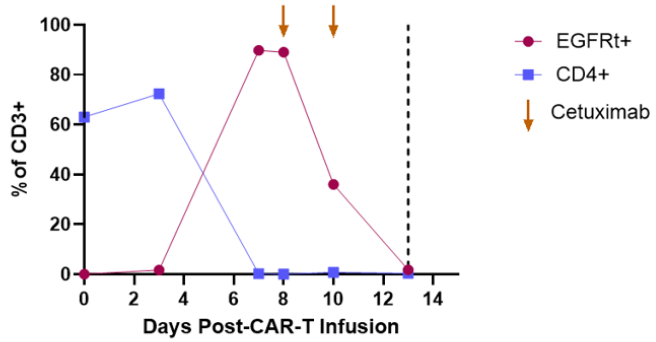

Figure 2. CAR expansion and CD4 depletion in an NHP model. Quantification by flow cytometry of CD4+ T cells and CAR+ cells via the truncated EGFR tag in peripheral blood after CAR infusion. Cetuximab was administered on days 8 and 10. End of study is indicated by the dashed vertical line.

260 CD19 CAR T Cells Generated In Vivo by T Cell Targeted Lipid Nanoparticles Demonstrate Robust and Durable B Cell Depletion in Non-Human Primates

T cells transduced ex vivo with lenti- or gamma-retro viral chimeric antigen receptor (CAR) targeting the CD19 and BCMA antigens have shown significant clinical benefit to patients with hematologic malignancies, resulting in six FDA-approved products to date. Despite this clinical success, these treatments require a complex manufacturing process that results in barriers to patient access. To obviate the complexities of ex vivo manufacturing, we are developing T cell targeted lipid nanoparticle (LNP)-based therapeutics that enable *in vivo* cell-specific reprogramming, providing off-the-shelf gene therapies to patients while eliminating the need for pre-conditioning treatments. Specifically, LNPs were engineered with a CD8-targeting NANOBODY® molecule on their surface which enables the delivery of anti-CD19-based CAR mRNA cargo to T cells in vivo. Rhesus macaques were infused with single or multiple doses of CD8-targeted LNPs containing CD19 CAR mRNA with no infusion-related toxicities observed. We demonstrate CD19 CAR expression on the surface of CD8+ T cells as early as 1 hour

following infusion of targeted LNP peaking at 24 hours. CD19 CAR expression is associated with a robust decrease in B cells (identified via CD20 expression) resulting in >95% B cell depletion in peripheral blood 24 hours after treatment relative to the baseline B cell frequencies before dosing. Maximal B cell depletion in the peripheral blood is observed at 24 hours post targeted LNP infusion, followed by a return to the pre-infusion baseline at 50 days post-infusion. Importantly, we also find that CD8+ T cells and NK cells in the bone marrow express CD19 CAR 24 hours after infusion of targeted LNPs and we observe a concomitant decrease of bone marrow resident CD20+ B cells >90% relative to control animals. Similar to peripheral blood, maximal B cell depletion in the bone marrow is observed at 24 hours post targeted LNP infusion and returns to baseline at 29 days post-infusion. We observe gross changes in B cell receptor CDR and isotype distribution from B cells harvested from the bone marrow at 57 days post initial infusion relative to B cells harvested from the bone marrow pre-infusion. In summary, the robust B cell depletion in peripheral blood and bone marrow following infusion with CD8 targeted LNPs containing CD19 CAR mRNA supports further development of T cell targeted LNPs towards clinical applications in oncology and autoimmunity.

Immune Cell Therapies

261 Armored HIV-specific CAR NK and Activated NK Cells Are Safe and Led to Viremic Control in a Subset of HIV-Infected Humanized DRAGA Mice

Over 39.9 million people are living with HIV-1 globally. Although small-molecule antiretroviral therapy (ART) has dramatically improved survival rates and quality of life, these drugs are expensive, have severe side effects, require lifelong adherence, and are not a cure. Reservoirs of HIV persist within B cell follicles of lymphatic tissues even during ART treatment. This persistence is partly due to a paucity of HIV-specific cytotoxic cells accumulating in these locations, as they largely do not express the follicular homing receptor CXCR5. Our group has pioneered the development of HIV-specific CAR T cell therapies, which also express CXCR5, allowing these cells to have heightened HIV-killing potential and specifically migrate to sites of viral replication within B-cell follicles. CAR T cell therapies are typically autologous, as treatment with allogeneic T cells can cause GVHD. This poses a challenge for treating HIV, as T cells are compromised and engineering HIV-infected cells may pose additional risks. We are now exploring CAR/CXCR5 NK cell therapies as an alternative as they can be used in allogeneic settings and have preexisting antigen-independent activation modalities for immunosurveillance of virally infected cells. We engineered bispecific, HIV-envelope-targeting CAR/CXCR5 NK cells armored with soluble IL-15 and knocked out PD-1 using base editor technology to prevent exhaustion. We evaluated these cells in vitro to determine their specific killing capacity and ability to migrate to CXCL13, the chemokine ligand of CXCR5. We then assessed the efficacy and safety of these therapies in vivo by treating HIV-infected humanized DRAGA mice (NRG background with HLA I and II transgenes for enhanced engraftment of human stem cells) with activated, armored CAR/CXCR5 NK cells (1-1.5X105 cells/g), treated 3 days post ART interruption). They were compared to mice treated with activated but unedited control NK cells or saline treatment. We monitored HIV viral loads, CD4 count, CAR NK levels, and adverse symptom onset for 2 months post-cell infusion. We found that CAR/CXCR5 NK cells had increased specific killing activity and migratory function to CXCL13 compared to unengineered NK cells in vitro. Our in vivo studies found that 62.5% of CAR/CXCR5 NK treated, 50% of activated NK treated, and 0% of saline-treated animals had viral loads below the detection limit at 56 days post-treatment. Despite this impact, all groups showed a continued decline of CD4+ T cell counts post-infusion. In CAR/CXCR5 NK-treated animals at 6 days post-treatment, abundant vRNA+ cells were detected within the follicle-like regions of the spleen. However, few CAR NK cells were detected and none were found in proximity to HIV+ cells. Importantly, we saw no evidence of

adverse health outcomes related to treatment. Our data indicate that armored CAR/CXCR5 NK cells and activated NK cells are safe and effective at reducing viral loads in a subset of treated animals. The low levels of CAR/CXCR5 NK cells in lymphatic tissues suggest that they may be inefficient at migrating into lymphoid tissues and may explain why they did not outperform unedited NK cells. This study demonstrates the promise of activated NK and engineered CAR NK therapeutics for clearing HIV infections and our future studies will focus on improving the lymphoid-homing potential of our therapies. This work supports further study of novel NK cell therapies for the durable remission of HIV.

262 Broadly-neutralizing antibodies and *CCR5*-edited hematopoietic stem cell transplantation synergistically delay virus recrudescence in a nonhuman primate model of HIV

Jason Murray[1], Teresa Einhaus[1], Carly Starke[2], Stefan Radtke[3], Katharine Bar[4], Keith Jerome[1], Christopher Peterson[5], Hans-Peter Kiem[3]
[1]Fred Hutchinson Cancer Center, Seattle, WA, [2]Fred Hutch Cancer Center, Seattle, WA, [3]Fred Hutchinson Cancer Center, Seattle, Washington, [4]University of Pennsylvania, [5]Fred Hutchinson Cancer Research Center

Introduction
Autologous, gene-edited hematopoietic stem and progenitor cell (HSPC) gene therapies have the potential to cure HIV, but require near-complete replacement of the host immune system in blood and tissues. In our vetted nonhuman primate (NHP) model, we are optimizing transplantation regimens to maximize engraftment of CRISPR-edited HSPCs, redirect cytoreductive approaches to reduce the number of infected cells *in vivo*, and merge orthogonal antiviral approaches. Here, we tested the hypothesis that infection-resistant D*CCR5* HSPCs would synergize with a humoral immunotherapy, intravenous delivery of a virus-specific broadly neutralizing antibody (bNAb), to eliminate latently-infected cells.

Methods
Rhesus macaques were infected with an HIV-like virus (simian/human immunodeficiency virus, SHIV.C.CH505.v2) and placed on antiretroviral therapy (ART) to model suppressed HIV infection. Bulk $CD34^+$ HSPCs were collected after G-CSF/Plerixafor mobilization, edited with NHP *CCR5*-specific CRISPR ribonucleoprotein (RNP) complexes, cryopreserved, and transplanted after conditioning with either myeloablative busulfan or an anti-CD45 antibody-drug conjugate (ADC). At week 26-30 post-transplant, ART was withdrawn and plasma viral load was monitored for signs of recrudescent virus replication. At ART withdrawal, a subset of animals received a single infusion of VRC07.523.LS, a safe and effective bNAb with potency against HIV and SHIV.C.CH505.v2, and is currently in clinical trials in people living with HIV (PWH).

Results
Myeloablative busulfan and CD45-ADC elicited mild lymphopenia while maintaining potent suppression of plasma viremia, with a similar range of *CCR5* editing efficiencies in peripheral blood. Shortly after transplantation, we observed depletion of $CD45^+$ cells in lymph nodes and spleen after ADC conditioning. Observed levels of *CCR5* editing in HSPC-derived PBMCs (~8-26%, Figure 1) did not impact the kinetics of post-RT viral rebound with either conditioning regimen compared to non-transplanted controls. While bNAb alone delayed rebound, the combination of transplant + bNAb further delayed recrudesence, by an average of 38 days compared to untreated controls (Figure 2).

Conclusions
Our NHP model of suppressed HIV infection is well- suited to identify conditioning regimens that replace or augment hematopoietic subsets with minimal impact on host immunity and their ability to synergize with other long-term treatment options for viral control. Our results advance our clinically relevant model, highlight long-term persistence of CCR5-edited HSPC and progeny *in vivo,* and confirm that antibody-based therapies augment HSPC-based approaches. Our ongoing efforts are focused on quantitative comparisons between busulfan- and CD45-ADC conditioning regimens, the latter of which may also directly deplete latently-infected cells.

Tumor-infiltrating lymphocytes (TILs) have emerged as a promising autologous cell therapy to treat solid tumors by expanding and reinfusing tumor-reactive T cells. While TIL therapy has had some success in specific cancers, including recent FDA approval for advanced melanoma, its efficacy has been limited by the heterogeneity of expanded TIL products and the prevalence of dysfunctional exhausted CD8+ T cells (T_{EX}). A subset of CD8+ TILs that are double-positive (DP) for the CD103 and CD39 cell surface proteins is enriched for tumor-reactive TILs across multiple cancer types, but also expresses other proteins associated with the T_{EX} state. To identify factors that may improve T_{EX} phenotype by reprogramming gene networks, we used a lentiviral Open Reading Frame (ORF) library encoding all human transcription factors (TFs) to screen for master regulators of proliferation in tumor-reactive human TILs from non-small cell lung cancer patients. Two proliferation screens were conducted in parallel by initially isolating either human CD8+ or DP TILs, activating with anti-CD3/CD28, transducing the lentiviral library the following day, and sorting highly proliferative or lowly proliferative cells after 16 days of culture via CellTrace staining. TFs associated with cell proliferation (e.g. MYC, MYC-L) emerged as top hits for the CD8+ TIL

screen, but only RELB and RELA emerged as top hits driving proliferation in DP TILs. Individual validation of RELB overexpression confirmed a drastic improvement in TIL proliferation, with up to a 10-fold change across four different human TIL donors and a skew towards CD8+ TILs after in vitro expansion. Transient delivery of RELB mRNA to TILs also conferred an improvement in proliferation and a skew towards CD8+ TILs that persisted for up to 8 days post-electroporation for one donor. Transcriptomic changes were measured via bulk RNA-seq on RELB-overexpressing TIL subsets (CD4+, CD8+, and DP+), revealing a more memory-like phenotype with upregulation of T cell memory genes (BATF3, SELL, CCR7) and downregulation of naïve (TCF7) and exhaustion markers (PD-1). T cell receptor diversity of the same TIL subsets overexpressing RELB was assessed via bulk T cell receptor sequencing (TCR-seq) before and after *in vitro* expansion, which demonstrated a maintenance in TCR repertoire diversity and a marginal improvement in diversity to the DP TILs across four distinct donors. To assess functional capacity of engineered TILs, TILs overexpressing RELB or RELA were armed with a chimeric antigen receptor (CAR) targeting a HER2-expressing breast cancer cell line. RELB and RELA conferred improved persistence after multiple rechallenges with the cancer cells, and a final surface marker staining of the remaining TILs revealed that RELB-overexpressing TILs were mostly CD8+, while RELA and CAR-only conditions had no remaining CD8+ TILs. Using the same CAR-TIL model targeting HER2, mice were xenografted with a HER2+ tumor line and CAR-TILs overexpressing RELB significantly improved tumor control over control CAR-TILs. Current work is focused on identifying tumor-reactive TCRs and tracking these TCRs after *in vitro* expansion in engineered TIL products, functional validation of RELB killing *in vivo* with matched patient-derived tumor organoid xenograft models in different cancer contexts, and using transient RELB delivery methods for clinical translation of enhanced engineered TIL products.

264 Producing Genetically Engineered, Cytokine-Secreting Allogeneic Monocytes from CD34+ Cord Blood Cells as Cell Therapy for Solid Tumors

Katherine Brempelis[1], Emily Hsieh[1], **Jared Pudiwitr[2]**, Carrie Stoltzman[1]*, Erika von Euw[1], Colleen Delaney

Introduction:
Solid tumors are challenging targets for existing cell therapies due to poor infiltration of the tumor mass by immune cells and immunosuppression in the tumor microenvironment (TME). Current approaches to overcoming these challenges have had limited success, with only two FDA-approved cell therapies (both autologous T cell-based) for solid tumors. In addition, autologous cell therapies are expensive, patient-dependent, and can require weeks to produce limited cell numbers. To address these issues, we developed an *ex vivo* process that first expands CD34+ hematopoietic stem and progenitor cells (HSPCs) from pooled healthy donor cord blood units and then differentiates the expanded HSPCs into therapeutically relevant numbers of cryopreservable monocytes, immune cells that traffic to and persist in solid tumors and play a large role in coordinating anti-tumor T cell and NK cell responses. Furthermore, we have engineered our monocytes to secrete cytokines to resist immunosuppression in the TME and to recruit immune effector cells, providing an allogeneic off-the-shelf cell therapy option with the potential to revolutionize the treatment of solid tumors.

Methods & Results:
Using RNA-seq analysis, we demonstrate that monocytes generated with our proprietary *ex vivo* culture process exhibit similar expression levels of differentiation, function, and immune-regulatory genes compared to peripheral blood-derived monocytes. We have also incorporated lentiviral delivery methods to transduce pooled cord blood-derived CD34+ HSPCs that are then expanded and differentiated to genetically engineered monocytes. Using the eGFP transgene, we demonstrate that lentiviral transduction during CD34+ HSPC expansion generates 75% eGFP+ myeloid progenitors and that these levels are maintained following *in vitro* differentiation to monocytes and macrophages. Though increased transgene size results in reduced transduction efficiency, we still achieve 51% CAR-EGFRt+ monocytes that can differentiate *in vitro* to 44% CAR-EGFR+ macrophages. We also demonstrate lentiviral delivery to HSPCs of four unique transgenes encoding immune activating cytokines followed by the mCherry reporter, resulting in stable transgene expression in differentiated myeloid cells (33-51% of monocytes, 42-59% of macrophages) and cytokine secretion by both monocytes and macrophages. With removal of the mCherry reporter from the transgene construct, we expect to achieve levels of cytokine transgene expression comparable to the high, stable levels seen with the eGFP transgene.

Conclusions:
We have validated that our proprietary *ex vivo* culture platform generates CD34+ HSPC-derived monocytes expressing a gene profile characteristic of peripheral blood-derived monocytes. Further, we have expanded the capacity of our platform, demonstrating production of genetically engineered monocytes and macrophages. The addition of lentiviral transduction to our platform allows for long-term, stable expression of transgenes resulting in engineered monocytes and macrophages that are capable of secreting cytokines. We are currently assessing the ability of these engineered monocytes and macrophages to drive anti-tumor immune responses while allowing the transduced cells to resist the immunosuppressive TME.

265 TITLE: TIGIT Deletion Rescues the Antitumor Activity of Low Avidity T cells by Increasing TCR Signal Strength

Ospendale San Raffaele, Milano, Italy, [11]Ospedale San Raffaele, Milano, Italy, [12]Università Vita Salute San Raffaele, Milan, Italy

Pancreatic ductal adenocarcinoma (PDAC) is a major unmet medical need, with a high mortality rate mainly related to the rapid development of the disease. This aggressive progression lowers the 5-year survival rate to 12%. While conventional treatment often fail, adoptive cell therapy (ACT) is a promising therapeutic option. A key barrier to the clinical success of ACT is the difficulty in isolating high-avidity tumor specific TCRs, and to generate T cells able to resist the signals from the immunosuppressive microenvironment. To select valuable target antigens, we first investigated published datasets and identified 19 relevant tumor-associated antigens. By clonal tracking of the TCR repertoire of T cells stimulated with autologous APCs loaded with immunogenic peptides derived from the selected antigens, we isolated 5 different HLA-A*0201 restricted TCRs specificities. Importantly, all these antigens are expressed in our internal cohort of primary and metastatic PDAC patients. We exploited a cytosine base editor (CBE) to generate TCR-edited T cells and enhanced their potency by knocking-out TIGIT, a key inhibitory molecule expressed on exhausted T cells infiltrating PDAC. We confirmed the specificity of each TCR-edited T cell product, which killed PDAC cell lines expressing the antigen and the proper HLA, while sparing negative controls. To boost the efficacy of anti-tumor T cells, we coupled TCR editing with TIGIT knockout (KO). By challenging $TIGIT_{KO}$ and $TIGIT_{COMP}$ T cells in orthotopic models of PDAC primary tumors and colorectal cancer liver metastases, established from patient-derived organoids, we noticed that TIGIT KO induced different effects according to the TCR avidity. Indeed, low-avidity TCR-edited T cells redirected toward MSLN controlled tumor growth only in the absence of TIGIT, which rescued their antitumor capacity against PDAC. On the other hand, high-avidity T cells controlled tumor progression independently from TIGIT expression. Mechanistically, TIGIT disruption enhanced the TCR signal strength of low-avidity T cells by increasing the phosphorylation of ZAP70, enforcing then cytoskeletal rearrangements that enhanced T cell avidity and stabilized the immunological synapse with cancer cells. These events ultimately improved the degranulation capacity of $TIGIT_{KO}$ low-avidity T cells, reaching the level of high-avidity lymphocytes. We then evaluated the safety profile of our manufacturing system, by targeted sequencing of sgRNA-dependent off-target events and ultra-deep whole exome sequencing for sgRNA-independent off-target events. By a direct comparison of CBE and CRISPR/Cas9, we observed that both editing procedures proved highly efficient in simultaneously disrupting *TRAC*, *TRBC1*, *TRBC2* and *TIGIT*. While T cell phenotype was unaffected, CRISPR/Cas9 treatment caused translocations between our four target loci and aberrant T cell expansion. We then confirmed that CBE produces high on-target editing with minimal off-target nucleotides conversion and observed that it did not introduce biologically relevant spurious DNA off-target mutations. Collectively, our findings suggest that our T cell manipulation procedure is safe and specific, and that the genetic disruption of TIGIT can rescue the anti-tumor capacity of low-avidity T cells, highlighting TIGIT KO as a potential

strategy to broaden the repertoire of exploitable TCRs for the treatment of PDAC and other solid tumors with adoptive T cell therapy protocols.

266 CRISPR-Engineered CAR T Cells for Targeting Senescence-Associated Urokinase-Type Plasminogen Activator Receptor (uPAR)

Lauren Sarko[1], David Givand[1], Claire Shepley[1], Allen Attar[1], Benjamin Kutler[1], Roshini Traynor[2], Anika Upadhyaya[1], Mackenzie Mnuk[1], Nat Murren[1], Tyler Ulland[1], Theresa Kotanchek[3], Krishanu Saha[1]*

Cellular senescence is a critical biological process that limits cell proliferation and prevents the propagation of damaged cells. However, the accumulation of senescent cells contributes to aging and disease, necessitating innovative therapeutic strategies for their selective elimination. Here, we present a novel approach leveraging nonviral CRISPR genome editing to generate potent chimeric antigen receptor (CAR) T cells to precisely target the human urokinase plasminogen activator receptor (uPAR), a senescence-associated surface protein highly expressed on pathological senescent cells.

By precisely integrating a uPAR-targeting CAR transgene into the T cell receptor, alpha chain (*TRAC*) locus, we produced CAR T cells that exhibited robust, selective cytotoxicity against both induced and patient-derived senescent cells while minimizing off-target effects on healthy proliferating cells. Additionally, uPAR-*TRAC*-CAR T cells underwent spontaneous fratricide-driven refinement, leading to the emergence of a highly pure (>99%) CAR+/TCR- population displaying a CD45RA+/CD62L+ stem cell memory-like phenotype within days (**Figure A-B**). This refinement signature is maintained post-cryopreservation, enhancing therapeutic potential and streamlining manufacturing efficiency. Furthermore, we demonstrated that this strategy can be broadly applied to enhance the manufacturing of potent CAR T cells across other targeting systems (e.g., GD2-CART, **Figure C**).

Our integration of a uPAR-CAR through precise genome engineering not only establishes a scalable and effective strategy for senescent cell clearance but also introduces a novel manufacturing strategy to autonomously generate a highly enriched population of CAR T cells. With future development, uPAR targeting CAR T cells could accelerate the development of therapeutics targeting age-related diseases, fibrosis, and cancer.

Background
CAR T-cell therapies have achieved extraordinary outcomes in hematological malignancies, but translating this success to solid tumors requires strategies to enhance T-cell functionality and durability in the challenging solid tumor microenvironment. The number of approved cell therapies for solid tumors remains limited, with tumor-infiltrating lymphocytes (TIL) expanded from patient tumors recently receiving approval in melanoma. However, these TIL products have a highly exhausted phenotype and require systemic high-dose IL-2 for their survival, leading to toxicity in patients. Additionally, failure of T cells to expand and persist long-term and a paucity of costimulatory signals in the tumor microenvironment further limit efficacy. Lyell has developed multiple genetic reprogramming technologies to address these challenges: 1) overexpression of the activator protein 1 (AP-1) family transcription factor, c-Jun, to delay exhaustion and increase sensitivity to IL-2/15 cytokine stimulation (Lynn RC et al. 2019); 2) a chimeric costimulatory receptor (CCR) incorporating an NKG2D extracellular domain coupled with intracellular costimulatory domains to enhance activation in the context of TCR signaling; and 3) membrane-bound IL-15 (mbIL-15) driving signal transducer and activator of transcription 5 (STAT5) signaling to promote T-cell proliferation and persistence. Together, these technologies may enable the generation of potent and durable T-cell therapies, demonstrating significant efficacy and persistence *in vitro* and *in vivo* in exhausted TIL.

Methods
T-cell products were manufactured using protocols designed to maintain stemness, activated with standard reagents, and transduced with a vector encoding the following technologies alone or in combination: c-Jun, NKG2D CCR, and mbIL-15. Technologies were tested in healthy donor T cells and exhausted donor TIL. Cytotoxicity, cytokine production, and phenotype were evaluated *in vitro* after repeated antigen stimulation assays. Engineered TIL were evaluated for antitumor efficacy and engraftment *in vivo* in NSG MHC I/II double knock out mice implanted with an A375 tumor cell line engineered to express a low-affinity αCD3 molecule to activate T cells and the NKG2D ligand MICA to engage the CCR.

Results
TIL engineered with all three technologies demonstrated superior expansion and cytotoxicity over six rounds of repeated antigen stimulation *in vitro*, proliferating and killing tumor cells for 1-3 additional rounds compared to TIL engineered with two technologies, and 4-5 additional rounds compared to non-engineered TIL. During this period, TIL engineered with all three technologies enriched 40-60% and secreted at least 2-fold higher IFNγ and 6-fold higher IL-2 compared to non-engineered TIL. *In vivo*, survival of non-engineered TIL is typically transient in the absence of cytokine support, preventing durable anti-tumor efficacy (Zhao Y et al. 2022). In contrast, TIL engineered with all three technologies successfully engrafted *in vivo* without exogenous IL-2 and exhibited robust antitumor efficacy and significantly improved survival compared to TIL lacking one or more technologies (p-value=0.02).

Conclusions
Engineered T cells combining c-Jun overexpression, costimulation, and mbIL-15-driven STAT5 signaling demonstrate potent activation, robust T-cell expansion without exogenous IL-2 support, and effective, durable antitumor activity in xenograft solid tumors.

Emerging Delivery Platforms for In Vivo Gene Editing

268 Engineered Extracellular Vesicles Enable Efficient Gene Editing in the Mouse Brain

Introduction
Gene editing holds immense promise for revolutionizing the treatment of human diseases. However, achieving safe and efficient non-viral delivery of gene editing tools in vivo remains a significant challenge, particularly to the brain. Extracellular vesicles (EVs) have emerged as promising vehicles for delivering Cas9 ribonucleoproteins (Cas9-RNPs), but their delivery efficiency is hindered by two key obstacles: suboptimal encapsulation of Cas9-RNPs and insufficient binding between single-guide RNA (sgRNA) and Cas9. Addressing these limitations is critical to unlock the full potential of EV-based gene editing.

Methods
Building upon advanced EV engineering strategies that enable highly efficient intracellular protein delivery (manuscript in revision in Nat Comm (X. Liang et. al, 2024), preprint available: https://doi.org/10.21203/rs.3.rs-3329019/v1), we further optimized the system for Cas9-RNP delivery. As reported in the preprint, our strategy for delivering Cas9-RNPs via engineered EVs utilized an intein-mediated self-cleavage. Cas9 was tethered to an EV-sorting protein via an intein linker, enabling active loading of Cas9-RNPs into EVs upon co-transfection with sgRNA. Intein's self-cleavage mechanism facilitated the functional release of Cas9 RNP from the EV-sorting domain. For further improvement of cargo release, novel temperature-sensitive intein variants were incorporated into engineered EVs. To address the second obstacle, the sgRNA binding to Cas9, we modified the sgRNA scaffold and validated its improved binding affinity using microscale thermophoresis (MST).

We tested the editing efficiency of these EV engineering strategies in vitro in reporter cells and on endogenous targets, either by flow cytometry or Sanger sequencing, respectively. Furthermore, using an osmotic minipump, we evaluated in vivo gene editing by intracerebroventricular (ICV) infusion of optimized engineered EVs into adult mice. Mice were sacrificed 2 weeks post-infusion, and the brain regions were dissected for bulk analysis with Sanger and next-generation sequencing.

Results
The use of an optimized modified sgRNA increased Cas9-RNP delivery efficiency by over 10-fold compared to our previous system in reporter cells. Further enhancement, exceeding 10-fold, was achieved by introducing a novel temperature-sensitive intein variant, which improved Cas9-RNP packaging into EVs. Combining the modified sgRNA and intein variant produced synergistic effects, resulting in a remarkable 100-fold improvement in editing efficiency for both, reporter cells and endogenous targets. To evaluate the in vivo potential of the engineered EVs, we infused them intracerebroventricularly (ICV) over 24h via an osmotic minipump to deliver Cas9-RNPs targeting the transthyretin (TTR) locus in mice. Selected brain regions were divided into infused vs. non-infused hemispheres and analyzed as a bulk sample with Sanger and next-generation sequencing (NGS), both of which methods confirmed over 30% TTR editing in the cortex and hippocampus and more than 25% in the cerebellum, irrespective of the infusion site.

Conclusion
Our work demonstrates innovative strategies to enhance EV-based Cas9-RNP delivery through sgRNA modification and improved packaging. The engineered EVs achieved remarkable gene editing throughout different brain regions

of adult mice, showing significant promise for treating central nervous system (CNS)-related diseases with non-viral delivery vector.

269 The First Coacervate-based Delivery System for Advanced Gene Therapy

Xiaofei Gao[1]*, Renxia Zhang[2], Peipei Zhu[1], Qing Zhang[2], Xiaoqian Nie[1]
[1]Westlake University, Hangzhou, Zhejiang, China, [2]Nanoportal Biotech, Hangzhou, China

Gene therapy marks a significant breakthrough in the pharmaceutical field, necessitating the development of advanced delivery technologies to facilitate its clinical application. Here, we report the identification of a mammalian endogenous protein capable of forming coacervates with various nucleic acids. These coacervates exhibit an mRNA encapsulation capacity 1000-fold greater than lipid nanoparticles (LNPs), demonstrating efficient cellular entry, robust cytoplasmic release of nucleic acids, and broad compatibility with diverse cell types, including primary human and mouse immune cells. Based on these properties, we developed the first coacervate-based system for gene delivery, named EASY, utilizing human and mouse endogenous proteins (PCT/CN2024/124967). EASY supports a wide range of genetic cargoes for gene overexpression, knockdown, and knockout.

With EASY, we achieved over 90% transfection efficiency for mRNA encoding green fluorescent protein (GFP) in primary human T cells, while maintaining 90% cell viability. GFP expression persisted in 64% of cells up to 12 days post-transfection, highlighting its high payload capacity. EASY also achieved high transfection efficiency across various types of primary cells, including NK cells, B cells, and hematopoietic stem cells (HSCs). Notably, EASY facilitated efficient gene knockout by co-delivering Cas9 mRNA and sgRNA. For example, EASY achieved >80% efficiency in targeting the TRAC, B2M, and PDCD1 genes in human primary T cells, improving the safety and efficacy of T cell therapies. Indeed, EASY demonstrated a robust capacity for delivering large genetic cargoes, enabling simultaneous editing of up to ten genes by co-delivering Cas9 mRNA and the corresponding sgRNAs in human primary T cells, with consistent editing efficiency across all targets. To further explore its therapeutic potential, we targeted BCL11A in HSCs, a transcription factor that represses γ-globin and fetal hemoglobin expression in erythroid cells. The knockout of BCL11A increases fetal hemoglobin expression, offering a potential therapeutic strategy for hemoglobinopathies. Our results showed that approximately 80% of alleles at this locus were successfully modified, with no evidence of off-target editing in HSCs using EASY, highlighting its potential for advancing cell therapy.

In addition to gene knockout, EASY supports targeted genomic integration through homology-directed repair (HDR). By inducing double-strand breaks and delivering single-stranded DNA (ssDNA) templates, EASY achieved >30% efficiency in inserting an anti-CD19 chimeric antigen receptor (CAR) sequence into the PDCD1 gene locus. This approach generated CAR-T cells with sustained CAR expression and disrupted PD1 expression. These enhanced CAR-T cells exhibited potent anti-tumor activity in NSG mice xenografted with $CD19^+$ Raji cells.

In conclusion, EASY is a versatile, non-viral, LNP- and electroporation-free gene delivery platform that combines high efficiency, low toxicity, and user-friendliness. By eliminating risks such as insertional mutagenesis and dependence on specialized equipment, EASY represents a transformative tool for gene editing and cell therapy manufacturing, significantly expanding the therapeutic potential of CAR-T, HSC other cellular therapies.

270 Engineered Protein Delivery Vehicles Enable Single Intrastromal CRISPR-Cas9 Therapy for TGFBI Corneal Dystrophies with High Efficacy and Safety: A Comprehensive Preclinical Assessment in Non-Human Primates

Changchang Xin[1], Qian Luo[2], **Zihua Jiang[3]**, Xichen Wan[4], Hua Lu[5], Mingrui Chen[4], Xujiao Zhou[4], Martin Chan[6], Xingtao Zhou[4], Zongli Zheng[7], Jiaxu Hong[8]
[1]Fudan University, Fundan, China, [2]Karolinska Institutet, Solna, Sweden, [3]Karolinska, Solna, Stockholm, Sweden, [4]Fudan University, Shanghai, China, [5]Geneditbio Limited, Beijing, China, [6]Geneditbio Limited, Hong Kong, Sha

Tin, Hong Kong, [7]City University of Hong Kong, Hong Kong, Kowloon City, Hong Kong, [8]Fudan University Eye Ear Nose and Throat Hospital Department of Ophthalmology, CHINA

Introduction
TGFBI corneal dystrophies (CDs), driven by mutations in the TGFBI gene (e.g., R124H, R555W), are a group of inherited disorders characterized by progressive corneal opacity and vision impairment. Current treatment regimes such as keratoplasty and laser therapy are invasive, associated with recurrence risks, and fail to address the underlying root genetic pathology. CRISPR-Cas9-mediated gene editing offers a curative approach by directly disrupting mutant TGFBI to halt pathogenic protein accumulation. However, the lack of efficient and transient in vivo delivery systems for corneal keratocytes remains a major translational barrier. To address this, we developed an investigational CRISPR-Cas9 ribonucleoprotein (RNP)-based therapy delivered via engineered protein delivery vehicles (PDVs), as an investigational single intrastromal treatment for CD. PDVs combine the selectivity of viral vectors with the transient nature of TGFBI-targeting RNPs, avoiding genomic integration and prolonged exposure risks.

Methods
Preclinical evaluation encompassed *ex vivo* human corneal organoids, biodistribution studies in Ai9 reporter mice, and efficacy/toxicity assessments in non-human primates (NHPs) and rodents. NHPs received intrastromal injections at low, medium, or high doses. Ocular safety was monitored via McDonald Shadduck scoring, intraocular pressure (IOP) tracking, and histopathology over 28 days. Pharmacokinetics, immunogenicity, and safety were assessed, including serum Cas9 and vehicle structural protein (p30) detection, anti-drug antibody (ADA) assays, and non-cornea tissues editing analysis. Acute hepatotoxicity and nephrotoxicity were evaluated in rodents.

Results
In human organoids, the PDV achieved 24.2% on-target editing efficiency. In NHPs, it demonstrated dose-dependent efficacy with significant stromal diffusion and local confinement. The medium dose group exhibited a 60.4% peak efficiency. No detectable Cas9 and p30 (structural component of PDV) proteins were noted in serum. Minimal editing (<0.05%) was observed in extraocular tissues. The ocular adverse reactions were transient and manageable: the high-dose NHP group developed reversible corneal neovascularization or opacity. Transient IOP reduction (≤6.0 mmHg) occurred in high-dose NHPs but self-resolved within 7 days. Systemic ADA response was limited to the two high-dose NHPs with pre-existing anti-Cas9 titers, whereas low and medium doses showed minimal systemic ADA responses. Rodent studies confirmed unremarkable hepatotoxicity and nephrotoxicity of the PDV.

Conclusion
In this preclinical study in NHPs, a single intrastromal dose of the PDV led to dose-dependent targeted knockout of the TGFBI gene and no severe adverse events were observed. Balancing high editing efficiency with controlled local inflammation, the PDV here is a promising therapeutic candidate for TGFBI CDs and a first-in-human trial is justified.

271 CRISPR/Cas9 delivery using acerola-derived nanoparticles for targeted gene editing in the central nervous system

We have developed drug delivery systems using extracellular vesicles including exosomes as carriers, and in particular, exosomes with cancer tissue-specific directivity by genetic modification were expected to have clinical applications. However, in consideration of drug development, (1) methods for mass purification of exosomes from cells, (2) low efficiency of nucleic acid loading into exosomes, and (3) immunogenicity issues associated with HLA expression have made practical application difficult. Therefore, to overcome the above issues, we focused on exosomes derived from edible plants instead of exosomes derived from animal cells. Previous studies have shown

that plant-derived exosomes themselves are not susceptible to degradation by digestive enzymes such as bile acids and pepsin, and from this it was inferred that they would be useful as DDS carriers that protect against degradation from digestive enzymes such as gastric acid and enable oral administration of protein and nucleic acid preparations, etc. Then we have attempted to isolate exosomes from various edible plants, and found that exosome-like nanoparticles (AELNs) derived from acerola have the most advantages in clinical applications. First, AELNs can be extracted from acerola fruit at low cost and in large quantities. Furthermore, the AELN-nucleic acid complexes are stable against digestive enzymes, indicating that AELNs can be used as DDS carriers for oral administration of nucleic acid drugs. In addition, previous studies have confirmed that fluorescently labelled AELNs administered orally to wild-type mice can reach the brain after systemic delivery. Therefore, the possibility that AELNs could be applied to brain treatment was considered. In this study, we developed a drug delivery system using acerola-derived exosome-like nanoparticles (AELNs) as carriers for oral and intranasal administration of CRISPR/Cas9 to edit genes within target organs, specifically the central nervous system (CNS). We chose AELNs due to their stability against digestive enzymes, which allows for the oral administration of sensitive protein and nucleic acid therapies. We extracted AELNs from acerola juice, achieving high recovery rates of particles sized between 200-400 nm. When these particles were combined with Cas9 protein and guide RNA (gRNA) to form ribonucleoprotein complexes (RNPs), they successfully edited the GLA gene in HEK293 and HUVEC cell lines. Notably, these complexes were as effective as RNAiMAX, a commercial gene delivery reagent, in editing genes. Furthermore, we explored using AELNs to deliver the CRISPR/Cas9 system designed to target the GGGGCC repeat expansion in the C9orf72 gene, which is implicated in ALS. By attaching GLP2 peptide to the AELNs/RNP complexes, we enhanced their uptake in cells expressing the GLP2 receptor, suggesting that GLP2 can direct these complexes to specific tissues. We demonstrated in a mouse model that oral and intranasal administration of these peptide-tagged AELNs/RNP complexes led to successful genomic editing within the brain, highlighting the potential of this system for treating neurodegenerative disorders. This study presents a novel, potentially transformative approach for in vivo genome editing using a targeted, non-invasive delivery system. Further research into the mechanisms of complex formation and the broader applicability of ligand-directed delivery systems is necessary to realize the full potential of this technology in gene thera

272 Enhancing Nanoparticle Delivery of Therapeutic Neurofibromatosis Type 1 Epigenetic Regulatory Protein Payloads *In Vivo*

Kenneth Sims[1], Emma Schmitz[1], Andrea McCue[1], Ashlee Colbert[2], Jacqueline Grible[1], Dean Constantine[1], Sam Farrar[1], Nick Andrioff[3], Miguel Pedrozo[3], Phil Denen[1], Pong Thongsavanh[4], Danielle Huk[3]

***Introduction & Methods*:**
Safe, effective delivery to the central nervous system is an ongoing challenge for the gene therapy field. One approach to solving this problem is by using an iterative design-build-test-learn (DBTL) polymer nanoparticle (PNP) discovery platform to produce and screen novel PNP designs *in vitro* and *in vivo*. For this study, top performing PNPs that had been previously produced via reversible addition-fragmentation chain transfer polymerization were intrathecally administered and evaluated for biodistribution in C57BL/6 wild type (WT) mice using proprietary nucleic acid barcoding technology. After characterizing the PNPs for size, polydispersity index (PDI), loading efficiency, transfection efficiency, and cell viability *in vitro*, three lead candidate PNP designs identified in the biodistribution study were loaded with a therapeutic payload, dosed intrathecally in WT mice, and evaluated against an FDA-approved drug, selumetinib, in a functional performance study for knockdown of multiple targets known to be associated with Neurofibromatosis Type 1 (NF1).

***Results*:**
Seven out of fifty-one PNP designs evaluated in the biodistribution study were found in either the brain or sciatic nerve tissue in WT mice. Two PNPs were found in both tissues. Altogether, these PNP designs reduced particle size and PDI, while maintaining loading efficiency and cell viability levels plus increasing transfection efficiency in Schwann cells. Four of the seven PNP designs were produced in a larger quantity using a proprietary “scale-out” approach to evaluate reproducibility and ensure sufficient material quantities were available for functional performance studies *in vivo*. Three of these four PNP designs were selected for *in vivo* testing and were safely administered intrathecally without any adverse effects in WT mice. Functional performance results revealed one

PNP design that significantly knocked down one of the gene targets in the brain. In addition, the selumetinib control caused significant knockdown of one gene in the liver, but none of the PNPs tested caused any significant knockdown of gene targets in the liver. Sciatic nerve test results are pending.

***Conclusions*:**
This set of studies evaluated biodistribution, scale-out production, and functional performance of multiple PNPs loaded with a therapeutic epigenetic regulatory protein payload. PNPs capable of delivering to sciatic nerve and/or brain tissue were identified, reproduced at larger scale, and down-selected for gene knockdown testing *in vivo*. The top 3 PNPs were safely administered intrathecally to WT mice and did not cause off-target gene knockdown effects as observed with the FDA-approved drug selumetinib. One PNP also showed significant knockdown of one gene target in the brain. Overall, these results demonstrate promising initial preclinical safety and efficacy outcomes for PNP delivery vehicles loaded with a therapeutic epigenetic regulatory protein payload intended for nervous system use.

273 *In vivo* Hematopoietic Stem Cells transduction to Deliver Neuroprotective Extracellular Vesicles for Parkinson's Disease Treatment

Karthik Karuppusamy[1], Akshara Velmurugan[1], Aidan Maynard[1], Sucheol Gil[2], Jiho Kim[3], Chang Li[4], Andre Lieber[1]

The therapeutic potential of delivering Glial Cell Line-Derived Neurotrophic Factor (GDNF) to neurons using macrophage/microglial cells is promising, as GDNF supports dopaminergic neurons, protects them from degeneration, and promotes their survival—key aspects in treating Parkinson's Disease (PD). Intranasal injection of ex vivo generated exosomes loaded with GDNF effectively alleviated PD symptoms in mice. However, the ex vivo production of engineered extracellular vesicles is costly cellular, requires labor-intensive purification from conditioned cell culture medium, and treatment necessitates repeated administration. Our goal is to engineer hematopoietic stem and progenitor cells (HSPCs) in vivo to produce GDNF-containing extracellular vesicles (EVs) from HSPC-derived, brain-localized macrophage/microglial cells and deliver GDNF to damaged neurons, resulting in the cross-correction of the PD phenotype. This strategy is based on an in vivo HSC gene therapy approach that we successfully employed in the past to treat hemoglobinopathies, hemophilia A, and cancer in moue models. This approach involves the mobilization of HSPCs from the bone marrow and the intravenous injection of an integrating, helper-dependent adenovirus (HDAd) vector. We demonstrated that HSPCs, transduced in the periphery, returned to the bone marrow and, after in vivo selection, effectively contributed to gene-modified circulating myeloid cells and brain-localized microglia cells. Towards our goal, we first engineered HDAd vectors for efficient production of extracellular vesicles that deliver reporter genes. The reporter genes (GFP, Nano luciferase, and Cre recombinase) are fused with a CD63-exosome sorting domain, which is released within EVs by mini-intein self-cleavage. We characterized EVs derived from transduced HEK293 cells for size and specificity by Dynamic Light Scattering and Western blot. We demonstrated the presence of GFP loaded into EVs using flow cytometry. We further showed successful cargo delivery by adding EVs from the supernatant of engineered HEK293 cells to recipient K562 cells, resulting in up to 90% GFP delivery. Confocal microscopy confirmed cell-to-cell transfer of EVs in producer cells. To further validate this process, we created a reporter K562 cell line using a lentiviral system to express CFP upon Cre delivery. We produced HDAd vectors encoding CD63-Cre, transduced them into K562 cells, and created a stable line that continually produces EVs containing Cre recombinase. In co-culture experiments, we observed efficient transfer of EVs, with up to 5% CFP expression in reporter cells at a 1:3 ratio of reporter to producer cells, further confirming EVs-mediated cell-to-cell transfer. For in vivo validation, we generated a double homozygous human CD46/Ai9 transgenic mouse model. (Human CD46 is the receptor for our HDAd vectors.) After injecting mobilized mice with HDAd vectors encoding Cre recombinase, with and without the CD63 sorting domain, we analyzed in vivo reporter gene (tdTomato) expression in tissues, including the brain. For PD therapeutic applications, we constructed HDAd-shuttle plasmids expressing CD63-GDNF from macrophage- and microglial-specific promoters, and transfected them into HEK293, THP-1, and BV-2 cells. GDNF loading into EVs, isolated from these cells, was demonstrated by ELISA. We are now preparing HDAd vectors for in vivo HSC transduction in a chemically induced PD mouse model.

274 Enabling Extracellular Vesicles for Targeted Gene Delivery Using Deep Learning Models-Designed Ligands

Xiaoshu Pan[1], Mei He[1], Zachary Greenberg[1], Zuo Ding[1], Peixin Huang[2], Hinrich Staecker[3], Yanjun Li[1]

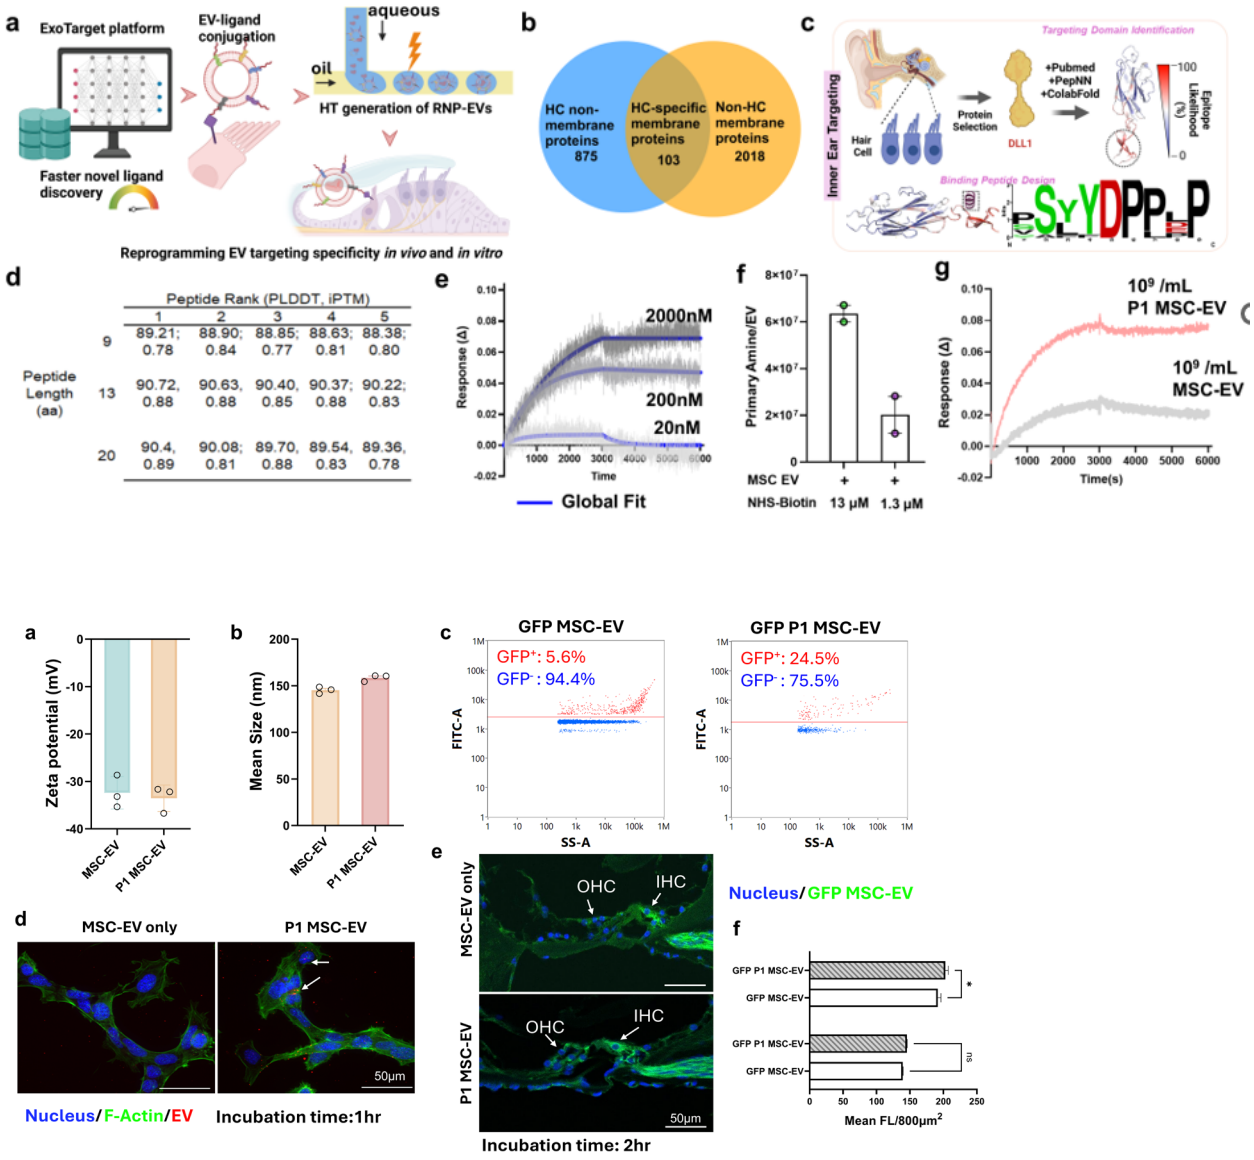
Effective drug delivery to the inner ear is essential for addressing hearing and vestibular impairments, improving health outcomes and quality of life. The inner ear, though small, is composed of highly specialized cells that perform distinct functions. Delivering the right cargo to the appropriate cell types in the inner ear is essential for developing safe and effective therapeutics for treating inner ear diseases. However, effectively generating ligands with high specificity and affinity for different cell types remains a significant challenge. Recent advancements in transcriptomic databases facilitated by single-cell sorting and sequencing technologies from gEAR portal provide valuable resources for ligand discovery for the inner ear-specific delivery.
We hypothesized that novel, cell-specific targeting ligands could be rapidly developed for the inner ear using inner ear transcriptomic database and Rosettafold-based deep learning models. The resulting ligands can then be feasibly conjugated to extracellular vesicles (EV) and screened for their ability to enhance EV-based gene delivery to the inner ear (Fig. 1a). Through database mining and comparative analysis (Fig. 1b), we identified 15 single-pass transmembrane proteins with relatively high expression in hair cells from a pool of 103 hair cell membrane proteins. Among these, Delta-like ligand 1 (Dll1) was selected as the most promising candidate for downstream ligand discovery, backed by comprehensive experimental studies. Using the PepNN model, the DSL domain of Dll1 was selected, and over 1000 peptides were generated with RFDiffusion and ProteinMPNN. AlphaFold were employed to rank and confirm peptide-protein interaction. (Fig. 1c-d) We then utilized biolayer interferometry (BLI) assays confirmed strong and consistent binding of Peptide 1 (one of the top 5 peptides) to Dll1 (Fig.1e). The N-hydroxysuccinimide ester functionalized biotinylation agent (NHS-Biotin) identified that around 10^7 primary amines per MSC EVs for the downstream peptide-EV conjugations via carboxyl-to-amine crosslinking chemistry. (Fig. 1f) The resulting Peptide1 MSC-EV (P1 MSC-EV) can effectively enhance the binding of MSC-EVs to the Dll1 protein in cell-free condition shown by BLI assay in Fig. 1g. The nanoparticle tracking analysis of P1 MSC-EV conjugates showed that there is no significant difference in size and zeta potential compared to natural MSC-EVs. The resulting P1 MSC-EVs were then electro-transfected with GFP proteins and free GFP was removed using immobilized metal affinity chromatography (IMAC) with nickel beads. The NanoFCM showed that 24.5% of GFP P1 MSC-EV has detectable GFP signals in the P1 MSC-EVs while MSC-EV has around 6%. *In vitro* cell uptake assays with $Dll1^+$ HEI-OC1 cells demonstrated effective binding within 1hr incubation period between P1 MSC-EV conjugates labelled with BioTracker 555 and target cells. The *in vivo* biodistribution study revealed differential targeting of inner hair cell (IHC) and outer hair cells (OHC) in the inner ear by P1 MSC-EV and MSC-EV. (Fig. 2e-f) These preliminary results demonstrate the feasibility of using deep learning models to design ligands for enabling EVs for targeted delivery in the inner ear.



AAV Gene Transfer (B): Ocular, Neurological & Immune Cell Systems

275 Introduction of a Lysine Acetylation Motif into the AAV2 VP1 to Enhance Macular Tropism and Intravitreal Administration

Shengjiang Liu[1]*, Alan Chen[2], Sameera Peraramelli[3], Jin Zhong Li[1], Minghua Dai[2], Yanbao Yu[4], Eduardo Santillan[5], Derrick Huynh[6], Mingwei Zhang[7], Ying Li[2]

Adeno-associated virus (AAV) vectors are the main gene delivery method for gene therapies, while capsid engineering is promising to improve tissue tropism and vector delivery efficiency. Lysine acetylation is a major posttranslational modification (PTM) involved in a broad array of physiological functions including rAAV-host cell interaction. In this study, rAAV constructs containing various peptide sequences were inserted into the VP1 loop III or IV region of AAV2 serotype. The peptide inserts contained a lysine acetylation motif within a consensus sequence of "xxxKP in which the x residues stand for those hydrophilic and uncharged amino acid residues (Q, S, T). A novel capsid AAV.N54, containing a lysine acetylation motif, xxxK_{595}P, having improved tropism to deep regions of retinas was identified through multi-species screening in mice, pigs, rabbits, and African green monkeys. Across the four species screened, AAV.N54 showed improved tropism over AAV2 and AAV.7m8, as evidenced by efficient delivery to the macular retina and detargeting from retinal ganglion cells. A 6-month study in Cynomolgus monkey eyes, injected with AAV.N54-GFP intravitreally, demonstrated a high and durable expression of GFP in macular and optic nerve head (ONH) regions. Highly purified AAV.N54-VEGF-Trap, manufactured using Sf9 and HEK293 cell culture systems was further characterized for lysine acetylation at K_{595} and was confirmed using LC-MS. The K_{595} lysine acetylation determines the selectivity of AAV.N54 capsid to target cells in retina tissue. In a laser-induced choroidal neovascularization (LCNV) mouse model, fluorescein angiography (FA) and flatmount analysis (FMA) showed that AAV.N54-VEGF-Trap prophylactically reduced retina lesions. In a DL-AAA rabbit disease model, AAV.N54-VEGF-Trap demonstrated remarkable efficacy in reducing vascular leakage and inflammation. In addition, a GLP toxicity study in NHPs demonstrated that AAV.N54-VEGF-Trap is well-tolerated. Overall, it was demonstrated that an engineered capsid, containing a K_{595} acetylation motif, has improved delivery to the macular retina and cross-species translatability was identified. A novel gene therapy using the capsid was developed for wet age-related macular degeneration (wAMD) including polypoidal choroidal vasculopathy (PCV).

276 Systemically delivered AAV5-based capsid variants enable up to 88% targeted RNA editing in primate brain

AAV-delivered gene therapies hold enormous potential to treat neurological disease, but remain constrained by the challenges of crossing the blood-brain barrier (BBB) and AAV's inherent liver tropism. For example, our RNAfix® technology achieves over 90% targeted RNA editing in non-human primate (NHP) brain, but initial experiments using wild type AAV required invasive cranial surgery, and efficient editing was limited to injection-proximal regions. Encouragingly, novel engineered AAVs are emerging that can efficiently cross the primate BBB following systemic injection, but these capsids are almost all variants of AAV9. Given the high prevalence of anti-AAV9 antibodies in humans, these capsids may be limited in their addressable patient population. To overcome this challenge, we developed an AAV capsid engineering pipeline based on AAV5, which shows markedly lower population seropositivity than AAV9. We first disrupted AAV5's natural liver tropism by removing its known sialic acid-binding surface region, and replaced it with a massive diversity of novel potentially tissue-targeting sequences. Through progression from a billion-plex primary screen to a 5,000-plex secondary screen, we identified 30 capsids that demonstrated strong BBB penetration in NHPs. Singleplex analysis of three candidates confirmed robust BBB-crossing, with delivery of AAV DNA to >50% of brain cell nuclei while achieving >30-fold liver detargeting relative to AAV9. However, despite enabling higher RNA expression in brain relative to wild-type AAV9, absolute RNA expression remained insufficient for broad therapeutic application. To enhance RNA expression from our CNS-targeting capsids, we performed a deep mutational scan in NHP across all 30 initial candidates, identifying lead capsids with superior RNA expression in the NHP CNS. Notably, we observed that AAV5-based capsids tend to exhibit a reduced AAV RNA-to-DNA ratio relative to AAV9-based capsids, indicating impaired functional transduction. We hypothesized that the VP1/2 unique region of AAV5, which is critical for intracellular trafficking and uncoating and is divergent from almost all other serotypes, might underlie some of this deficiency. Through systematic screening of mutations and domain shuffles, we identified novel VP1/2u sequences that significantly boosted in vitro transduction across multiple cell lines for both wild-type AAV5 and its

variants. We then engineered a high performing VP1/2u sequence into our top CNS-targeting capsids and packaged a construct expressing an ADAR-based RNA editing guide RNA (gRNA) and a marker gene mRNA. We intravenously delivered to cynomolgus macaques at a dose of 1E13 vg/kg and harvested tissues after 4 weeks in life. Two highly promising capsids demonstrated robust payload expression (gRNA and mRNA detected in >40% of NeuN+ neurons across the brain) and achieved widespread targeted RNA editing (median 25-35% across brain regions). We observed particularly high transduction from these capsids in the substantia nigra (SN), a deep brain region of critical importance in Parkinson's disease (PD), with ~80% transduction of NeuN+ neurons and 69-88% editing of target RNA in this region. Together, our results represent three significant advances: the first demonstration of systemically delivered RNA editing in a primate brain; the highest primate neuronal targeting by a BBB-crossing AAV5 variant; and the highest targeting of the primate SN seen with any novel brain.

277 Rational Design to Develop Novel AAV Variants for Improved Gene Delivery to Retinal Microglia

Recombinant adeno-associated virus (AAV) vectors have been widely used in gene therapy applications for central nervous system (CNS) diseases and have yielded favorable outcomes. These vectors can successfully transduce post-mitotic cells, such as neurons and astrocytes. Emerging evidence indicates that the microglia, the resident immune cells in the CNS and retina, play a central role in the pathobiology of neurodegenerative diseases. Consequently, these cells have become the focus of new treatment approaches. However, the targeted and effective manipulation of microglia is hampered by the lack of efficient viral and non-viral targeting methods. In addition, most studies on microglia have so far focused on the more accessible CNS population, while other populations, such as retinal microglia, have been less explored due to lower cell numbers and the lack of efficient primary culture methods.

To overcome these limitations, we have established easy and reproducible culture conditions that enable isolation, expansion and long-term culture of postnatal mouse retinal microglia cells. The method yields a high number of viable and pure cells (>85% Cd11b+Cd45+ cells) with intrinsic microglia features such as phagocytosis. The method can also be adapted to human retinal donor tissue samples from which we obtained a pure retinal microglia population (75% CD11b+CD45+ cells) displaying a characteristic immune-related marker and proteomic profile. We have used this unique *in vitro* model of retinal microglia as a screening platform to test novel AAV variants based on AAV1 and AAV6 capsids carrying genomes with a CMV-eGFP reporter expression cassette. The capsid variants carried single-point mutations of surface-exposed tyrosine, lysine, threonine, serine residues, and/or arginine residues, or the GL or NN peptide insertions from previously described AAV2.GL and AAV2.NN capsids. Capsid variants of AAV1 with the GL insertion showed transduction efficiencies that were more than 10-fold increase over the AAV1 wild-type and around 5-fold compared to the triple mutant AAV6 TM6 at 5 dpi. The increased transduction efficiency has been confirmed in resting and chemically activated microglia and allowed us to achieve dCas9-VPR (epi)genome editing to transactivate endogenous genes as well as gene knock-out without causing pro-inflammatory activation of the targeted microglia cells. Mechanistic studies suggest a more efficient nuclear entry and a higher affinity to cell-surface AAV receptors of the AAV1.GL variants. Finally, we started to validate our variants in mouse models of retinal disorders. In the Rd1 mouse model, which shows a strong induction and activation of microglia, we reached around 20% of Cd11b+Cd45+ cells after intravitreal and subretinal injection of AAV1.GL variants.

In summary, our newly developed culture method facilitates functional and molecular studies of retinal microglia cells, which have been poorly investigated to date. This innovative retinal microglia culture platform has helped to identify new, more efficient AAV capsids that could facilitate the development of future gene therapy and genome editing approaches.

278 A novel dual affinity selection (DAS) capsid screening platform for engineering AAV capsids with enhanced photoreceptor transduction via intravitreal delivery

Jianghui Wang[1], Mengtian Cui, Claudio Punzo[1], Guangping Gao[1]
[1]UMass Chan Medical School, Worcester, MA

Inherited retinal diseases (IRDs) are a prime target for recombinant AAV (rAAV)-based gene therapy, exemplified by the FDA-approved Luxturna. Current therapies rely on invasive subretinal injections to target photoreceptors, the primary cells affected in IRDs, but this method suffers from localized efficacy and procedural risks. To address these limitations, novel AAV capsids are being engineered to enable efficient photoreceptor targeting via less invasive intravitreal (IVT) injections.

Prior studies using animal models to screen capsids for improved retinal transduction achieved only modest IVT-mediated photoreceptor targeting compared to existing capsids like 7m8. While reducing heparan sulfate (HS) binding enhanced retinal penetration, this strategy alone inconsistently improved transduction. We found HS localized to the inner limiting membrane (ILM) and inner retinal cells but absent in photoreceptors across mice, pigs, and NHPs. Conversely, sialic acids, a potential receptor class, were expressed on photoreceptor surfaces in these species.

We hypothesize that capsids with reduced HS binding and enhanced sialic acid affinity will achieve superior photoreceptor transduction via IVT injection. As proof of concept, we developed a dual affinity selection (DAS) capsid screening platform: (1) an HS-mediated transwell system to select capsid variants with reduced HS binding, followed by (2) a sialic acid-based magnetic bead pull-down assay to enrich variants with increased sialic acid affinity. A 12-mer peptide library was inserted at position N587 of the AAV2 capsid, generating a diverse library for first HS-based screening. Next-generation sequencing (NGS) identified 1,638 uniquely enriched capsid variants from the first screen with potentially reduced HS-binding ability. Among these, a leading candidate, termed IvtAAV.12mer1, was selected for in vivo validation. We produced single-stranded (ss) IvtAAV.12mer1.CB6.GFP and compared its transduction efficiency in mice via IVT injection ($2x10^9$ vg/eye) to ssAAV2.CB6.GFP and ss7m8.CB6.GFP. Our preliminary data revealed that IvtAAV.12mer1 achieved significantly more robust panretinal transduction, demonstrating a 14-fold increase compared to AAV2 and a 4.5-fold increase compared to 7m8. Additionally, IvtAAV.12mer1 showed enhanced GFP expression across all inner retinal cell types. Most notably, it exhibited a dramatic 174-fold improvement in photoreceptor transduction compared to AAV2 and a 3.5-fold improvement over 7m8, without inducing significant inflammatory cytokine expression compared to other two vectors, including TNFα, IL-6, IL-1β, and IFNγ.

To assess its performance in large animal models, we administered ssIvtAAV.12mer1.CB6.GFP and ss7m8.CB6.GFP ($1x10^{11}$ vg/eye) via IVT injection in pig eyes. Retinal whole mounts revealed similar transduction patterns for both vectors, primarily localized to the optic nerve head with gradual radial spread and diminished GFP intensity. Immunostaining confirmed transduction across all retinal cell types, including photoreceptors, but homogeneity was limited, likely due to inadequate photoreceptor-specific receptor binding. While reduced HS binding improved retinal penetration, robust photoreceptor transduction required a second screening step targeting sialic acid. We are currently conducting the second screening phase to identify capsids with optimized sialic acid binding for uniform photoreceptor transduction.

279 Targeted DART-AAVs as *In Vivo* Gene Delivery Platform for the Selective Transduction of TME Cell Subsets

In vivo gene delivery has emerged as powerful tool for novel therapeutic concepts. A major challenge is the development of vectors capable of mediating highly selective gene transfer specifically into therapy-relevant cells. For this purpose, we have developed the concept of rational-based receptor-targeting of AAV vectors harnessing designed ankyrin repeat proteins (DARPins) in order to specifically deliver therapeutic genes into particular cell types of the tumor microenvironment (TME) such as CD8+ T cells and tumor cells (DARPin Targeting AAV: DART-AAV).

In our recent work [1], we engineered AAV2- and AAV6-based capsids displaying high-affinity DARPins specific for murine or human CD8 to specifically manipulate CD8+ cytotoxic T cells. In contrast to conventional AAV vectors, the modified vectors exhibit high selectivity for both murine and human CD8+ T lymphocytes. Upon systemic injection, the targeted vectors achieved an impressive *in vivo* gene transfer rate of up to 80%, which represents a breakthrough in the *in vivo* modification of T cells with AAV vectors. Most remarkably, near absolute selectivity for CD8+ T cells was observed in immunocompetent mouse models. The CD8-AAVs were detargeted from liver, where unmodified vectors caused a strong signal. Building on this platform, we engineered AAV9, which is known to be able to pass the blood-brain-barrier (BBB), for receptor-targeted delivery into tumor cells. Specifically, we developed HER2-AAV9 vectors displaying DARPins against the HER2/neu tumor antigen, resulting in significantly enhanced transduction of HER2+ tumor cells *in vitro*. When equipped with an anti-PD-1 or IL2 expression cassette, these vectors conferred robust checkpoint-inhibitor or IL2 secretion. In mice bearing subcutaneous HER2+ SKOV-3 xenografts, HER2-AAV9 mediated tumor-targeted delivery of a luciferase reporter with minimal hepatic transduction. To capitalize on the ability of AAV9 to penetrate BBB, we next evaluated the performance of DART-AAV9 in a glioblastoma model. The vector demonstrated a clear preference for HER2+ GL261 cells within the brain, with minimal transduction observed in healthy neural tissue after local or notably also systemic AAV administration. Moreover, when we inserted peptides described to enhance BBB penetration into the AAV9 capsid in combination with DARPin insertion, BBB penetration was further enhanced without increasing the liver transduction.

Collectively, these receptor-targeted AAV vectors exhibit exceptional efficiency and specificity, opening new avenues for directly modifying therapy-relevant cell populations *in vivo*. This platform holds promise for both, basic research and the development of next-generation gene therapy strategies, particularly in the context of tumor-specific immunomodulation.

Demircan MB, Zinser LJ, Michels A, Guaza-Lasheras M, John F, Gorol JM, Theuerkauf SA, Günther DM, Grimm D, Greten FR, Chlanda P. T-cell specific in vivo gene delivery with DART-AAVs targeted to CD8. Molecular Therapy. 2024 Oct 2;32(10):3470-84.

280 Selective Improvement in Retinal Bipolar Cell Targeting with Intravitreal Injection of a Novel AAV Capsid in Mouse and NHP

Amanda Miles[1], Carrie Maryak[1], Lindsey Campion[1], Barbara Diaz-Rohrer[1], Kathy Lin[1], Jude Verdieu[1], Abigail Sheridan[1], Shireen Abesteh[1], Nishith Nagabhushana[1], Christopher Reardon[1], Sarah Hilton[2], Erik Lykken[1], Jamie Kwasnieski[1], Mugdha Deshpande[1], Adrian Veres[1], Eric Kelsic[1]
[1]Dyno Therapeutics, Watertown, MA, [2]Dyno Therapeutics, Seattle, WA

Intravitreally (IVT) delivered optogenetic therapies that selectively target secondary neurons like retinal bipolar cells, such as in the RESTORE and STARLIGHT clinical trials, are demonstrating efficacy for patients with advanced vision loss. These trials rely on delivery by the natural AAV2 serotype with a bipolar cell-specific promoter, despite AAV2's limited transduction of bipolar cells when injected via IVT. To address this challenge, we developed and validated a novel AAV capsid that when injected via IVT has selectively improved transduction in bipolar cells across multiple animal models, outperforming all tested externally engineered capsids. This capsid's

cell tropism underscores its transformative potential in advancing optogenetic therapies for restoring vision in patients with severe retinal degeneration.

We engineered this novel capsid through in vivo screening and validation in adult cynomolgus macaque eyes. Analysis of a multiplexed capsid library delivered by IVT injection, revealed that this capsid achieved over a ~40-fold improvement in broad retinal transduction compared to AAV2, and outperformed all externally engineered capsids tested. To further validate its transduction efficiency, we conducted a head-to-head comparison by co-injecting four cynomolgus macaque eyes intravitreally with the novel capsid and an externally engineered capsid (1e10-1e11vg doses per capsid). Histological analysis revealed that the novel capsid showed expanded transduction from the peripheral retinal into the central retina, demonstrating broad and robust targeting. Notably, transduction efficiency across the retina increased by 3-4-fold compared to the externally engineered capsid, with the most significant improvement observed in retinal cells within the inner nuclear layer (INL), where transduction was increased by 4-5-fold. Co-staining with retinal markers confirmed that this transduction was primarily in PKC-α+ bipolar cells within the INL. Transduction levels in other retinal layers were not as improved, indicating that the enhanced efficiency was specific to bipolar cells. Similar evaluation in mouse retinas further supported these findings, also showcasing improved targeting to PKC-α+ bipolar cells after IVT injection. Specifically, the novel capsid showed a ~1.5-fold increase in mouse INL transduction compared to the externally engineered capsid, with over 40% of the INL layer transduced. The conserved transduction efficiency across both primates and mice illustrates the utility of this capsid for preclinical model testing of gene therapies and increases confidence in the translatability of its properties to other species, including humans.

These findings highlight the promise of this novel capsid as a powerful tool for advancing targeted gene therapies for retinal degeneration.

281 Generative AI Discovers GMU037, a Dual-Fitness Capsid with Simultaneous Superior NHP Ophthalmic Transduction and High Production Yield

Jason Wu[1], Tess Torregrosa[1], Rachna Manek[2], Yumeng Cao[3], Yu Qiu[2], Johanna Adams[4], Margaret Hennessy[1], Michael Ryan[1], Mehmet Takar[5], Pavitra Ramachandran[6], Eugenia Lyashenko[1], Christian Mueller[7], **Sourav Choudhury[1]**
[1]Sanofi, Waltham, MA, [2]Sanofi, Cambridge, MA, [3]MIT, Cambridge, [4]Sanofi, Bridgewater, NJ, [5]UT Southwestern Medical Center, Dallas, TX, [6]Genzyme, a Sanofi Company - Cambridge, MA, Waltham, MA, [7]Sanofi Genzyme, Waltham, MA

AAV gene therapy has made great progress in addressing previously intractable diseases. Despite this, many of these therapies have faced significant challenges, chief among them is the high cost to payers which limits uptake and presents a barrier to patient access, and toxicity associated with large clinical doses. Improving biodistribution and producibility of capsids could address both issues. Current molecular biology-based capsid engineering approaches have focused on improving only one property at a time, often to the detriment of the other. The capsid sequence search space (20^{735} combinations) is too large to simultaneously probe biodistribution and yield in a single capsid. Due to its ability to digitally simulate at whole-genome scale, the rapidly evolving field of generative artificial intelligence is ideal for this purpose. We have developed a pipeline that comprises a proximal exploration-based GenAI framework processed through a dual-fitness filter, to develop novel capsids with simultaneously improved tropism and manufacturability. This pipeline allowed us to investigate the unexplored sequence space around a current ophthalmic clinical capsid, interrogating >100-fold more capsids than the maximum possible by unbiased biological high-throughput screening. Using this pipeline, we uncovered a novel capsid, GMU037. Intravitreal administration of GMU037 in cynomolgus macaques resulted in 10-fold greater transduction of non-human primate peripheral retina compared to the current ophthalmic clinical capsid. At the same time, production of GMU037, either by research-grade triple transfection method or by a CMC-compatible process, yielded 10-fold higher vector genomes/cell than the current ophthalmic clinical capsid. Intriguingly, both properties are associated with a novel mutation, suggesting that our GenAI dual-fitness engine could accelerate discovery of complex first-principles of AAV biology.

Novel Models and Advances for Heart, Lung, and Kidney Gene Therapy

282 AAV-Mediated Gene Replacement Preserves Exercise Tolerance and Prevents Cardiac Remodeling in a Murine Knockout Model of SLC25A4 Deficiency

Abigail Benkert[1], David Wolfson[2], Trevor Gonzalez[3], Beatrice Sewell[4], Sophia Fergione[5], Kevin Strauss[6], Aravind Asokan[7]
[1]Duke University Medical Center, Durham, NC, [2]Solid Biosciences, Charlestown, MA, [3]Torque Bio, Durham, NC, [4]Duke University School of Medicine, Durham, NC, [5]Duke University, Durham, NC, [6]Clinic for Special Children; Plain Inspiration Project, Strasburg, PA, [7]Duke University, Durham, North Carolina

Solute carrier family 25, member 4 (SLC25A4) is a gated pore that exchanges cytosolic ADP for mitochondrial ATP across the inner mitochondrial membrane of heart and skeletal muscle tissues. This exchange is necessary to supply substrate to complex V of the respiratory chain; functional SLC25A4 is thus a critical member of mitochondrial oxidative phosphorylation. Biallelic loss-of-function variants in *SLC25A4* result in skeletal myopathy, hypertrophic cardiomyopathy, exercise intolerance, and lactic acidosis marked by proliferation of hypofunctional mitochondria in myocytes. An ancestral frameshift variant of *SLC25A4* (c.523delC; p.Q175RfxX38) is relatively common among North American Mennonites and individuals homozygous for this variant exhibit cardiac dysfunction and progressive myocardial thickening that can culminate in end-stage heart failure necessitating transplantation.

We hypothesized that replacement of SLC25A4 activity through recombinant adeno-associated viral (rAAV) delivery could restore myocyte bioenergetics, prevent cardiac remodeling, and improve exercise capacity while normalizing tissue biomarkers and mitochondrial copy number. We generated a cross-species evolved, liver de-targeted AAV capsid (AAV.cc84) packaging the *SLC25A4* transgene under the control of a cardiac/musculoskeletal promoter. When delivered to human induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs) and mouse myoblasts *in vitro*, rAAV-SLC25A4 vectors enabled robust expression of SLC25A4 protein, which localized appropriately to the inner mitochondrial membrane.

We next generated and characterized an *Slc25a4* knockout mouse model (*Slc25a4 -/-*). By 14 weeks of age, *Slc25a4 -/-* mice have plasma alanine concentrations nearly two-fold higher than those of age-matched control mice ($p=0.022$). *Slc25a4 -/-* mice develop a concentric dilated cardiomyopathy characterized by increased cardiac mass, ventricular dilation, reduced contractile performance ($p=0.018$), and fibrosis. Exercise tolerance is also significantly reduced by 4 months of age ($p<0.0001$). Treatment of *Slc25a4 -/-* mice with a single systemic dose of rAAV-SLC25A4 resulted in robust SLC25A4 protein expression in cardiac and skeletal muscle target tissues, and reduced biodistribution and expression in off-target organs, including the liver. Neonatal rAAV-SLC25A4 treatment improved survival (log-rank $p=0.0482$), preserved exercise capacity ($p=0.0020$), and prevented cardiac remodeling in *Slc25a4 -/-* mice (0.0032). Functional outcomes from ongoing studies over longer time intervals will also be presented. In summary, AAV-mediated gene replacement is a promising therapeutic strategy for the treatment of SLC25A4 deficiency.

283 misiRNA: A Dual-Action mRNA Therapeutic to Treat Atherosclerosis

Isabella Hetherington[1], Hana Totary-Jain[2]
[1]University of South Florida, Bradenton, FL, [2]University of South Florida, Tampa, FL

Atherosclerotic cardiovascular disease (ASCVD) remains the leading cause of mortality and morbidity worldwide, placing a severe economic burden on healthcare systems. Current therapies, including lipid-lowering and antihypertensive drugs, primarily manage risk factors rather than directly targeting the diseased cells within atherosclerotic plaques. While percutaneous coronary intervention (PCI) with stenting is a common treatment for those experiencing acute coronary syndromes, it comes with significant risks, including in-stent thrombosis and neo-atherosclerosis, caused by delayed endothelial healing. One of the biggest limitations in the field is the lack of cell-

selective therapies that can specifically target diseased segments of the vasculature without harming the protective endothelium. Recently, the groundbreaking CANTOS trial demonstrated that inhibiting interleukin-1β (IL-1β) reduces recurrent cardiovascular events, highlighting inflammation as a critical driver of disease progression and demonstrating the need for targeted anti-inflammatory strategies.

To address this gap, we developed misiRNA, a pioneering, dual-action mRNA therapeutic that integrates miRNA-switch and siRNA technologies into a single mRNA construct to simultaneously inhibit plaque progression and suppress inflammation, while preserving endothelial integrity. This innovative therapeutic encodes the cyclin-dependent kinase inhibitor $p27^{kip1}$ to halt vascular smooth muscle cell (VSMC) proliferation and includes an endothelial-specific miRNA-responsive element to restrict translation in ECs, and an IL-1β siRNA within its poly(A) tail to knockdown inflammation. This unique design allows for precise therapeutic action, targeting pathogenic cells while safeguarding vascular homeostasis.

To ensure precise delivery, we used a self-assembling nanoparticle system using cell-penetrating peptides that selectively target to inflamed and damaged vascular regions, avoiding healthy tissues. *In vitro*, misiRNA effectively suppressed VSMC proliferation, reduced IL-1β expression, and preserved endothelial integrity. *In vivo*, systemic administration of misiRNA nanoparticles to $ApoE^{-/-}$ mice fed a high-fat diet led to preferential accumulation in atherosclerotic plaques and resulted in a significant reduction in plaque burden.

This novel, cell-selective mRNA-based nanotherapy has the potential to reduce the reliance on stents and could transform ASCVD treatment by selectively modulating plaque-forming cells while sparing protective endothelial cells. Furthermore, this platform technology could be adapted for other vascular diseases, representing a major breakthrough in precision medicine.

284 Corrective Editing to Treat Pseudoxanthoma Elasticum

Lauren Testa[1], Hooda Said[2], Ping Qu[3], Mohamad-Gabriel Alameh[3], Kiran Musunuru[1], Qiaoli Li[4], **Xiao Wang[1]**
[1]University of Pennsylvania, Philadelphia, PA, [2]Children's Hospital of Philadelphia, Philadelphia, PA, [3]the University of Pennsylvania, Philadelphia, PA, [4]Thomas Jefferson University, Philadelphia, PA

Pseudoxanthoma elasticum (PXE) is a rare, autosomal recessive connective tissue disorder caused by pathogenic variants in ABCC6, resulting in ectopic calcification of elastic fibers in the arteries, skin, retina, and gastrointestinal tract. Arterial calcification can lead to coronary artery disease, myocardial infarction, stroke, and intermittent claudication of peripheral arteries. The multisystemic manifestations of PXE contribute to substantial morbidity and mortality, and there are currently no targeted therapies.

Among the >300 ABCC6 variants reported in ClinVar, c.3490C>T (p.R1164X) and c.3421C>T (p.R1141X) are the two most frequent single-nucleotide variants and are potentially correctable with adenine base editing. The ABCC6 gene encodes an ATP-binding cassette protein, which functions as an efflux transporter localized to the plasma membrane mainly in the liver. While its specific substrate remains unknown, ABCC6 is a major regulator of pyrophosphate (PPi), and hepatic ABCC6 is a primary contributor of PPi to the circulation.

Motivated by these findings, we aim to develop adenine base editing therapeutics for PXE. Using prime editing or lentiviral transduction, we generated HuH-7 human hepatoma cell lines carrying the R1164X or R1141X variant. Screening various adenine base editors (ABEs) and guide RNAs (gRNAs), we identified ABE8.8 with PXE1 gRNA (targeting R1164X adenine at position 4 of its spacer sequence) and SpG-ABE8.8 with PXE2 gRNA (targeting R1141X adenine at position 5) as the most efficient at corrective editing.

To assess off-target editing with PXE1, we performed OligoNucleotide Enrichment and sequencing (ONE-seq) and targeted amplicon sequencing, verifying several off-target sites. While none pose oncogenic risks, to minimize off-target editing we explored a strategy using hybrid gRNAs in which certain positions of the spacer sequence are substituted with DNA nucleotides. We designed a series of 21 hybrid gRNAs (PXE1_hyb1 through PXE1_hyb21) with single, double, or triple DNA nucleotide substitutions and screened them in R1164X HuH-7 cells. In particular,

PXE1_hyb18, with substitutions at positions 5, 6, and 7 of the spacer sequence, reduced off-target and bystander editing while increasing on-target efficiency.

For in vivo evaluation, we developed a humanized mouse model in which a portion of mouse Abcc6 was replaced with the orthologous human sequence with the R1164X variant. Homozygous R1164X mice displayed reduced blood PPi levels and substantial muzzle calcification, mirroring PXE patients. We formulated lipid nanoparticles (LNPs) with ABE8.8 mRNA and either PXE1 standard or PXE1_hyb18 gRNA and administered them to R1164X mice. We observed that, compared to the PXE1 standard gRNA, the PXE1_hyb18 gRNA significantly increased the corrective on-target editing while reducing both off-target and bystander editing in vivo. LNP treatment of homozygous R1164X mice rescued the deficiency of PPi in the blood and, remarkably, eliminated muzzle calcification, suggesting that variant correction in the liver alone is sufficient to prevent ectopic elastic fiber calcification in distant sites and potentially address all multisystemic manifestations of PXE.

These findings support the feasibility of in vivo adenine base editing to permanently correct the two most frequent single-nucleotide pathogenic ABCC6 variants and, as a result, PXE phenotypes. This approach holds promise as one-time, long-term therapy for PXE patien

285 Delivery Route and Species-Specific Transduction Mechanisms Enable Robust Proximal Tubule Transduction of AAV-KP1 and AAV9 Irrespective of Neutralizing Antibodies in Non-Human Primates

Ranjan Das[1], Taisuke Furusho[2], Hideyuki Hakui[3], Anusha Sairavi[3], Pratheppa Rajagopal[4], Lena Li[1], Masahiro Horikawa[1], Kentaro Yamada[1], Nicole Andeen[1], HIROYUKI NAKAI[3]*

Kidney gene therapy using adeno-associated virus (AAV) holds promise for treating monogenic kidney diseases; however it is hindered by the organ's complex anatomical and functional structure. Additionally, presence of neutralizing antibodies (NAbs) further complicates effective transduction, limiting the eligible patient population and the potential for vector re-administration. It has been reported that even a low titer of pre-existing anti-AAV NAbs abolishes in vivo AAV transduction in non-human primates (NHPs) when administered systemically. We hypothesized that a local injection in renal pelvis can evade preexisting NAbs against AAV due to thousand times less immunoglobulin concentration in the urine than that in the blood. Here, we demonstrate that both AAV-KP1 and AAV9 can effectively and selectively transduce proximal tubules (PTs) following a real-time image-guided retrograde transureteral renal pelvis (RP) injection in both NAb-positive and negative NHPs. In addition, we reveal distinct renal transduction mechanisms via RP in mice and NHPs, where RP overcomes NAbs only in NHPs but not in mice, and enables AAV9 to effectively transduce PTs in NHPs despite its inability to transduce PTs in mice. This study involved a cohort of seven female rhesus macaques. In the initial experiments, AAV-KP1 and AAV9 were administered via RP in NAb negative NHPs and in the second experiments, AAV-KP1 and AAV9 were administered to NHPs with pre-existing NAbs. Blood samples were collected pre-injection and at multiple time points post-infusion for pharmacokinetic analysis, while tissues were harvested 3-weeks post-injection to assess AAV vector transduction and biodistribution. Similar to NAb-negative NHPs, robust transduction was observed by fluorescence microscopy in the cortex of the kidney of all three NAb-positive NHPs. Transduction pattern was also segmental corresponding to the injection path and the transduction was predominantly observed in the PTs, with no detectable transduction in glomerular cells. Notably, off-target liver transduction was almost completely suppressed in AAV-KP1 and AAV9-injected NHPs with pre-existing NAbs. In these animals, AAV was cleared from the bloodstream more rapidly compared to NHPs without NAbs. This accelerated clearance is likely attributable to the rapid removal of neutralized viral particles from the bloodstream by host immune mechanisms, implying beneficial effect of pre-existing NAbs in minimizing transduction in off-target organs including the liver. In contrast, mice injected with AAV-KP1 via RP were unable to overcome pre-existing anti-AAV-KP1 humoral immunity resulting in no significant kidney transduction in the presence of NAbs. Based on these observations, we have proposed a mechanistic model for RP-mediated PT transduction. In the model, PT transduction via RP is predominantly facilitated by basolateral entry in mice. In contrast, the primary route of PT transduction in NHPs occurs through

direct vector entry from the urinary (apical) side. This apical pathway minimizes interactions between AAV and blood or interstitial fluid containing anti-AAV NAbs, thereby enabling the vector to evade neutralization in NHPs. Thus, this study demonstrates for the first time that effective AAV-mediated gene delivery to PTs can be achieved using both AAV9 and AAV-KP1 in NHPs, even in the presence of anti-AAV NAbs. Therefore, local administration of AAV vectors via RP holds promise for clinical applications.

286 Podocyte Gene Therapy Enables Kidney Complement Modulation for IgA Nephropathy (IgAN) Treatment

Sarah Smith-Moore[1], Ambra Cappelletto[2], Rowan Asfahani[3], James Matthews[3], Alice Gennari[3], Hannah Wood[3], Sam Illingworth, Gavin Welsh[4], Moin Saleem[5], Alice Brown[6]
[1]Purespring Therapeutics, LONDON, London, United Kingdom, [2]Purespring Therapeutics, London, Greater London, United Kingdom, [3]Purespring Therapeutics, London, United Kingdom, [4]University of Bristol Medical School, UNITED KINGDOM, [5]University of Bristol Medical School, BRISTOL, Bristol, City of, United Kingdom, [6]Purespring, LONDON, London, United Kingdom

Adeno associated vector (AAV) gene therapy has the potential to treat a wide range of kidney diseases via targeted delivery of genes to podocytes, a kidney cell type instrumental in renal function. We have developed a novel AAV gene therapy platform able to deliver transgenes effectively, specifically and safely to podocytes. This approach was previously exemplified through pre-clinical development of PS-001, an AAV gene therapy that delivers the podocin gene, *NPHS2*, to the podocyte.

Here, we present a novel AAV gene therapy candidate, PS-002, that delivers the gene for complement factor I, *CFI*, to podocytes, enabling them to become bio-factories for the secretion of the complement regular CFI to specifically modulate complement activation in the glomerulus. Complement activation has been identified to play an important role in the pathogenesis of many kidney disorders including glomerularnephritis (GN). Immunoglobulin A nephropathy (IgAN) is one of the most frequent forms of GN world-wide, accounting for 25 – 50% of patients with primary GN.

PS-002 consists of a capsid that is highly effective at transducing human podocytes, and a promoter that drives gene expression of CFI specifically in the podocyte. Functional gene expression of CFI was demonstrated in *in vitro* studies in human podocytes, and PS-002 efficacy, safety, and potential for clinical translation was demonstrated in a rodent disease model and in large animal studies in Gottingen Minipigs.

Murine *in vivo* proof of concept studies were conducted in grouped ddY mice, a highly translationally relevant mouse model for IgAN. Using a murine analogue of PS-002, CFI expression was measured in kidney glomeruli and significant efficacy demonstrated via rescue of kidney function. Complement activation was inhibited in treated mice as demonstrated by a reduction in C3 deposits, and amelioration of disease phenotype by preservation of podocytes, reduction in histopathology, and decreased proteinuria.

Administration of PS-002 in pigs resulted in transgene mRNA expression across all kidney glomeruli at 28 days (100% glomeruli, n=3 pigs) and 56 days (99% glomeruli, n=3 pigs) post dosing as assessed by RNAscope, with a dose-response observed by RNAscope, qPCR and RT-qPCR. Using qPCR, RT-PCR, it was shown that, following local administration, CFI was expressed almost exclusively in the kidney glomerulus where podocytes are located, with gene expression undetectable in off-target organs such as the spleen and pancreas, and only low levels of gene expression detected in the liver. AAV delivered human CFI was detected at levels <1000 times physiological levels in the serum, demonstrating that systemic pig CFI activity would not be perturbed. Toxicological assessments of renal and other organ function and post-study histopathological assessments revealed no treatment-related safety concerns. These data demonstrate safe, consistent, and sustained transduction of all kidney glomeruli using PS-002.

Collectively, we present data that demonstrate (i) the feasibility of podocyte targeted gene therapy for glomerular specific modulation of complement, (ii) substantial non-clinical data to enable translation of PS-002 to clinical development for the treatment of IgAN, and (iii) the potential to use podocyte targeting AAV candidates to regulate complement activation in diseases beyond IgAN.

287 Developing Hotspot Prime Editors to enable therapeutic correction of multiple *CFTR* mutations in Cystic Fibrosis

Eric Zheng[1], Dewi Harjanto[1], Sascha Hernandez[1], Marine Hatit[1], Dorjee Shola[1], Jun Mao[1], Katie Holland[1], Rafaela Mendes[1], Zihan Zhang[1], Charitha Guruge[1], Mallikarjuna Putta[1], Yunchao Gai[1], Andrea De Erkenez[1], Vivian Choi[1]*, Jeremy Duffield[1]
[1]*Prime Medicine, Cambridge, MA*
**Corresponding Author*

Cystic fibrosis (CF) is a life-threatening, monogenic autosomal recessive disease caused by mutations in the *CFTR* (Cystic Fibrosis Transmembrane Conductance Regulator) gene. The presence of these genetic mutations impairs the normal transport of chloride ions across epithelial cell membranes, consequently leading to the abnormal accumulation of mucus within multiple organ systems, most notably the lungs and pancreas. The mucus in the lung promotes chronic bacterial infections, inflammation and progressive lung damage, which are the primary causes of mortality in CF patients. Despite significant advancements in therapies such as CFTR modulators, patients that are responsive to the modulators require live-long treatment and more than 15% of CF patients with non-responsive mutations are left without treatment. Genetic therapies for CF have been under development utilizing various delivery methods, yet with limited success thus far. There remains a substantial unmet medical need for a single, disease-modifying treatment that can address the underlying causes of this disease for these patients. Prime Medicine is developing Prime Editors to durably and precisely correct multiple mutational hotspots with high unmet need and aiming to achieve permanent restoration of CFTR expression under endogenous control and normal CFTR function. These Hotspot Prime Editors taken together could address >93% of all CF patients.

Comprehensive high-throughput screening for Prime Editors led to the identification of potent editors capable of precisely correcting prevalent and nonsense *CFTR* mutations across multiple mutational hotspots, including the common G542X mutation. These Prime Editors demonstrated over 60% precise correction in patient-derived primary human bronchial epithelial (HBE) cells and were able to restore CFTR expression in HBE cells differentiated air-liquid interface culture. Correction of *CFTR* mutations also normalized chloride current in an electrophysiology assay, indicating a functional rescue of CFTR. To further evaluate the *CFTR* Prime Editors *in vivo* in a humanized mouse model with *CFTR* p.G542X mutation (*Cftr* $^{CFTR\ \text{p.G542X}/Cftr}$), we developed a lipid nanoparticle (LNP) system to deliver the Prime Editor components in the form of RNA (LNP-PE). We also delivered Prime Editors using a dual-AAV (adeno-associated virus) system in development. Following single doses of our LNP-PE or Dual-AAV PE, we observed encouraging editing activity in lung epithelium, including epithelial progenitor cells, prior to further in vivo optimizations, suggesting this approach can be disease-modifying. Additional data will be presented at the upcoming conference.

These findings demonstrate that Prime Editors delivered via LNPs or AAVs have the capability to accurately and effectively correct the high unmet-need pathogenic mutations causing CF. Prime Editing holds promise as a safe and efficacious curative approach for individuals affected by CF.

288 Optimized Non-Viral Fusogenix Proteolipid Vehicles for Precision Gene Therapy in the Lungs

Douglas Brown[1], Arun Raturi[1], Ping Wee[2], Prakash Bhandari[3], Luis Morales[1], Natasha Rana[1], Tejal Aslesh[1], Amirali Bukhari[2], Natasha Govindasamy[2], Somnath Gupta[1], John Lewis[4]*
[1]*Entos Pharmaceuticals, Edmonton, AB,* [2]*Entos Pharmaceuticals, San Diego, CA,* [3]*Entos Pharmaceuticals US Inc, San Diego, CA,* [4]*Entos Pharma, San Diego, CA*
**Corresponding Author*

Despite the promise of gene therapy in treating various lung disorders, numerous clinical trials have failed to produce meaningful improvements in lung function primarily due to the limitations of current delivery platforms. Specifically, targeting the lungs after systemic injection is particularly challenging for non-viral platforms like lipid nanoparticles (LNPs) because of poor extrahepatic delivery and significant dose-limiting toxicity. The Fusogenix proteolipid vehicle (PLV) addresses these concerns by enabling efficient extrahepatic delivery while maintaining

tolerability. PLVs achieve robust intracellular nucleic acid delivery by incorporating a proprietary fusion-associated small transmembrane protein into a well-tolerated lipid formulation where it catalyzes fusion of the PLV bilayer with the membrane of target cells.

To optimize PLVs for lung-selective delivery, a panel of 20 novel PLV formulations were developed by manipulating manufacturing parameters and lipid composition. These formulations were screened for systemic DNA-GFP delivery, and we identified one formulation, called PLV-Lung (PLV-Lu), that successfully de-targeted the liver and achieved greater than 95% gene delivery to the lungs, as evaluated by GFP ELISA. Histology confirmed GFP expression in type I and II alveolar cells, as well as club cells of the conducting airways. Lung-tropism was maintained with other nucleic acid cargos, as systemic delivery of mRNA-GFP or mRNA-FLuc achieved significant expression of both reporters in the lungs with minimal expression in liver, kidneys, and spleen. Subsequently, we evaluated the ability of PLV-Lu to deliver gene editing technologies. In the Ai9 mouse model, PLV-Lu was used to deliver mRNA-Cre, leading to lung-selective tdTomato expression. Cell profile analysis using immunofluorescence and flow cytometry confirmed extensive tdTomato expression in club, ciliated, and basal stem cells of the conducting airways, as well as type I and II alveolar cells. We then optimized the PLV-Lu formulation for CRISPR-mediated gene editing and successfully co-delivered mRNA-Cas9 and sgRNA targeting the Ai9 'STOP' cassette. *In vivo*, this resulted in significant gene editing in type I and II alveolar cells, as well as club and basal cells in the conducting airways. To enhance delivery to the conducting airways, we tested whether PLV-Lu retained activity following aerosolization. Using a mesh nebulizer, we delivered PLV-Lu encapsulating mRNA-Cre and mRNA-Cas9/sgRNA to Ai9 mice and observed notable tdTomato expression in basal, club, and ciliated cells of the trachea and bronchioles.

To ensure broader applicability, we evaluated the platform's compatibility with siRNA by delivering siRNA targeting a housekeeping gene with PLV-Lu. Systemic delivery achieved 80% knockdown in the lungs and no measurable knockdown in the liver, kidneys, or spleen. Building on this, we assessed the efficacy of PLV-Lu in delivering siRNA targeting the clinically relevant endothelin 1 (EDN1) gene, implicated in pulmonary hypertension. We observed significant EDN1 knockdown in the lungs, with no knockdown detected in the liver or kidneys. This was associated with a decrease in circulating and lung EDN1 levels, as well as a decrease in endothelial-specific EDN1 expression. Overall, these results demonstrate the feasibility of using this unique PLV to selectively deliver nucleic acids to the lungs and modulate gene expression using gene editing technologies.

Modulation of Humoral Immune Responses in AAV Gene Transfer

289 Development of an Adeno-Associated Virus Expressing a Secreted T Cell Engager for Long-Term B Cell Ablation with High Transgene Expression to Minimize Vector Dose

Mark Currier[1], Allen Reha[2], Brian Hutzen[3], Pin-Yi Wang[4], Chun-Yu Chen[3], Andrea Glaspell[5], Siddhi Paudel[6], Akila Venkataramany[7], Debashree Das[8], Danielle Hanlon[8], Allan Kaspar[8], Samit Varma[8], Brian Kaspar[8], Jacob Scott[9], Pablo Morales[10], Peter Ralph[11], Tonny Johnson[11], Tania Weiss[11], **Timothy Cripe[12]**
[1]Nationwide Children's Hospital, [2]Vironexis Biotherapeutics, Millstone Township, NJ, [3]The Research Institute at Nationwide Children's Hospital, Columbus, OH, [4]The Research Institute at Nationwide Children's Hospital, Columbus, OH, [5]Nationwide Children's Hospital, Columbus, OH, [6]The Ohio State University, Columbus, OH, [7]Abigail Wexner Research Institute at Nationwide Children's Hospital, [8]Vironexis Biotherapeutics, Inc., San Diego, CA, [9]Cleveland Clinic, Cleveland, OH, [10]Mannheimer Foundation, [11]Marin Biologic Laboratories, Inc., Novato, CA, [12]Nationwide Children's Hospital, Columbus, Ohio

We previously reported an adeno-associated virus (AAV) expressing a secreted CD19-targeted bispecific T cell engager (PMID 35857488). A single intravenous dose resulted in persistent serum levels of the transgene product, GP101, and long-term elimination of B cells in marrow-humanized mice. Like CAR-T, AAV gene therapy is a single infusion with long-lasting effects, but potential advantages of AAV over CAR-T include it is off-the-shelf,

provides a gentle onset of action, doesn't require lymphodepletion chemotherapy, engages all T cells including those continuously produced from the bone marrow, and signals through the native T cell receptor. We have now made several modifications to the original construct to create a next generation vector. To reduce transgene-mediated immunogenicity, we used alternative codons to eliminate CpGs (toll-like receptor agonists), which maintained robust expression in cultured primary human hepatocytes. Based on our FDA INTERACT meeting, we also modified the downstream RNA stabilizing element derived from woodchuck hepatitis virus (WPRE) to prevent expression of "protein X," due to its theoretical potential for oncogenicity. We found that the construct using a ubiquitous promoter (CAG) exhibited higher transgene-encoded protein expression than a liver-selective promoter (LP1) in both primary cultured human liver cells transfected with plasmids and mice given intravenous AAV. The CAG promoter construct was also superior to a self-complimentary version, possibly in part due to the size constraints that necessitated using a shorter promoter (EFS) and eliminating the WPRE. We thus selected the CAG-driven vector utilizing an AAV capsid with high liver tropism, termed VNX-101, for further development. A single intravenous dose of VNX-101 in peripheral blood humanized NSGS mice was effective in eliminating leukemic cells in widely disseminated human xenograft mouse models. Treatment also eliminated bone marrow disease at the endpoint. GP101 was also still effective a year after the AAV dose as low as 1E10 vg/kg in animals initially given vector alone then challenged with tumor at day 340 and given huPBMCs at day 346. In a dose-range finding study, we found that a 3-fold increase in AAV dose resulted in ~10-fold increase in serum levels. Serum levels of GP101 were consistently above the lower threshold of the human therapeutic target range (300 pg/mL, based on clinical experience with blinatumomab) at doses of 3.0E10 vg/kg (females) and 1.0E10 vg/kg (males). In a 12-week GLP toxicity study, we observed a dose-dependent increase in serum GP101, with the lowest tested dose of 1.0E11 vg/kg resulting in GP101 concentration well above the target threshold. The No Observed Adverse Event Level was >2.7E13 vg/kg. VNX-101 treatment at 2.7E12 vg/kg was also well tolerated in hamadryas baboon monkeys with no significant changes in body weight or clinical signs reported. Collectively, these preclinical data support the efficacy and safety of VNX-101 as an off-the-shelf solution to achieve single-dose, long-term CD3 T cell – CD19+ cell engagement. We have now opened a Phase 1/2 clinical trial of VNX-101 starting at 1E11 vg/kg, called SENTRY-ALL, in patients with relapsed or refractory B cell precursor ALL, which is the first FDA-approved AAV immune-gene therapy for cancer clinical trial. Based on the mechanism of action, VNX-101 may also be applicable to B cell lymphoma, chronic lymphocytic leukemia, and autoimmune diseases.

290 Successful AAV Vector Re-administration via Two Distinct B Cell Immunomodulation Strategies in Non-Human Primates

Nicholas Giovannone, Julia Provino, Carley Tasker, Krystal Ching, Johanna Napetschnig, Jamie Orengo, Christos Kyratsous, Andre Limnander, Katherine Cygnar, Andrew Baik*
Regeneron Pharmaceuticals, Tarrytown, NY
**Corresponding Author*

Introduction:
Adeno-associated viral vector (AAV) gene therapies have shown exciting promise for treatment of genetic disorders. However, a current limitation is the inability to re-dose due to development of high-titer AAV neutralizing antibodies (NAbs) that block transduction. In preclinical studies, immunomodulation has shown promise as a strategy to attenuate AAV NAb responses and enable re-dosing. However, in the clinic, common approaches such as B cell depletion with rituximab have so far yielded only modest NAb suppression. Here, in non-human primates, we tested two distinct strategies that we hypothesized would more effectively block development of AAV NAbs. First, we tested whether a more potent B cell depleter, a bispecific antibody targeting CD20 and CD3 (CD20xCD3), could enable AAV re-dosing by eliciting deeper B cell depletion in lymphoid tissues. In parallel, we tested if transient blockade of CD40, a receptor critical for B cell activation, affinity maturation, and formation of immunological memory, could also enable AAV re-dosing.

Methods:
Twenty-two AAV8-seronegative cynomolgus macaques received either no immunomodulation (Groups 1 & 2), CD40 antagonist mAb (Group 3, 50mg/kg weekly for 12 weeks), or CD20xCD3 bispecific antibody (Group 4, 0.1-0.5mg/kg weekly for 5 weeks). After three initial doses of CD20xCD3 or CD40 antibody, animals in Group 2-4 were administered an AAV8 CAG eGFP vector (1st AAV) i.v. at 1e13 vector genomes per kilogram (vg/kg). AAV NAb titers were longitudinally evaluated for 10 weeks. Subsequently, all animals (including previously AAV-naive

Group 1) received a second AAV8 vector encoding a secreted human transgene driven by a liver-specific promoter (2nd AAV) i.v. at 1e13 vg/kg. Four weeks later, the study was terminated, and transduction was assessed.

Results:
As expected, macaques receiving no immunomodulation (n=4) mounted a robust AAV8 NAb response after the 1st AAV exposure, peaking 10 weeks post AAV in most animals (NAb titer >1:1000 in 3 of 4 animals). Strikingly, however, CD20xCD3-treated animals (n=6) showed no evidence of a NAb response over the entire 10-week period. CD40 mAb-treated animals (n=6) exhibited a transient NAb response; however, titers peaked earlier and lower (2 weeks post AAV; peak titers ≤1:160) before declining to undetectable or near-undetectable levels by week 10 post AAV (4 of 6 animals ≤1:5). Animals were subsequently dosed with a 2nd AAV8 vector, and liver transduction was assessed by dPCR. As expected, animals treated with both AAVs, but without immunomodulation, showed few detectable vector genomes per diploid genome (vg/dg) in liver (Median: 0.28 vg/dg). By contrast, CD20xCD3-treated and anti-CD40-treated animals achieved much higher levels of transduction (Median: 59.4 and 40.2 vg/dg, respectively) approaching that of previously-naïve positive control animals (Median: 86.0 vg/dg). Similarly, transgene mRNA (in liver) and protein were detectable in CD20xCD3-treated, CD40 mAb-treated animals, and previously-naïve positive control animals, but not in AAV re-dosed control animals that were not treated with immunomodulation.

Conclusions:
Our findings suggest systemic AAV vector re-administration is achievable via both B cell depleting (CD20xCD3) and non-depleting approaches (CD40 blockade). Considerations of re-dosing timelines and magnitude of immunosuppression should be investigated further to understand the utility and use-case for each approach.

291 Innovative Strategies to Enhance AAV Gene Transfer in the Muscle in the Presence of Pre-existing Immunity

Elena Campbell[1], Jake Yates[2], Yanlong Pei[3], Harper Griffin[1], Madison Hughes[1], Arielle Gillies[1], Khalil Karimi[3], Leonardo Susta[1], Logan Banadyga[4], Sarah Wootton[1]
[1]University of Guelph, Guelph, ON, [2]Guelph, ON, [3]University of Guelph, [4]PHAC

Adeno-associated virus (AAV) vectors are widely used for gene therapy due to their ability to achieve stable transgene expression in a variety of tissues. However, their clinical application is often limited by host immune responses, including the development of anti-capsid and anti-transgene antibodies, which can reduce initial efficacy and prevent vector re-administration. Strategies to mitigate these immune responses are essential to extending the therapeutic potential of AAV gene therapies, particularly for chronic or progressive diseases that require repeated dosing. In this study, we focus on the muscle as a target organ for AAV-mediated gene delivery. Muscle is not only directly implicated in various genetic disorders but also serves as an efficient organ for the systemic secretion of therapeutic proteins, such as monoclonal antibodies (mAbs). Our goal is to identify vector modifications and combinatorial immunomodulatory strategies that enhance initial gene transfer and suppress anti-capsid and anti-transgene immune responses to enable safe and effective AAV re-administration.

We first evaluated whether co-administering known immunomodulatory agents could mitigate anti-capsid responses, allowing for efficient vector re-administration. Groups of C57BL/6 mice were IM administered $1x10^{11}$vg of AAV6.2FF expressing a human mAb mixed with doxorubicin(200uM), sirolimus(0.08mg/kg), SVP[Rapa](200ug), or SVP[empty](200ug). Mice were boosted in the same manner 3- and 6-months following the initial administration. Serum analysis revealed significantly lower anti-capsid antibody levels in the SVP[Rapa] treated mice compared to AAV alone, both pre and post boost; no significant increase in transgene expression was observed. As there was reduction but not ablation of anti-capsid antibodies, we then investigated whether the inclusion of a miR-142 binding site in the AAV-expressed mRNA (AAV-mAb-4x.mir142) would help suppress transgene expression in hematopoietic cells. Inclusion of the 4x.mir142 sequence in combination with SVP[Rapa] completely ablated both anti-transgene and anti-capsid responses demonstrating that genome modifications can synergize with SVP[Rapa] to further reduce antibody responses to AAV. T cell analysis was conducted on C57BL/6 mice that were administered AAV-mAb-4x.mir142 alone or in combination with SVP[Rapa] or SVP[empty], either as a single dose or two doses 3 months apart. Analysis of spleen and muscle tissue 5 days post second dose showed

an increase in exhausted $CD4^+$ and $CD8^+$ T cells (defined by $TIM3^+$, $LAG3^+$, $PD1^+$) in the muscle of the AAV-mAb-4x.mir142 + SVP[Rapa] treated mice but no impact on Treg quantity.

We then moved to using AAV expressing a model antigen, GFP-SEAP, to monitor transgene expression over time as well as facilitate more advanced immunological analyses. A total of 8 different GFP-SEAP genomes including all combinations of 4x.mir142, io2 (TLR9 antagonist sequence) and MAVI1(microprotein that suppresses type I IFN signaling) were designed. Groups of C57BL/6 mice were IM administered 3 doses of $1x10^{11}$vg of each vector 1 month apart to evaluate impacts on re-administration. Serum SEAP levels of mice treated with AAV-GFP-SEAP encoding 4x.mir142 or 4x.mir142-io2 were significantly higher than that of the control, there was no impact on the anti-capsid response. Ongoing work aims to further characterize the T cell response to both candidates with and without co-administration of SVP[Rapa] particles

292 Early Time Post-vector Activation of Complement by AAV Vectors in Nonhuman Primates

Jonathan Rosenberg[1], Bishnu De[2], Anthony Caragiulo[1], Stephen Kaminsky[1], Heather Martin[3], Samuel Butler[4], Jordi Rodo[5], Dolan Sondhi[1], Ronald Crystal[6]
[1]Weill Cornell Medical College, New York, NY, [2]Weill Cornell Medical College, New York, New York, [3]Center for Comparative Medicine and Pathology, Memorial Sloan Kettering Cancer Center and Weill Cornell Medicine, New York, NY, [4]Svar Life Science, Malmö, Skane lan, Sweden, [5]Svar Life Science, Cambridge, MA, [6]Weill Cornell Medical College, New York

In clinical trials with intravenously administered high dose adeno-associated vector (AAV) gene therapy, there are reports of complement activation-related serious adverse events (SAEs), including thrombotic microangiopathy and atypical hemolytic uremic syndrome. Although AAVs have been well tolerated in preclinical animal models, SAEs observed in clinical trials involving high dose AAVs suggest a need for improved preclinical models to understand AAV-induced complement-related immune responses. As a model for AAV-related complement-mediated adverse events, the present study assessed immediate (first hour post-vector administration) and late (1-10 days post-vector administration) complement activation in African Green non-human primates (NHP) with pre-existing immunity to AAV vectors. A NHP (7 kg) previously exposed to AAVrh.10 (serum AAVrh.10 neutralizing antibody titer, $2.7x10^2$) was administered AAVrh.10mCherry ($1.2x10^{13}$ gc/kg; intravenous), with repeat administration of AAVrh.10mCherry ($1.2x10^{13}$ gc/kg; intravenous) 2 wk later. Blood was collected before and at 10, 30, and 60 min, and then at 1, 3, and 10 days post each administration and serum assessed for terminal complement complex, the end-product of all complement pathways (Terminal Complement Component (TCC) ELISA, Svar). No immunosuppression was administered. No abnormal clinical signs, or abnormalities in hematology or serum chemistry parameters were observed. There were increases in serum total and neutralizing anti-AAVrh.10 antibodies resulting from the AAVrh.10 administration. No complement activity was present prior to 1st AAVrh.10 challenge but increased TCC levels (2,950 ng/ml at 10 min, peaking at 3,869 ng/ml at 60 min) were observed during the 1st hr post-AAVrh.10 challenge. By 24 hr timepoint post-1st challenge, TCC levels were reduced to 113 ng/ml and were undetectable at 10 days. A similar pattern was observed after the 2nd AAVrh.10 challenge, with TCC levels at 5,381 ng/ml at 10 min, peaking to 6,680 ng/ml at 30 min. Higher complement activation following the 2nd AAV administration suggests the effects were mediated by antibody binding to AAV capsids. The TCC levels were barely detectable >24 hr timepoint post-2nd challenge, with 195 ng/ml at 24 hr, 163 ng/ml at 72 hr and 180 ng/ml at 10 days. These data demonstrate repeatable AAV-mediated serum complement activation in an NHP with TCC activation limited to within the 1st hr post-AAV challenge and disappearing by 24 hrs. Importantly, this AAV-mediated early time point activation might be missed in clinical trials unless assessments of complement activation are made within the 1st hr post vector administration.

293 Potential for AAV-SLB101-mediated gene transfer treatment in the context of natural seropositivity and after an AAVrh74 treatment

Jessica Boehler[1], Marla Bazile[1], Prushti Bhavsar[1], Sharon McGonigle[1], Kruti Patel[2]
[1]Solid Biosciences, Charlestown, MA, [2]Solid Biosciences, Boston, MA

Adeno-associated virus (AAV)-mediated gene therapy is dependent on effective viral transduction and transgene expression in the target organs. Several studies have shown that pre-existing antibodies to AAV acquired either from natural infection or a previous AAV gene therapy treatment leads to inhibition of AAV transduction. Pre-existing titers are measured using a transduction inhibition assay for anti-AAV neutralizing antibodies (NAb) or an ELISA for anti-AAV total IgG antibodies (TAb). Often, the assay cut-off determined by the sensitivity of the assay is the titer threshold used for determining eligibility of patients for gene therapy treatment, however, this assay cut-off does not take into consideration the impact of the pre-existing antibodies on transduction. To evaluate the relationship between pre-existing titers and their effect on transduction, passive transfer studies were performed in mice to identify the TAb IgG titer values that reduced AAV transduction in target organs.

Immunocompromised Rag2 KO mice were infused with human serum at various anti-AAV-SLB101 TAb IgG titers 1 day before administration of 2.5E13 or 1E14 vg/kg AAV-SLB101-Luciferase. AAV-SLB101 biodistribution and expression were measured by whole body IVIS imaging and in target tissues to determine the impact of pre-existing titers. Loss of luciferase expression was dependent on pre-existing TAb IgG titer, AAV-SLB101-Luciferase dose, and the target organ. Luciferase expression at the 1E14 dose was observed in the quadriceps at titers up to 1:320 while expression in heart and diaphragm tissues was equivalent to control and not impacted at any of the TAb titers tested up to >1:640. These data highlight the capacity for AAV-SLB101 transduction in the presence of low anti-AAV titers. Findings warrant further investigation in larger models to enhance characterization of the relationship between assay cutoff and impact on transduction for clinical trial inclusion.

Several studies have shown that pre-existing NAb/TAb titers associated with natural AAV infections are orders of magnitude lower than the anti-AAV antibody titers post gene therapy treatment. To investigate the potential for effective AAV-SLB101 transduction after an AAVrh74 treatment, anti-AAVrh74 and anti-AAV-SLB101 NAb titers were measured in serum from mice, NHPs, and Duchenne muscular dystrophy (DMD) patients previously dosed with an AAVrh74 gene therapy. While AAVrh74 NAb titers were extremely high, the cross-reactive AAV-SLB101 NAb titers were substantially lower in magnitude, in a range closer to natural seropositivity. These low cross-reactive titers may provide the intriguing possibility of a therapeutic window for dosing patients with an AAV-SLB101 treatment after an AAVrh74 gene therapy.

294 KJ103: An igg-Degrading Enzyme That Reduces Neutralizing Antibodies Against AAV2 and AAV8 to 10% with a Single Dose, with Repeat Dosing Capability Allowing Further Reductions and Potential for AAV Re-dosingkj103: An igg-Degrading Enzyme That Reduces Neutralizing Antibodies Against AAV2 and AAV8 to 10% with a Single Dose, with Repeat Dosing Capability Allowing Further Reductions and Potential for AAV Re-Dosing

Clara Chang[1], **Yunxia (Erica) Xu[2]**
[1]Baopharma, Taiepi, Taipei, Taiwan, [2]Bao Pharma, Shanghai, Shanghai, China

The presence of pre-existing AAV-neutralizing antibodies (NAbs) in humans significantly challenges AAV-based gene therapy. We developed KJ103, a novel recombinant human IgG-degrading enzyme from a non-human, non-pathogenic subspecies, characterized by rapid action, high efficiency, and low immunogenicity. It is anticipated as a pretreatment strategy to reduce NAbs, broadening patient eligibility and enhancing gene therapy safety and efficacy.

In two randomized, placebo-controlled, single-ascending dose Phase 1 trials (0.01, 0.04, 0.12, 0.25, and 0.40 mg/kg) with healthy volunteers in New Zealand and China, we evaluated KJ103's safety, tolerability, pharmacokinetics (PK), pharmacodynamics (PD), and IgG cleavage efficacy. The data confirmed KJ103's safety and tolerability, with no serious adverse events (SAEs) or infections. IgG levels rapidly decreased within 45 minutes, staying minimal for a week before gradually returning to baseline, with results from both trials showing high concordance.

Notably, we assessed AAV2 and AAV8 NAb titers in clinical samples to validate KJ103's potential in enhancing gene therapy outcomes. A single dose of KJ103 exceeding 0.25 mg/kg was generally effective in increasing the NAb titer threshold for AAV-based gene therapy by approximately tenfold, regardless of the initial titer. For subjects with

high titers, an additional dose of KJ103 may be necessary to further reduce NAbs. We correlated IgG, F(ab')2 levels, and NAb titers to define therapeutic time windows for various clinical applications.

Overall, KJ103 can elevate the enrollment threshold for AAV NAb titers, enabling broader patient inclusion. This positions KJ103 as a promising candidate for reducing toxicity through lower dosing while also decreasing treatment costs. Furthermore, by effectively lowering NAbs and permitting its own repeat dosing, KJ103 may unlock viable re-dosing strategies for AAV-based therapies.

295 AAV-vectored PD-L1 Co-Expression as a Strategy to Enhance AAV-Delivered bNAb Efficacy

Michael Kuipa[1], Abubakarr Koroma[1], Isai Leguizamo[2], Priya Dhole[3], Matthew Gardner[1]
[1]Emory University, Atlanta, GA, [2]Emory University School of Medicine, Atlanta, GA, [3]Emory University, Atlanta, GA, Decatur, GA

Background: Immune responses often lead to the loss or subtherapeutic expression of rAAV-vectored transgenes. Such immune responses are a major barrier to the efficacy of AAV-vectored anti-HIV-1 broadly neutralizing antibodies (bNAbs) for the treatment and prevention of HIV-1 infection. The immune checkpoint molecule programmed cell death protein ligand 1 (PD-L1) interacts with programmed cell death protein 1 (PD-1) on T cells to suppress immune activation and promote tolerance. We previously reported that co-delivery of AAV9-vectored PD-L1 and 10-1074, (a bNAb), could suppress host anti-10-1074 immune responses, enabling persistent 10-1074 expression, which conferred protection against SHIV-AD8 challenge in nonhuman primates. Here, we extend these findings to 3BNC117, a more somatically hypermutated and thus more immunogenic bNAb, demonstrating applicability of this approach to other AAV-delivered therapeutics.

Methods: Five groups of six rhesus macaques each received the following vectors: 1) AAV9.PD-L1; 2) AAV9.10-1074; 3) AAV9.PD-L1 and AAV9.10-1074; 4) AAV9.3BNC117; and 5) AAV9.PD-L1 and AAV9.3BNC117. Serum antibody concentrations were determined by gp120 ELISA and B and T cell reactivity were assessed by anti-drug antibody ELISA and by ELISpot assay, respectively. Beginning at 20- or 30-weeks post AAV9 administration, all animals were challenged biweekly via low-dose, intrarectal challenge using SHIV-AD8. Protection from SHIV challenges was determined by monitoring plasma viremia by qPCR. Additionally, to assess the safety of our approach, we have ongoing studies to determine the immunomodulatory effect of AAV9.PD-L1 in PBMCs by RNA-seq and off-target AAV transduction in various organs by droplet digital PCR post necropsy.

Results: All six macaques that received AAV9.10-1074 and AAV9.PD-L1 had sustained concentrations of 10-1074 throughout the study compared to four of six macaques that only received AAV9.10-1074. Five of six macaques that received AAV9.3BNC117 and AAV9.PD-L1 had sustained concentrations of 3BNC117, compared to three of six macaques that only received AAV9.3BNC117 over the 52 weeks of the study. Macaques that had sustained bNAb expression for the duration of the study had lower anti-10-1074 or anti-3BNC117 antibodies and lower T cell reactivity to bNAbs compared to macaques that had declining bNAb expression. Lastly, all macaques that achieved sustained expression of 10-1074 resulted in significant protection from SHIV-AD8 challenges. Macaques that received AAV9.3BNC117 and AAV9.PDL1, but not AAV9.3BNC117 alone were significantly protected from SHIV-AD8 challenges, underscoring the utility of AAV9.PD-L1 in this study.

Conclusions: These studies suggest that co-expression of PD-L1 at the site of administration reduces the host immune response to an AAV-expressed transgene in rhesus macaques. We propose that our vectored PD-L1 co-expression strategy can facilitate the sustained expression of other viral-vectored transgenes.

Lipid Nanoparticles II

296 Novel Cyclohexane Based Ionizable Lipids (CHILs) for Non-viral Liver Delivery of Complex Nucleic Acid Genetic Medicine Payloads

Lijun Huang[1], **Gopi Nath Vemuri[1]**, Khalid Hajj[1], Alicia Davis[1], Sang Lee, Fernando Lopez Espinoza[2], Johnnatan Tamayo[2], Kevin Johnson[1], Ritam Das[1], Le Thien[1], Mu Li[1], Chris Deng[1], Pranavanand Nyshadham[1], Oscar Alvarez[1], Brian Sloat[1], Michael Bennett[1], Joshua Rychak[1]
[1]Poseida Therapeutics, San Diego, CA, [2]Poseida Therapeutics, San Diego

Gene editing technologies have the potential to transform medicine, especially if one can optimally deliver such technologies into patients as an in vivo genetic medicine. Key advancements include the development of powerful but complex technologies requiring co-delivery of multiple nucleic acid payloads, such as high-fidelity nucleases and transposon systems. These technologies offer the possibility for functional cures of genetic diseases. However, nucleic acid delivery to preferred cell types remains a challenge; in particular, mixed nucleic acid or DNA-containing payloads must be delivered in a safe and efficient manner.

Compared to viral systems, lipid nanoparticle (LNP) systems offer potential immunogenicity, nucleic acid payload versatility, repeat dosing, and manufacturing advantages. LNPs are typically comprised of a mixture of ionizable (IL), naturally occurring, and pegylated lipids. Most used ILs were designed to deliver single RNA(siRNA or mRNA) payloads and not mixed nucleic acid payloads like two guide RNAs (gRNAs) and a mRNA (as required for Cas-CLOVER™) or mRNA and a plasmid DNA (pDNA) (as required for the Super piggyBac transposon system (SPB)). We have recently identified a novel ILs containing cyclohexane hydrophobic moieties(aka CHILs). Cyclohexane was selected based on its ability to adopt different confirmations to form stronger hydrophobic associations than linear hydrophobic moieties. Cyclohexanes are also more resistant to oxidation than linear moieties containing double bonds such as those found in common ILs, like Dlin-MC3-DMA (MC3), and may have stability advantages.

A panel of CHILs was prepared to optimize cyclohexane placement. An initial screen in adult mice was performed using LNPs comprised of a base lipid composition and either mRNA or pDNA encoding luciferase. LNPs containing promising CHILs were further optimized utilizing a design-of-experiment (DoE) approach to optimize liver bioluminescence and minimize cytokine release and transaminase levels in adult mice. This yielded an evaluation of cyclohexane-based hydrophobic tails and identification of a preferred monoamine core,which was key for maximizing DNA delivery efficacy and tolerability. These findings provide insights into the structure-function relationships of CHILs and offer a promising platform for developing liver-directed nucleic acid delivery systems.

The lead CHIL, HBC365, has been deployed in PoseidaTherapeutics' hereditary angioedema (P-KLKB1-101) and hemophilia A (P-FVIII-101) programs. For P-KLKB1-101, LNPs containing HBC365 and the requisite Cas-CLOVER™ mRNA and guide RNAs have been optimized to promote robust gene editing, a sustained reduction in plasma kallikrein, and a desirable safety profile in adult mice and non-human primates. For P-FVIII-101, the durable expression of clinically relevant levels of clotting Factor VIII was achieved in adult mice when DNA cargo-optimized HBC365 LNPs were used containing an mRNA encoding the SPB transposase and a pDNA containing the Factor VIII transposon. Data demonstrating the evolution of this novel class of CHILs from conception through the identification and integration of HBC365 into P-KLKB1-101 and P-FVIII-101 programs will be covered in this presentation.

297 A CNS-Tropic Lipid Nanoparticle Platform Inspired by Natural Brain Chemistry

Menggui Huang[1], Rebecca Haley[1], Saigopalakrishna Yerneni[2], Ursula Andreo[3], Sapanna Chantarawong, Ryshone Duncan, Ryan Gaudlip, Lozen Robinson, Kathryn Whitehead[2], Ravi Iyer[4]*

**Corresponding Author*

Neurological conditions are the leading cause of illness and disability worldwide, but for many of these conditions, there are no disease modifying therapies available. While symptomatic treatments have improved quality of life for some patients, there remains a clear clinical need for targeted medicine development in this field. In recent years, genetic medicine—including gene replacement (mRNA), gene silencing (RNAi), and gene editing (such as CRISPR-Cas9) approaches—has emerged as a promising alternative to conventional small molecule drugs. Furthermore, human genetic studies have identified several genes that modifying onset and or progression of neurological diseases such as Huntington's disease, Parkinson's disease and many others. Although such genetically validated targets are attractive candidates for modulation by nucleic acid therapeutics, translation to the clinic remains challenging primarily due to difficulties in efficient and safe delivery of nucleic acids to central nervous system (CNS).

To overcome this barrier, Script Biosciences is using a proprietary CNS-specific lipid nanoparticle (LNP) platform—originally developed in the Whitehead Lab at CMU—capable of delivering nucleic acid cargo directly to the mammalian CNS, with minimal distribution to peripheral organs such as liver or spleen (Figure 1A). These novel LNPs incorporate lipids inspired by those found naturally in the brain but have similar physiochemical characteristics to previous FDA-approved LNPs used clinically.

Here we demonstrate that Script's CNS-LNP can not only efficiently encapsulate mRNA, siRNA and CRISPR-Cas complexes, but also effectively deliver them to cells both in vitro and in vivo. We show LNP-mediated transfection of ~95% of cells in vitro resulting in robust reporter mRNA expression (Figure 1D). Intrathecal injection of LNP-encapsulated mRNA results in widespread biodistribution throughout the brain and spinal cord of transgenic rodents as judged by TdTomato reporter gene activation in ~80% of neurons (Figure 1B, C). We also demonstrate efficient siRNA encapsulation and delivery: using the MALAT1 gene as a model target, our LNP-encapsulated MALAT-1 specific siRNAs achieved ~85% knockdown of MALAT-1 in vitro (Figure 1E). Finally, encapsulation and delivery of Script's proprietary gene editing system—CasPlus—can be also achieved using the CNS-LNP. In initial in vitro tests using TRAC as a model gene editing target, indel formation was seen in ~95% of sequences (Figure 1F), indicating high efficiency of cargo encapsulation, delivery, and functionality.

In conclusion, this CNS-LNP platform shows significant distribution and delivery to the rodent brain and can efficiently deliver various therapeutic RNA types. Our proprietary LNP platform paves the way towards addressing a wide range of neurological diseases by RNAi-mediated knockdown, CRISPR knockout, or gene augmentation approaches.

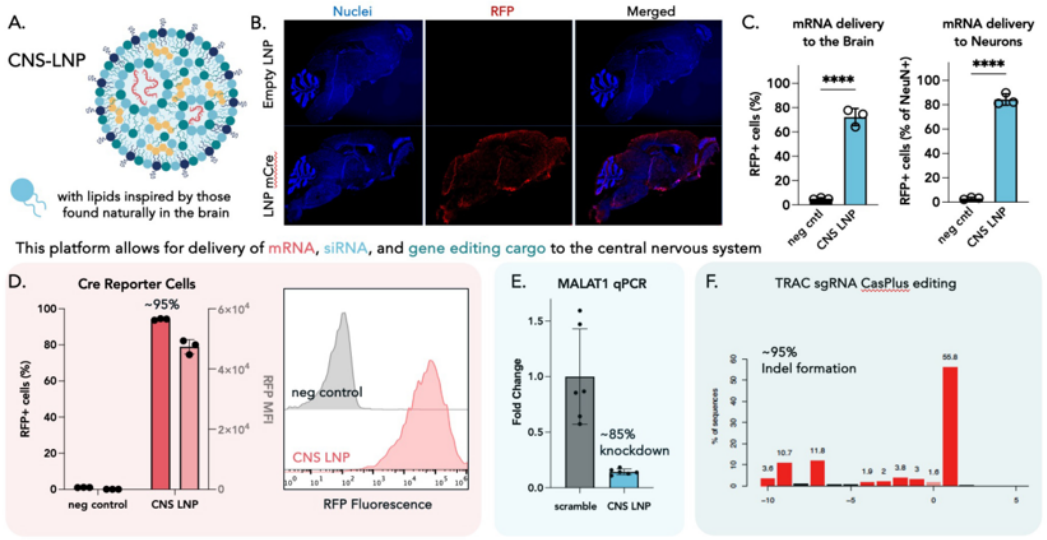

Figure 1. (A) A CNS lipid nanoparticle (LNP) platform for the delivery of multiple nucleic acid cargoes. (B) In Cre-reporter rodents, mRNA delivery and functionality can be seen throughout the brain. Visualized using immunofluorescence imaging. (C) The CNS-LNP delivers to ~70% of the brain and ~85% of neurons, measured using flow cytometry. (D) Cre mRNA can be delivered to ~95% of cells in vitro using the CNS-LNP. (E) MALAT1-targeting siRNA can be delivered to cells in vitro using the CNS-LNP, resulting in ~85% knockdown, measured by qPCR. (F) The CasPlus editing system—including sgRNA targeting TRAC—can be delivered via the CNS-LNP, resulting in indel formulation in ~95% of sequences, using Sanger sequencing and TIDE analysis

298 Ocular Gene Therapy Using the Proteolipid Vehicle Nucleic Acid Delivery Platform

Prakash Bhandari[1], Arun Raturi[2]
[1]Entos Pharmaceuticals US Inc, San Diego, CA, [2]Entos Pharmaceuticals, Edmonton, AB

Purpose:
Age-related macular degeneration, Stargardt disease, and glaucoma are prevalent eye conditions that lead to vision loss. Gene therapy holds potential to combat and prevent vision impairment; however, conventional viral and non-viral gene delivery platforms face limitations due to challenges with nucleic acid delivery, immunogenicity, and tolerability. To address these limitations, we developed the Fusogenix™ proteolipid vehicle (PLV™) nucleic acid delivery platform. The PLV platform utilizes a proprietary fusion-associated small transmembrane (FAST) protein and well-tolerated lipid formulations to achieve efficient nucleic acid delivery to tissues throughout the body. FAST protein catalyzes the fusion of the PLV bilayer with the plasma membrane of the target cells, enabling delivery of encapsulated nucleic acid cargo directly into the cytoplasm, resulting in efficient and highly tolerable nucleic acid delivery to various tissues throughout the body. Here, we assess ocular gene delivery using the FAST-PLV platform.

Methods:
The FAST-PLV platform was used to deliver mRNA or DNA in vivo in mice, rats, and non-human primates. Routes of administration in vivo included subretinal injection, intravitreal injection, and subconjunctival administration. Evaluated outcomes included gene expression, protein expression and localization, tolerability (including pro-inflammatory markers, optical coherence tomography, and immunohistochemistry), and gene function.

Results:
The FAST-PLV platform enabled robust delivery and expression of mRNA and pDNA cargo in primary mouse and human retinal cell cultures without cytotoxicity. Intravitreal (IVT) injection of FAST-PLVs encapsulating pDNA or mRNA encoding firefly luciferase or eGFP resulted in localized and prominent expression in the eyes of both mice and rats. Immunofluorescence analysis confirmed stable expression in retinal ganglion and photoreceptor cells. To evaluate gene editing with PLVs, we assessed the co-delivery of mRNA-Cas9 and sgRNA targeting the Ai9 mouse

'STOP' cassette. IVT injection in Ai9 mice induced high tdTomato expression in photoreceptor cells, indicating effective gene editing. OCT imaging confirmed that PLVs were well tolerated. Next, we assessed the ability of PLVs to deliver clinically relevant cargo. We designed a pDNA vector encoding an anti-VEGF antibody as a potential treatment for wet AMD. IVT injection of PLVs encapsulating this construct in rats and mice resulted in high antibody expression detected in the vitreous for 60 days post-injection. The antibody was functionally active, and markedly reduced angiogenesis in a model of corneal neovascularization induced by alkali burn injury, 21 days post-PLV administration. We then designed a pDNA vector encoding the ABCA4 gene, which is impaired in Stargardt disease, encapsulated it within PLVs, and delivered it in rats by IVT injection. Expression of ABCA4 was observed 7 days post-injection in the retina, and co-localized with rhodopsin-positive photoreceptors. Building on these findings, we evaluated PLV activity in non-human primates. Subretinal injection of PLVs encapsulating pDNA led to widespread, robust expression in photoreceptor cells and the retinal pigment epithelium. Furthermore, slit-lamp examinations and OCT confirmed high tolerability following these injections.

Conclusions:
These findings highlight the promising potential of the FAST-PLV gene therapy platform for the treatment of multiple ocular diseases

299 Applying RNA-lipid nanoparticles to modulate protein expression in swine

Francesca Ferraresso[1], Massimo Cau[2], Monica Seadler[3], Katherine Badior[4], Chad Skaer[5], Halen Turner[5], Laura Ketelboeter[4], Amanda Wietrzny[6], Mitchell Dyer[6], Pieter Cullis[7], Eric Jan[2], Christian Kastrup[8]
[1]The University of British Columbia, Vancouver, BC, [2]The University of British Columbia, [3]Medical College of Wisconsin, Milwaukee, WI, [4]Versiti Blood Research Institute, [5]Versiti Blood Research Institute, Milwaukee, [6]Medical College of Wisconsin, [7]University of British Columbia, Vancouver, BC, [8]Versiti Blood Research Institute, Milwaukee, WI

Background:
Genetic manipulation of rodents is fundamental to research in biology and medicine, however it is costly and challenging in large animal models. In vivo delivery of RNA is promising for the study of gene expression and the treatment of genetic diseases. Lipid nanoparticles (LNP) efficiently deliver small interfering RNA (siRNA) and messenger RNA (mRNA) to either knock down or overexpress specific proteins, representing a potential system for creating genetically modified large animals. LNP naturally accumulate in the liver, a major synthesis site for many blood circulating proteins. Swine are a preferred animal model for studying the cardiovascular and immune systems, but there are limited strategies for genetic manipulation, as they are sensitive to LNP-induced complement activation-related pseudoallergy (CARPA).

Aims:
Develop siRNA- and mRNA- LNP agents that can knock down or overexpress proteins in swine and subsequently determine the biodistribution of mRNA-LNP protein expression in a large animal model.

Methods:
We identified siRNA sequences targeting two coagulation proteins in swine: fibrinogen (siFga) and plasminogen (siPlg). We tested these sequences in silico and developed an mRNA sequence to express a reporter protein, NanoLuciferase (mNLuc). siFga, siPlg, and mNLuc were encapsulated in a clinically relevant LNP formulation and injected intravenously at a medicinal dose in swine. Knockdown and expression were analyzed based on antigen and mRNA expression levels.

Results:
siFga and siPlg efficiently modulated systemic blood coagulation and knocked down fibrinogen or plasminogen plasma protein, respectively, to below 5% of baseline values. When swine were injected with mNLuc, protein expression was detected in the liver, spleen, lung, heart, uterus, colon, stomach, kidney, small intestine, and sometimes brain. Furthermore, protein expression was found in the bone marrow, including megakaryocytes, hematopoietic stem cells (HSC), granulocytes, and in circulating blood cells such as white blood cells and platelets but not red blood cells. Swine treated with these LNP agents showed no clinical signs of CARPA.

Conclusion:
These findings advance RNA therapies in swine, and create a platform for generating large animal models for protein deficiencies and other genetic defects.

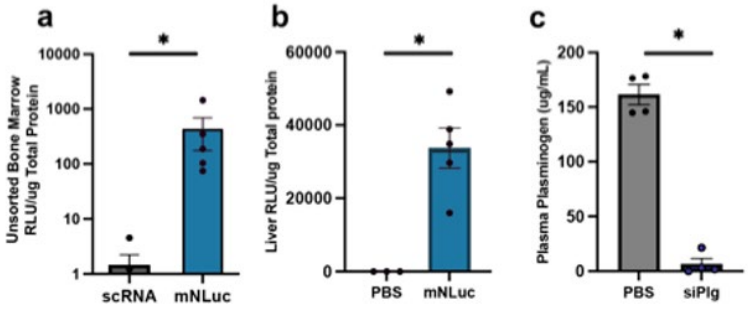

Figure 1: Proteins can be overexpressed or knocked down by intravenously injecting RNA therapies in swine. a) Bone marrow and b) hepatic NanoLuciferase protein signals measured *ex vivo* 24 h post-injection. c) Plasma levels of circulating plasminogen following siPlg or PBS. N = 4-5, **P<0.05*; Error bars represent mean ± SEM.

300 Leveraging Novel PEG-free Lipid Nanoparticles for Tissue and Cell Targeting While Reducing Immunogenicity and Toxicity

Leveraging Novel PEG-free Lipid Nanoparticles for Tissue and Cell Targeting While Reducing Immunogenicity and Toxicity

Purpose:
Lipid nanoparticles (LNPs) are promising non-viral vehicles for delivering nucleic acids *in vivo* for gene and cell therapies. However, conventional LNPs primarily accumulate in the liver when systemically delivered, limiting their ability to target extrahepatic tissues and cells while also contributing to liver toxicity. Furthermore, these LNPs struggle to maintain integrity during nebulization for aerosol formation, making it difficult to deliver them to the lungs via inhalation. Additionally, conventional LNPs typically contain polyethylene glycol (PEG)-lipid, which can provoke PEG-mediated immunogenic responses, potentially leading to anaphylaxis, pseudo-allergic reactions, accelerated blood clearance, and challenges in repeated dosing. In this study, we present a groundbreaking LNP system, Cytofinity™ LNP, which is entirely PEG-free and can target T cells in the blood and spleen, as well as hematopoietic stem cells (HSCs) in the bone marrow through systemic delivery. The Cytofinity™ LNP can also effectively deliver nucleic acids to the lungs via nebulization and inhalation.

Approach:
We aimed to replace the PEG-lipid in conventional LNP formulations with gangliosides, which are naturally occurring in humans and animals, making them unlikely to be toxic or immunogenic. Gangliosides consist of a hydrophilic head with carbohydrates and sialic acids, and a lipid tail. Each ganglioside can bind to Siglec receptors on various cell types, allowing Cytofinity™ LNPs to target specific cells. By varying the type and amount of ganglioside, we can create LNPs with different tissue and cell targeting capabilities and performance characteristics.

Results:
We developed Cytofinity™, a PEG-free LNP that exhibits several unique features: 1) The exclusion of PEG eliminates PEG-mediated immunogenicity and allows for repeat dosing. 2) It enhances the delivery of RNAs to bone

marrow cells, increasing transfection efficiency by 3.5 times compared to conventional LNPs. 3) It boosts the delivery of RNAs to T cells by threefold. 4) It reduces liver expression of the delivered payload by ninefold. 5) The Cytofinity LNP retains its integrity during the nebulization process, whereas conventional LNPs experience increased particle sizes and reduced encapsulation efficiency. We further demonstrated that nebulized luciferase mRNA-loaded Cytofinity™ LNPs can be delivered to mice through inhalation, leading to successful expression of bioluminescence in the lungs. Immunohistochemistry studies of lung tissue collected from mice that inhaled the luciferase mRNA-loaded Cytofinity™ LNPs showed that various lung cells, including endothelial, epithelial, and ciliated cells, were all successfully transfected by the inhaled Cytofinity™ LNPs. 6) The Cytofinity LNP incorporating a Cas9 and a LoxP sgRNA demonstrated effective gene editing in CD34+ cells in the bone marrow in Ai14 mice.

Conclusions:
We have successfully developed Cytofinity™, a PEG-free LNP, by substituting the PEG-lipid with a natural ganglioside. These LNPs not only avoid PEG-related issues but also deliver nucleic acid payloads to various extrahepatic tissues and cells, including the bone marrow, lungs, T cells, and HSCs.

301 Retargeting Lipid Nanoparticles for Optimized mRNA Delivery in Non-Human Primates

Carly Starke[1], Jilian Melamed[2], Teresa Einhaus[3], Michael Kegel[2], Edward Kreider[2], Hans-Peter Kiem[4], Drew Weissman[2], Christopher Peterson[3]
[1]Fred Hutch Cancer Center, Seattle, WA, [2]University of Pennsylvania, Philadelphia, PA, [3]Fred Hutchinson Cancer Center, Seattle, WA, [4]Fred Hutchinson Cancer Center, Seattle, Washington

Messenger RNA-lipid nanoparticles (mRNA-LNPs) have been widely investigated and FDA-approved as intramuscular (IM) vaccines. Notably, mRNA-LNPs are under investigation in numerous therapeutic settings beyond infectious disease prophylaxis. We are interested in developing mRNA-LNPs as boosting agents to augment antigen-specific lymphocytes and engineered effectors such as chimeric antigen receptor (CAR) T cells. We and others have described antigen boosting strategies for solid tumors as well as infectious diseases such as human immunodeficiency virus (HIV). Whereas the IM dose route predominantly delivers antigen to draining lymph nodes to initiate potent adaptive immune responses, alternate dose routes and lipid composition may enhance the potency and efficiency with which mRNA-LNPs boost adaptive immune cells, particularly in secondary lymphoid tissues. We present a novel non-human primate (NHP) model to identify and evaluate innovative LNP formulations and dose routes. Our model provides unique and unprecedented opportunities to extend and preclinically qualify disease-specific applications for mRNA-LNPs. We established latent infection with an HIV-like virus (simian/human immunodeficiency virus, SHIV.C.CH505.v2) in rhesus macaques (RMs, n = 9). Each animal was injected intravenously (IV) or intranodally (IN) with one of two LNP formulations encapsulating eGFP reporter mRNA. Twenty-four hours later, animals were sacrificed in order to systemically quantify mRNA-LNP trafficking, cellular uptake, and expression of eGFP by flow cytometry and immunohistochemistry. We assayed toxicity via serum chemistry, histology, and cytokine assays, focusing specifically on the liver. LNP formulations and routes were well-tolerated, with no adverse reactions or liver toxicity. LNP-A contained typical 4-lipid components approved for use in humans, while LNP-B was supplemented with an anionic phospholipid. When injected IV, both LNP-A and LNP-B efficiently delivered eGFP mRNA to PBMC subsets including classical monocytes (CM, 33% eGFP+), nonclassical monocytes (80% eGFP+), and myeloid dendritic cells (mDCs, 62% eGFP+), but not plasmacytoid dendritic cells (pDCs, 8% eGFP+). In contrast, LNP-B displayed enhanced splenic delivery to CM (24% for LNP-A vs. 54% for LNP-B) and DCs (mDCs: 30% vs. 60%; pDCs: 16% vs. 38%). Relative to IV dosing, IN-delivery resulted in significantly greater eGFP expression in deep lymph nodes (CM: 22% for IV vs. 58% for IN; pDCs: 13% IV vs 32% IN), with high levels of protein expression observed within the subcapsular and medullary sinus by immunohistochemistry. Additionally, altering mRNA-LNP delivery route enabled targeting of genetic cargo to SHIV-infected cells, as detected by in situ hybridization. Dose route and LNP composition drastically altered biodistribution and the number of phagocytic and antigen presenting cells responsible for uptake and expression of mRNA-LNPs within distinct tissues, while detargeting the periphery. Our findings highlight the power and flexibility of mRNA-LNPs for customized targeting to specific tissue sites. Future studies will test delivery of mRNA encoding i) rationally designed HIV/SIV Envelope immunogens to stimulate virus-specific lymphocytes in

sites of HIV/SIV persistence, ii) broadly neutralizing antibodies (bNAbs) to reduce viral reservoirs and overcome barriers of inefficient tissue trafficking, and iii) CAR T cell cargoes to directly clear the latent viral reservoir.

302 Anionic double-layered nanocomplexes with receptor-targeting motifs penetrate Cystic Fibrosis mucus better than cationic LNPs and retains effective transfection efficiency *in vivo*.

Ruhina Maeshima[1], Aristides Tagalakis[2], Stuart Jones[3], Stephen Hart[4]*
[1]UCL Institute of Child Health, London, London, United Kingdom, [2]Edge Hill University, Ormskirk, Lancashire, United Kingdom, [3]King's College London, London, United Kingdom, [4]UCL Great Ormond Street Institute of Child Health, LONDON, London, United Kingdom
**Corresponding Author*

Background: Lipid-nanoparticles (LNPs) have emerged as promising vectors to deliver therapeutic nucleic acids such as siRNA and mRNA to the airway to treat respiratory diseases such as cystic fibrosis (CF). To achieve this, LNPs must first overcome the mucociliary barrier which consists of a network of anionic mucins. First generation LNPs used in clinical trials for CF were cationic which can become entrapped in the mucin network. Anionic LNPs may offer enhanced mucus diffusion rates but typically lower transfection efficiency. The aim of this study was to develop anionic, peptide-targeted LNPs that offer enhanced diffusion rates in mucus while retaining effective transfection properties *in vivo*.

Methods: We formulated cationic and anionic receptor-targeted nanocomplexes (RTNs) consisting of cationic, anionic, neutral and PEGylated lipids, and receptor-targeting peptides with a sixteen-lysine tail, and RNA molecules in different proportions and orders of mixing. Formulations were then characterised for formation of stable nanocomplexes by size and zeta potential measurement. Stable anionic formulations containing fluorescently-labelled RNAs were then analysed for their diffusion rates in CF mucus using a static mucus barrier model, which comprises CF mucus on polyester membrane inserts with 3.0 µm pores in 24-well plates. Transfections were also performed in *vitro* in CF basal cells and *in vivo* in murine lung.

Results: We developed a double-layered mixing method, in which a cationic liposome, receptor targeting peptide, and nucleic acid were mixed, and then mixed with a PEGylated anionic liposome. A stable anionic formulation termed LPRL3 containing mRNA was identified with a size of approximately 175.5±6.26 nm, PDI 0.13±0.01 and the strongly anionic zeta potential of -33.2±3.09 mV. The encapsulation efficiency was 98.1±0.31%. The diffusion rate of LPRL3 with mRNA in CF mucus (Dm) was $6.2x10^{-9}$±$0.09x10^{-9}$ cm^2s^{-1}, compared with cationic RTN ($2.01x10^{-10}$± $0.97x\ 10^{-10}$ cm^2s^{-1}), it was faster. The impedance (Dw/Dm) between the diffusion rate in water (Dw) and in CF mucus (Dm) was 4.9±0.8, which is approximately 62-fold less than that of the cationic RTN. The impedance of ionisable LNP formulation (D-LinDMA-MC3) was similar to LPRL3. On the other hand, the size and zeta potential of LPRL3 containing siRNA were 188.2±16.3 nm, PDI 0.30± 0.06 and -39.3±2.27 mV. The encapsulation efficiency was 98.2± 0.34%. The diffusion rate of LPRL3 containing siRNA in CF mucus was $3.23x10^{-8}$±$7.63x10^{-9}$ cm^2s^{-1} and the impedance (Dw/Dm) was 1.14±0.23, which was approximately 10-fold faster than that of a cationic RTN. The in vitro transfection efficiency of LPRL3 containing luciferase mRNA ($2.84x10^8$ RLU/mg protein) was approximately 20-fold lower than that of a cationic peptide targeted LNP in Cystic Fibrosis epithelial cells at submerged culture. which was not unexpected due to the high anionic charge although this was not observed in vivo. Anti-ENaC siRNA transfections in wild-type mouse lungs were performed with the double-layered formulation, LPRL3, which achieved approximately 30% ENaC mRNA knockdown ($p<0.001$), which was similar to a cationic formulation.

Conclusion: LPRL3 formulation is a novel anionic, receptor targeted lipid-nanoparticle that can penetrate CF mucus better than cationic LNPs while the transfection efficiency *in vivo* was at a similar level to cationic ones. Hence, it is promising in gene delivery for CF therapy via airway route.

AAV Preclinical and Proof-of-Concept Studies for Neurological Diseases

303 AAV9-Mediated Gene Targeting of a Natural Antisense Transcript as a Novel Treatment for Dravet Syndrome

Juan Antinao Díaz[1], Ellie Chilcott[2], Amanda Almacellas Barbanoj[3], Anna Keegan[4], Sonam Gurung[2], Amy McTague[3], Helen Cross[3], Stephanie Schorge[3], Gabriele Lignani[5], Simon Waddington[6], Rajvinder Karda*

**Corresponding Author*

Dravet syndrome (DS) is a severe childhood genetic epilepsy which leads to life-long disability. Symptoms usually manifest in the first year of life and include prolonged tonic-clonic seizures, afebrile or febrile seizures, developmental delay and severe intellectual disability. DS patients have an increased mortality rate, due to sudden unexpected death in epilepsy (SUDEP). Approximately 90% of patients carry a heterozygous loss-of-function mutation in the *SCN1A* gene, which encodes a voltage-gated sodium ion channel, $Na_V1.1$. The $Na_V1.1$ channel is expressed in the brain and at a lower level, in the heart. A long non-coding RNA (lncRNA) from the natural antisense transcript (NAT) of *SCN1A* has been identified to specifically downregulate *SCN1A* expression. Previous studies have developed AntagoNATs, small synthetic oligonucleotides to inhibit *SCN1A* NATs and demonstrated a reduction in seizure phenotype after repeated intrathecal AntagoNAT injections to adult DS knock-in mice.

Here, we have developed novel AntagoNATs and incorporated these into a clinically relevant adeno-associated virus serotype 9 (AAV9) gene therapy vectors, to provide a one-off treatment to a heterozygous DS mouse model (*Scn1a*$^{+/-}$).

Eighteen AntagoNATs were tested *in vitro* in Neuro2a cells; of which thirteen significantly increased endogenous *Scn1a* expression compared to control. From the best performing candidates, we selected two AntagoNAT sequences (H and K) for *in vivo* assessment, as they had the highest homology (90%) to the human *SCN1A* NAT. The vectors were administered to newborn *Scn1a*$^{+/-}$ mice via intracerebroventricular (ICV) injection to target the brain and a combination of ICV and intravenous (IV) injections to target the brain and heart. AAV9-AntagoNAT-H & K demonstrated a higher survival when delivered via ICV & IV administration (total dose = $3.5x10^{10}$vg/pup), compared to ICV alone ($1x10^{11}$vg/pup). ICV & IV AAV9-AntagoNAT-H significantly increased survival to 84%, while ICV AntagoNAT-K resulted in 58% compared to 50% of PBS-treated controls over 100 days. ICV & IV AAV9-AntagoNAT-H treated *Scn1a*$^{+/-}$ mice demonstrated significant reduction in febrile seizures and reduced spontaneous seizure frequency compared to the PBS control group. Furthermore, we observed a significant increase in endogenous *Scn1a* expression in the brain and an increase of *Scn1a* expression in the heart. We also observed an increase in $Na_V1.1$ protein expression in the brain of ICV & IV treated AAV9-AntagoNAT-H group. We also administered AAV9-AntagoNAT-H to P14 *Scn1a*$^{+/-}$ mice *via* ICV & IV injection (total dose = $1x10^{10}$vg/pup), we observed an increase in survival, significant increased *Scn1a* and increased $Na_V1.1$ expression in the brain compared to PBS controls.

In this proof-of-concept study, we have demonstrated that the delivery of AntagoNATs via an AAV9 vector can be effective and thus offering the possibility of a one-time treatment for DS patients.

304 Development of a Secretable Frataxin for Enhanced Efficacy in Treating Friedreich's Ataxia

Friedreich's Ataxia is a debilitating genetic disorder caused by loss of frataxin protein, resulting in progressive ataxia due to nervous system dysfunction and a shortened lifespan due to cardiac complications. The dual involvement of neuronal and cardiac tissues in the disease's pathophysiology has posed significant challenges for developing therapies that can treat all disease manifestations. Achieving frataxin repletion with a one-and-done therapeutic approach using a minimally invasive administration route has been a long-standing goal.

We have developed a first-of-its-kind, innovative gene therapy to address both cardiomyopathy and ataxia phenotypes using a single intra-CSF delivery of an AAV encoding an engineered frataxin variant. This approach integrates multiple innovations to enhance therapeutic efficacy. First, we engineered frataxin to enable secretion from transduced cells and uptake by non-transduced cells, facilitating cross-correction. This innovation expanded the therapeutic footprint beyond the AAV transduction area. Cross-correction of engineered human frataxin in mouse models rescued both neuronal and cardiac phenotypes, demonstrating unprecedented therapeutic potential. Second, we developed a novel capsid capable of transducing critical target tissues, including the cerebellum, dorsal root ganglia, and cardiomyocytes, with a single intra-CSF administration. This capsid demonstrated robust transduction and therapeutic efficacy in both mouse and non-human primate models. Third, we designed a tissue-enriched promoter to optimize frataxin expression. This promoter enhanced expression in cardiomyocytes, maintained therapeutic levels in the nervous system, and minimized expression in peripheral organs like the liver, ensuring safety and efficacy.

Pharmacology studies in non-human primates further validated our approach, showing widespread frataxin repletion in both the CNS and heart. Notably, therapeutic levels of frataxin were achieved in the heart following intra-CSF administration, with expression levels remaining within tolerable safety parameters. These findings, for the first time, demonstrate the therapeutic potential of secretable frataxin to simultaneously address neuronal and cardiac pathology associated with Friedreich's Ataxia. This groundbreaking approach offers a promising one-and-done gene therapy solution for this debilitating disease.

305 FDA-Aligned Strategy for AAV-Based TSC1 Gene Therapy: Advancing Preclinical Development Without Non-Human Primates

**Corresponding Author*

Introduction:
Apertura Gene Therapy has developed AGTX-1111, an AAV-based gene therapy leveraging a novel transferrin receptor-targeted capsid, TfR1 CapX, for the treatment of epilepsy associated with Tuberous Sclerosis Complex (TSC1). AGTX-1111 addresses critical challenges in delivering therapeutic genes across the blood-brain barrier (BBB) to treat refractory epilepsy in TSC patients. A key focus of this program is the use of innovative preclinical models that exclude non-human primates (NHPs), supported by a robust regulatory strategy to streamline development and ensure scientific rigor.

Regulatory Framework:
Our approach was guided by published FDA guidances and insights from our FDA INTERACT meeting, which confirmed key aspects of our development strategy, including the classification of TSC1-associated epilepsy as a neurodegenerative disorder. This designation enabled the application of neurodegenerative disease-specific FDA guidelines. The FDA also concurred with the suitability of human transferrin receptor knock-in (B-hTfR1) mice as a definitive model for biodistribution and toxicology studies, given Apertura's position that NHPs are not a

pharmacologically relevant species for TfR1 CapX, which does not bind NHP transferrin receptor orthologs. This strategy significantly reduces costs and timelines, eliminating the need for large-scale NHP studies.

Preclinical Studies:
Key preclinical studies used a stepwise approach: (1) validating CNS-targeting efficacy of TfR1 CapX in B-hTfR1 mice, (2) using PHP.B as a surrogate capsid to establish proof-of-concept (POC), and (3) demonstrating superior CNS biodistribution and therapeutic benefit in TSC1 disease models. Studies confirmed that intravenously administered TfR1 CapX achieves broad CNS delivery via receptor-mediated transcytosis, providing a critical therapeutic advantage for addressing refractory epilepsy in TSC patients. Notably, biodistribution studies in NHPs corroborated the absence of CNS transduction, reinforcing the pharmacological irrelevance of NHPs for TfR1 CapX.

Potency Assay Development:
A cell-based ELISA assay using a TSC1 knockout cell line was developed to measure total and phosphorylated p70S6 kinase (P70S6K), a downstream target of mTOR. Loss of TSC1 leads to mTOR hyperactivation and increased phosphorylation of P70S6K, making it a key functional readout for TSC1 restoration. In vitro studies confirm that the P70S6K assay effectively measures mTOR pathway activity and is responsive to AAV-mediated TSC1 expression. This assay forms the basis for potency assessment in Phase 1/2 trials. FDA feedback further supported its use as a release assay while providing recommendations for future assay validation to support licensure.

Impact of Excluding NHPs:
This strategy aligns with the 3Rs of ethical animal use and achieves significant reductions in material requirements, costs, and timelines. Additionally, this approach emphasizes the translational relevance of alternative models, such as the B-hTfR1 mouse, for CNS-targeting gene therapies.

Conclusion:
AGTX-1111 exemplifies a streamlined regulatory and preclinical development pathway. This case study highlights the potential for innovative gene therapy approaches to address unmet needs in rare neurodegenerative disorders while reducing reliance on traditional animal models. These principles pave the way for efficient clinical translation and future applications of receptor-targeted AAV gene therapies.

306 Benefit and Tolerability of AAV Gene Replacement in ECHS1D Mice

Meghan Eller[1], Krishanna Knight[2], Karina Alvarado[2], Rachel Bailey[3]
[1]UT Southwestern Medical Center, Dallas, Texas, [2]UT Southwestern Medical Center, Dallas, TX, [3]University of Texas Southwestern medical Center, Dallas, TX

ECHS1 Deficiency (ECHS1D) is a rare Leigh syndrome-like disorder that lacks treatment. Loss of function mutations in ECHS1 impair the activity of short-chain enoyl-CoA hydratase, which oxidizes short-chain fatty acids and branched-chain amino acids (valine, leucine, isoleucine) within mitochondria. Patients present with severe developmental delays/regressions, hypotonia, dystonia, and infantile onset epilepsy. As a monogenic, loss-of-function disorder, ECHS1D is a viable candidate for gene replacement therapy using recombinant adeno-associated virus (rAAV) delivery, but this approach has yet to be explored. Towards this, we developed two vectors containing a ubiquitous promoter to drive expression of a codon-optimized form of human ECHS1, with or without additional CpG depletion (V1 and V2, respectively). Prior to packaging into AAV9, both plasmid constructs were validated to express similar levels of functional ECHS1 upon treatment in N2A cells. Interestingly, treatment with the viruses in Lec2 cells revealed that V1 resulted in much greater protein expression than V2, suggesting CpG depletion may enhance AAV-mediated transgene expression within this cell line. To determine if gene replacement can offer therapeutic benefit, the ECHS1D mouse model was used. This model has been previously shown to have significantly reduced ECHS1 expression with increased seizure susceptibility in adolescence and exercise intolerance throughout aging. For efficacy assessments, ECHS1D mice received vehicle treatment or 5e11vg of V1 or V2 via an intrathecal lumbar puncture (IT) at post-natal day 10 (P10). A short-term cohort was subjected to seizure induction at 3 months post-injection, while a long-term cohort underwent repeat endurance testing at 6, 9 and

12 months. After behavior, tissues were collected for biochemical analysis. While 80% of vehicle treated ECHS1D mice died following seizure induction, survival was increased to 50-60% in the virus treated groups. Wild-type (WT) mice retain 100% survival in this paradigm, so these results demonstrate a partial rescue of the epileptic phenotype. Further, virus treatment prevented the early exercise fatigue observed in untreated ECHS1D mice and restored performance to WT levels. While both viruses demonstrated similar behavioral efficacy, V1 treatment significantly increased ECHS1 expression compared to V2 treated mice and naive WT mice, in agreement with prior cell culture findings. To determine if high levels of ECHS1 are well-tolerated, WT mice were treated with a high (6e11vg) and low (1.5e11vg) dose of V1 at P10 via IT delivery. Weight was unaffected by treatment, but there was a mild reduction in survival in a dose-dependent manner. Unexpectedly, 80% of high dose treated mice developed progressive hindlimb clasping that did not resolve up to 1-year post-injection. This was not associated with any abnormalities noted by clinical blood chemistry or histopathology, however clasping appeared to correlate with degree of ECHS1 overexpression. Taken together, these findings support that gene replacement may be a viable therapeutic approach for ECHS1D patients; however, caution must be taken to avoid toxic levels of ECHS1 overexpression. Future work will develop vectors to allow cellular control of expression as a means to provide a safe and effective treatment for patients with this devastating disorder.

307 Proof-of-Concept AAV Gene Therapy for Christianson Syndrome (CS) in CRISPR-targeted Rat Model

Eric Morrow[1], Gajendra Kumar[1], Qing Ouyang[1], Suhui Qian[1], Morgan Fleishman[1], Matthew Pescosolido[1]
[1]*Brown University, Providence, RI*

Christianson syndrome (CS) is a profound neurological disorder caused by loss-of-function mutations in the gene encoding the endosomal Na+/H+ exchanger 6 (NHE6) protein. CS is among the most common forms of X-linked intellectual disability. CS is characterized by intellectual disability, epilepsy, postnatal microcephaly, ataxia, and poor weight gain. Currently, there is no treatment for CS. In patient-derived induced pluripotent stem cells (iPSCs), we have shown that gene replacement leads to a cell-autonomous rescue of neuronal functions *in vitro* (Lizarraga et al., *Science Trans Medicine*, 2021). We are now investigating the efficacy of AAV9-NHE6 gene therapy in our CS rat model in vivo. We generated the CS rat model by CRISPR/Cas9 gene-targeting, and the CS rat strongly recapitulates several core CS symptoms such as ataxia and low body weight (Lee et al., *Brain*, 2022). We have now developed AAV vectors expressing the human *NHE6* gene. We then examined the efficacy of our therapeutic NHE6 vectors using our CS rat model. CS and WT male rats were assigned to 3 treatment groups: hNHE6 vector (AAV9-hNHE6), control vector (AAV9-eGFP), or sham surgery. Bilateral ICV injections or sham surgeries were performed at 7 to 8 weeks-old. This age was selected as we have previously shown CS rats exhibit motor dysfunction and neuropathology as early as 1-month-old. Using ubiquitous promoters, we detected NHE6 distribution throughout the brain using confocal microscopy. Outcome measures include body weight and functional motor tests. We also use computer vision and machine learning (ML) methods to assess naturally behaving rats in their home cage settings. Measurements were collected at baseline (i.e. 1 week prior to injection) and monthly through 6 months post-injection (PI). CS rats treated with the hNHE6 AAV9 vector (CS+NHE6) displayed significant and prolonged improvement in body weight compared to control-vector (CS+AAV-GFP) and sham (CS+sham) CS rats. Further, NHE6-AAV9 treated CS rat body weight was consistent with WT rats (all conditions). CS+NHE6 rats exhibited significantly greater motor activity, largely indistinguishable from control, in the open field task as compared to both CS+AAV-GFP and CS+sham rats through 6 months. Motor coordination, as measured by the rotorod assay, was significantly improved in CS+NHE6 rats compared to CS+AAV-GFP and CS+sham rats, although mutant rats demonstrated varying degrees of impaired coordination relative to WT rats. Gait abnormalities and ataxia were measured using DigiGait analysis. While both untreated CS rat groups (AAV-GFP and sham) displayed a wider gait, CS+NHE6 rats had a shorter gait similar to WT rats. Interestingly, our computer vision and ML methods are able to distinguish treated from untreated animals in a number of behavioral features in the natural setting, and these methods cluster the treated animals with the control animals. In conclusion, we show, that *NHE6* gene replacement therapy using AAV9 technology successfully ameliorates core symptoms in a CS rat model, such as low body weight and motor impairment *in vivo*. Importantly, these improvements in CS features observed in a CS rat model were long-lasting, through 6 months post-injection of our therapeutic NHE6 AAV treatment. Taken together, our *in vivo* results support proof-of-concept efficacy of *NHE6* gene therapy, with prominent improvements in motor behavior.

308 Development of a Self-Regulating AAV Gene Therapy for the Safe and Effective Treatment of Rett Syndrome

Monique Otero[1], Simon Wentworth[2], Olivia Morales[3], McKenna Watson[4], Tyler Mola[5], William Callahan[3], Ananya Uppalapati[3], Ana Rita Batista[3], Miguel Sena-Esteves[3]
[1]UMass Chan Medial School, Worcester, MA, [2]University of Massachusetts Medical School, Worcester, MA, [3]UMass Chan Medical School, Worcester, MA, [4]University of Massachusetts Chan Medical School, Worcester, MA, [5]UMass Chan Medical School, Leominster, MA

Background:
Rett Syndrome (RTT) is a debilitating X-linked neurodevelopmental disorder that affects 1:10,000 girls. RTT is characterized by a period of normal development until 6-18 months, followed by rapid loss of previously acquired skills, resulting in severe neurological and physical disability. RTT is caused by mutations in *MECP2* which encodes methyl-CpG binding protein 2 (MeCP2), an epigenetic regulator that is highly abundant in neurons and critical for neurodevelopment and function. Affected females are heterozygous and due to random X-chromosome inactivation are mosaics of healthy and mutant cells. *MECP2* is a dosage sensitive gene, therefore effective gene therapies need to regulate *MECP2* expression to rescue mutant cells but avoid overexpression in healthy cells, which could be toxic as suggested by MeCP2 duplication syndrome where phenotypic presentation is similar to Rett syndrome.

Methods:
Our lab developed self-regulating, AAV-*MECP2* vectors for gene therapy of RTT. MeCP2 expression homeostasis is controlled by the upstream positive and negative regulators, Brain-Derived Neurotrophic Factor (BDNF) and microRNA-132 (miR-132), respectively. Our vector encodes the MeCP2 transgene with miR-132 recognition elements to exploit this negative feedback loop. We compared the therapeutic efficacy of these vectors delivered by intracerebroventricular (ICV) injection in neonatal (P0-P1) *Mecp2*$^{y/-}$ mice. *Mecp2*$^{y/-}$ males have neurological abnormalities and a survival expectancy of 8-12 weeks. We monitored mice for long-term survival and performed short-term (8-10 weeks) behavior testing and molecular analysis.

Results:
We performed a long-term survival study to screen five different AAV9 vectors encoding human MeCP2 under the mouse 229-bp promoter and various modifications of non-coding sequences. We identified a top AAV-*MECP2* vector that significantly extended lifespan in Mecp2$^{-/y}$ mice from median survival of 11 to 27 weeks with a range from 16.9 to 52 weeks. We assessed several behavioral parameters at 8-10 weeks of age and found significant improvements in motor coordination in Mecp2$^{-/y}$ mice treated with the lead candidate AAV9-MeCP2 vector compared to PBS controls. There was no significant improvement in treated Mecp2$^{-/y}$mice in locomotion, anxiety, or nesting behavior relative to controls. Western blot analysis showed that treatment restored MeCP2 protein expression in the brain and spinal cord of Mecp2$^{-/y}$ mice. Immunostaining of brain sections for MeCP2 expression revealed robust widespread distribution of MeCP2-positive cells in cerebral cortex but more sparse transduction in deep brain structures and cerebellum. We also performed bulk RNAseq of brain and liver from AAV9- and PBS-treated Mecp2$^{-/y}$ mice at 8-10 weeks of age to determine the impact of gene therapy in the transcriptomic profile of these mice.

Conclusion:
The AAV-*MECP2* treatment significantly extends lifespan of Mecp2-/y mice, rescues some behavioral phenotypes, and restores MeCP2 expression to the CNS. Future plans include exploring vector engagement with the regulatory loop, as this may be important for translation into our target heterozygous female population who have a mixture of healthy and mutant cells.

309 EXG202: A Next Generation AAV-based Gene Therapy for Neovascular AMD Delivered by Intravitreal Injection with Superior Retinal Transduction in NHPs and Remarkable Inhibitory Effect on Retinal Detachment in a Severe Neovascular Mouse Model

Guo-Jie Ye[1], Jikui Shen[2], Li Dai[3], Shuyuan Chen[4], Chunjuan Song[5], Mingliang Zhang[2], **Zhenhua Wu[6]**, Peter Campochiaro[7]
[1]Exegenesis Bio Inc, Gainesville, FL, [2]Johns Hopkins University, Baltimore, [3]Exegenesis Bio Inc, Lower Gwynedd Township, PA, [4]Exegenesis Bio Inc, Hangzhou, Zhejiang, China, [5]Exegenesis Bio Inc., Wayne, PA, [6]Exegenesis Bio Inc., Lansdale, PA, [7]Johns Hopkins Hospital, Baltimore, MD

The success of AAV-based gene therapy for most ocular diseases including wet AMD and DME depends on efficient delivery of the vector to the photoreceptors (PR), and/or retinal pigment Epithelium (RPE). While subretinal administration provides the most direct access to PR and RPE, it is more invasive, with a risk of damage to the retina. Intravitreal (IVT) injection is a safe, non-surgical procedure and has been widely used for delivery of protein therapeutics to treat common retinal diseases.

Here, we report the efficacy and preliminary safety of EXG202, a next generation rAAV-based gene therapy that expresses a fusion protein that binds all subtypes of VEGF as well as ANG2 and is packaged in a novel engineered AAV capsid designed for intravitreal injection.

The test systems are nonhuman primates (NHPs) and the Tet/opsin/VEGF double transgenic mouse model. In NHPs, 6 animals received EXG202 intravitreally in one eye and AV7m8 (a benchmark IVT capsid carrying the same transgene expression cassette as that of EXG202) in the contralateral eye (1×10^{11}vg/eye). Post injection animals were followed for 8 weeks. Levels of the transgene product were measured in aqueous and vitreous humors collected at week 4 & 8, as well as ocular tissues (iris-ciliary body, retina, RPE/choroid) collected at week 8. The levels of the transgene product in eyes that received EXG202 were consistently higher (up to 3-fold) than those in eyes that received AV7m8. Intravitreal injection of 1×10^{11} vg/eye of EXG202 was well-tolerated with no test article-related changes except for minimal vitreous cells in one of six eyes. There were mild vitreous cells in three of six eyes dosed with AAV7m8.

Efficacy of EXG202 delivered by intravitreal injection was tested in a dose-ranging study in Tet/opsin/VEGF double transgenic mice, with inducible expression of $VEGF_{165}$ that develop severe vascular leakage and exudative retinal detachment (RD) when treated with doxycycline Adult Tet/opsin/VEGF mice (n =7-9/group) were given an intravitreal injection of EXG202 at doses of 1×10^7, 3×10^7, 1×10^8, 3×10^8, or 1×10^9 vg/eye in one eye, and the negative control vector AVT-Luc in the other eye. Four weeks post injection, the mice were given doxycycline and after 4 days, fundus photographs were obtained. The results were categorized as no, partial, or total exudative RD. Compared with control vector-injected fellow eyes, total exudative RD was reduced by 61%, 71%, 86%, or 100% in mice treated with 3×10^7, 1×10^8, 3×10^8, 1×10^9 of EXG202. Compared to the first-generation gene therapy vector EXG102, which carries the same payload as EXG202 but is packaged in a wild-type AAV2 capsid for subretinal gene therapy, EXG202 delivered via intravitreal injection was ~10-fold more potent in prevention of RD in Tet/opsin/VEGF mice.

In conclusion, EXG202 demonstrated superior retinal transduction efficiency compared to the benchmark control AV7m8 in NHPs and strongly suppressed VEGF-induced vascular leakage and exudative retinal detachment. These data strongly support the clinical development of EXG202 for the treatment of nAMD or DME.

AAV Vector Manufacturing: Plasmids & Cell Line Development

310 Enhancing Upstream Processes for High-Yield, High-Quality AAV Vector Production Using a Novel In-House Cell Line

Richard Gilmore[1], Shannon Wallace[2], Chase Rebidue[3], Hannah Stewart[4], Magda Reis[5], Louis Frost[6], Eli Wiberg[7], Jin Yin[7], Marissa Stanvick[7], Diane Golebiowski[8], Ifeyinwa Iwuchukwu[8]
[1]OXB, Medford, MA, [2]OXB, Oxford, MA, United Kingdom, [3]Oxford Biomedica (UK) Limited, Bedford, MA, [4]OXB, Oxford, Oxfordshire, United Kingdom, [5]Oxford Biomedica (UK) Limited, Oxford, United Kingdom, [6]Oxford

Biomedica (UK) Limited, Oxford, Oxfordshire, United Kingdom, [7]Oxford Biomedica Solutions, [8]Oxford Biomedica Solutions, Bedford, MA

High productivity and product quality have been critical in developing novel AAV-based drug candidates, not only to fuel clinical trials but also to reduce the high manufacturing cost per patient dose. The pursuit of high AAV productivity has led to an increased focus both on upstream process optimization, and the development of clonal cell lines that are highly transfectable and able to produce high titers across multiple serotypes.

A SV40 large T antigen knock-out HEK293 cell line was generated using Mad7-based genome editing of HEK293T cells. Clones were screened for vector genome productivity at shake flask scale and confirmation of removal of the SV40 large T loci via targeted nanopore sequencing. The top clone candidate (HEX2s52) was confirmed for full SV40 large T antigen and associated NeoR cassette removal via PacBio whole genome sequencing and lack of expression of large T antigen and NeoR with mass spectrometry.

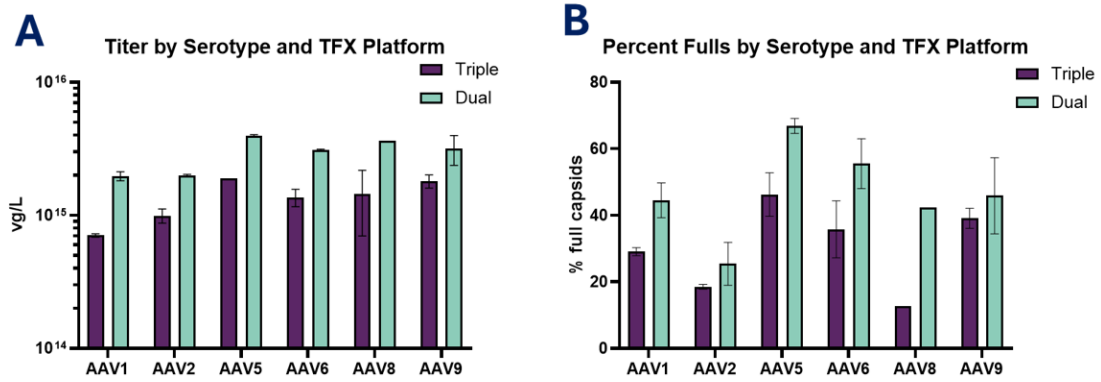
Performance of top clone HEX2s52 was confirmed at 2L bioreactor scale using OXB's dual plasmid inAAVate™ platform with AAV9 and was able to achieve a bioreactor titer of 5.7e14 vg/L and 35.7% full capsids. To improve HEX2s52 performance in the hopes of surpassing 1e15vg/L and 40% full capsids, further process development was performed focusing on factors such as transfection parameters, alternative transfection reagents, and incorporation of post-transfection additives.

With the implementation of this newly optimized process and the OXB in-house cell line at 2L bioreactor scale, AAV9 bioreactor titer increased >5-fold to 3.2e15vg/L, and percent full capsids increased to 45.9%. 2L bioreactor evaluation (N=2) was also performed in AAV1, AAV2, AAV5, AAV6, and AAV8 serotypes using this new process with HEX2s52 and ≥2e15vg/L was achieved for all serotypes using the dual transfection system, with AAV5 being the highest at 4.0e15vg/L and 66.9% full capsids.

2L bioreactor material was purified through to drug substance for all six tested serotypes and confirmed for good product quality and equal, if not better, final vg yield. Relative potency improved in OXB cell-line with optimized process material compared to historical platform Process C data for AAV1, AAV8, and AAV9 serotypes, with AAV1 showing >2.5x increase in potency.

Improvements from this optimized upstream process are not limited to OXB's in-house cell line. The commercial cell line also saw a >3-fold improvement in vector genome titer at 2L bioreactor scale when using the optimized upstream process for dual plasmid transfection in AAV9.

In summary, OXB's new in-house cell line alongside intensified upstream process delivers high quality, highly potent AAV vector across multiple capsid serotypes with bioreactor titers as high as 4e15vg/L. The benefits of this optimized process extend beyond OXB's in-house cell line, demonstrating a minimum three-fold increase in titer when applied to another commercially available cell line.



311 Establishment of a Novel Human Cell Line, HAT, for High-Yield and High-Quality AAV Manufacturing

Yu-Hsin Chang[1], Ryo Asahina[2], Arisa Yamamoto[3], Rena Moromizato[4], Kazuko Aizawa[5], Manami Miyai[5], Michi Kubota[4], Takayuki Horiuchi[4], Kazuaki Nakamura[6], Yugo Hirai[7]*

Introduction:
The field of AAV-based gene therapy has witnessed a rapid progression, with an accelerating number of product approvals and clinical trials over the last decade. However, manufacturing capacity cannot keep up with the growing demand using currently employed platforms, resulting in prohibitively high costs and limited accessibility of these treatments. In addition, though infrequent, the reported severe adverse effects in high-dose AAV administration further highlight the urgent need to improve AAV vector production. Despite considerable efforts to subclone and develop the commonly used HEK293 host cells, challenges remain in producing high-yield and high-quality AAV vectors. To address this, our study introduces a newly established Human Amniotic epithelial cell line for gene and cell Therapy (HAT cells).

Methods:
Placental tissues as raw materials for HAT cells were obtained from healthy expectant mothers after scheduled cesarean section. Written informed consent was obtained from all subjects before deliveries to comply with ethical and legal requirements. HAT cells were generated by transforming primary cells isolated from placental amnion, with DNA fragments encoding adenovirus 5 E1 genes. Adherent HAT cells selected from among a large pool of candidate lines were then adapted to serum-free suspension culture in chemically defined medium and single cell cloned with fully traceable history for widespread industrial adoption. The identity and quality of HAT cells were characterized to avoid the inherent risk of contamination in products manufactured in them. AAV vectors were produced using a triple plasmid transfection method. Genomic and capsid titer were measured by qPCR, ddPCR, and ELISA. The percentage of full capsids was determined by qPCR/ELISA ratio. Full capsid content was also estimated by anion-exchange chromatography (AEX). The scalability of HAT cells was assessed using a benchtop bioreactor.

Results:
The cell line identification analysis indicated that HAT is an authentic human-origin cell line. HAT cells exhibited high levels of proliferation and transfection efficiency. AAV productivity of adherent HAT cells and infectivity of HAT-produced AAV vector particles were equal or superior to those of HEK293 cells. HAT cells tested negative for adventitious pathogens and mycoplasma. These features indicate that HAT cells are suitable as a host cell platform. High-yield AAV vector production, routinely exceeding 6E13 vg/L, was achieved across multiple serotypes in clonal, suspension-adapted HAT cells. AAV2 and AAV8 vectors produced from HAT cells contained substantially higher full capsid content, greater than 1.5-fold compared to those produced from suspension HEK293 cells. A significantly higher peak in the AEX chromatogram presumed to be enriched for full particles was also observed in HAT-produced AAV vectors. Finally, we demonstrated a successful scale-up production of AAV8 vectors to 2-liter scale. The yield and capsid content were comparable and reproducible from shake flask to bioreactor.

Conclusion:
Here, we report the establishment of novel HAT cells and the potential of HAT cells to serve as a host for AAV vector production. We believe with further cell line development, process optimization, and comprehensive characterization of HAT-produced vectors, HAT cells will provide a promising manufacturing option that can enhance therapeutic efficacy and safety at lower AAV doses.

312 Improved Adeno-Associated Vectors for High-Yielding AAV Manufacturing

Bhargavi Kondragunta, Catalent, Rockville, MD

Introduction
Adeno-associated viral (AAV) have emerged as a promising gene delivery tool for in vivo gene therapy, frequently requiring high doses to achieve the desired therapeutic effect. This underscores the critical need for enhancing AAV production titers while ensuring optimal AAV characteristics. However, achieving the higher production titers remains a significant challenge, driving the need for improved AAV vector design, along with production processes. A key element influencing AAV production is the membrane-associated accessory protein (MAAP), which is encoded from a frameshifted open reading frame in the viral protein 1 (VP1) capsid gene. Discovered as an egress factor, MAAP plays a role in AAV replication and infection. We have designed over 15 types of novel vectors per serotype by making substitution mutations to the MAAP protein (termed RepCapExcel vectors). Our current Catalent® Off-the-shelf (OTS) plasmids result in superior performance for titer and product quality and were an improvement over competitor, both in the Catalent HEK-293 cell-line, and commercial cell-lines. Work here investigates novel vectors conceived as additional possibilities for future improved versions of the RepCap plasmid. RepCapExcel vectors were evaluated using Catalent's® baseline AAV platform process and compared to Catalent® Off-the-shelf (OTS) plasmids. Vectors were evaluated for their potential to improve AAV product titers, without impacting the viral proteins expression, or the AAV product characteristics.

Methods
In this work, we generated a matrix of unique single-codon substitutions, amino acid substitutions, deletions, and combinations thereof in the membrane accessory protein across several AAV serotypes, including AAV5, AAV6, AAV8, and AAVrH10. We evaluated over 75 RepCapExcels vectors across various serotypes using the Catalent baseline UpTempo^{SM} platform process in shake-flasks, and compared their performance with the Catalent OTS RepCap vectors. AAV titer and quality attributes were compared with the Catalent version #1 OTS RepCaps, using the Catalent clonal HEK-293 Cell-line. Specific changes such as stop codon modifications, and amino acid substitutions had unique effects on the AAV product titer fold-increase, when tested using our model pGalacorin^{TM} as a gene-of-interest. In all cases changes were made to alter MAAP protein alone, while ensuring the Viral protein expression itself remained unchanged.

Results and Conclusion
Using these novel RepCapExcel vectors several key findings were observed: (1) AAV titers improved by 3-7 fold compared to RepCap plasmid controls (for example, an AAV5 RepCap variant achieved titers of up to 8 x 10^{11} vg/mL in shake-flasks, representing over a 3-fold increase over control RepCap, without a significant rise in residual packaged host cell DNA (hcDNA) or a decrease in percent full capsids; (2) The percent full capsid, and purity by viral proteins VP1, VP2, VP3 expression and protein ratios remained consistent, as confirmed by LC-MS and PTM analyses using samples from a single step affinity purification; (3) RepCapExcel variant #5 played a critical role in in recombinant AAV production across all serotypes; (4) A RepCapExcel vector variant #2 that exhibited the highest vector genome titer increase, as well as the highest AAV particle titer increase was identified.

313 Unveiling small non-coding RNA dynamics during rAAV production

Sonja Lochmüller[1], Madina Burkhart[2], Katrin Langenbach[3], Karl-Heinz Holzmann[4], Nadine Hornung[3], Jamie-Ann Baiz[3], Kerstin Otte[5]
[1]University of Applied Science Biberach, Biberach, Baden-Wuerttemberg, Germany, [2]University of Applied Sciences Biberach, Biberach an der Riss, Baden-Wuerttemberg, Germany, [3]Hochschule Biberach, BIBERACH AN DER RISS, Germany, [4]University Hospital Ulm, 89081 Ulm, Germany, [5]University of applied sciences Biberach, Ulm, Germany

Recombinant adeno-associated viruses (rAAVs) are a cornerstone of modern gene therapy, offering precise delivery and stable transgene expression with minimal immunogenicity. Despite clinical advancements, large-scale rAAV production faces significant challenges such as low yield, high costs, and variability. Addressing these hurdles is critical to meet rising demand.

In this study, we explored the expression profiles of microRNAs (miRNAs) and small nucleolar RNAs (snoRNAs), which are increasingly recognized as key regulators in viral replication, during rAAV plasmid transfection and production in HEK293F cells. Therefore, HEK293F cells were either mock- or rAAV transfected and cultivated over 72 h. During cultivation and production, samples were taken to analyse cellular parameters and rAAV titers. Ultimately, RNA specimens of each sampling time point were isolated and analysed via microarray expression analysis.

Using a detailed and multi-faceted comparative approach, we identified a substantial number of miRNAs that were differentially expressed compared to both the non-transfected mock control and to the basal expression pre-transfection. The most significant differences in expression were observed during the main phase of rAAV production, particularly between 24- and 72-hours post-transfection (hpT). Here, 142 miRNAs were differentially expressed in all comparisons and of these, 128 miRNAs were associated with the GO term “viral process” based on enrichment analyses of their validated target genes.

In contrast, snoRNA analysis showed overall fewer differential expression events, with a higher number being upregulated relative to mock transfection and downregulated compared to basal expression. During the main rAAV production phase, five snoRNAs were identified as significantly differentially expressed across multiple time points, pointing towards their potential involvement in viral replication and production processes.

These findings provide valuable insights into cellular and viral responses underpinning rAAV production. By elucidating the regulatory roles of miRNAs and snoRNAs, this study lays the groundwork for future advancements in gene therapy manufacturing through host cell line engineering.

314 Enhancing Gene Therapy Access: Standardizing AAV Production With Cell Line Development

Ben Hudjetz[1], Thu Bauer[2], Sabine Schmidt-Hertel[3], Tamara Grabeck[1], Keerthana Srinivasan[1], Julio Hernandez[4], Kelly Cybulski[5], Michael Michael Mühle[1], Michelle Peabody[4], Christian Niehus[3], Tobias Bonifert[2], Michelle Hussong[2]
[1]Cytiva, Cologne, Nordrhein-Westfalen, Germany, [2]Cytiva, Köln, Nordrhein-Westfalen, Germany, [3]Cytiva, Cologne, Germany, [4]Cytiva, Westborough, [5]Cytiva, Marlborough, MA

As gene therapies approach widespread adoption, advanced adeno-associated virus (AAV) manufacturing platforms are essential to accelerate clinical and market entry. With the growing global demand, driven by the trend for higher recombinant AAV (rAAV) doses—62% of systemically administered rAAVs are now dosed between 10^{14} and 10^{16} vg—achieving high scalability, reducing production costs, and minimizing batch-to-batch variability are crucial. Ensuring the safety and efficacy of rAAV therapies, particularly at high doses, is becoming increasingly important. The industry must innovate to produce these viral vectors more robustly while reducing specific impurities.

Stable production methods have paved the way for monoclonal antibody production. However, rAAV poses unique challenges in cell line development and process-related impurities. While industrial production methods have advanced, most GMP rAAV processes still rely on transient transfection and plasmids. Contaminant removal traditionally focuses on impurities in solvents or vector surfaces, but contaminants encapsidated within rAAVs can't be removed with classical downstream purification technologies without disrupting the vector.

Leveraging high-throughput sequencing technologies alongside synthetic biology and gene editing tools, we have developed a highly efficient, helper-virus-free, stable rAAV producer cell line (PCL) that overcomes these challenges, enabling cost-effective, large-scale production of high-quality rAAV. Our proprietary, genetically modified HEK293 PCL integrates all necessary genetic components for vector production into the producer cell genome, eliminating the need for transient transfection or helper viruses. Additionally, our proof-of-concept cell lines use genetic modifications to inhibit specific cellular pathways, reducing host cell DNA encapsidation (including potential oncogenes) by up to 95% without affecting vector titers.

By embracing next-generation cell line development, the industry can tackle major challenges, ultimately enhancing global access to gene therapies.

315 Optimising AAV Vectors Quality and Characterisation Using Synthetic Linear DNA

Celine Winckler[1], Binh Nguyen[2], Aditya Iyer[2], Amy Walker[3], Heikki Lanckriet[4]
[1]4basebio, CAMBRIDGE, Cambridgeshire, United Kingdom, [2]4basebio, Over, Cambridgeshire, United Kingdom, [3]CAMBRIDGE, United Kingdom, [4]4basebio, Cambridge, United Kingdom

Recombinant Adeno-associated virus (rAAV) remains a popular vector for gene therapy, with over 250 trials recorded in the past ten years using rAAV as a delivery system. However, rAAV manufacturing still faces several challenges to keep pace with the demand for large scale, high quality batches. Indeed, the gold standard plasmid triple-transfection as a favoured mode of production presents several issues. One, availability of GMP grade plasmid and costs. Two, sequence fidelity of the Inverted Terminal Repeats (ITR). And three, FDA safety concerns over non-specific encapsidations of sequences from the plasmids used during manufacturing that may be a trigger for innate immunity.

As new forms of template DNA become available for rAAV manufacturing, assessing the quality of the produced vectors is of paramount importance. 4basebio has developed a proprietary, scalable enzymatic synthesis process for the production of linear, closed-end DNA constructs via its Trueprime™ amplification technology. The hpDNA™ produced is devoid of any bacterial backbone and circumvents cumbersome fermentation processes required for plasmid DNA. It also allows unprecedented conservation of the notoriously unstable Inverted Terminal Repeat (ITR) sequences. The process can significantly reduce the turnaround time for GMP grade DNA production.

Here, we compared the production of rAAV using synthetic linear hpDNA™ encoding for the typical Adenovirus helper functions, *rep* and *cap* genes, and an expression cassette consisting of AAV2 ITRs and a reporter gene driven by an ubiquitous promoter, with conventional plasmid triple-transfection as a control. We emphasised our focus on validating methods that take in account the fundamental difference of this new template with plasmid DNA to ensure the accuracy of our data, including physical titers and examination of packaged DNA.

We first looked at the Sanger and nanopore sequencing of various batches of hpDNA™, which revealed that 4basebio amplification process maintains ITR integrity across multiple constructs, even with wild-type sequences. We then optimised the transfection of our synthetic DNA through DOE and reached equivalency with their plasmid counterpart, in both an adherent and a suspension-adapted HEK293 lines. We also showed that various DNAseI were not as efficient as removing free floating DNA on synthetic DNA as they are on plasmid DNA. Following this important finding, we validated a new assay using a new high salt DNAse. Afterward, we looked into the detection of template backbone in rAAV productions made from either plasmid or synthetic DNA, and showed that while batches made from plasmid had up to 10% of beta-lactamase copies, these were below the qPCR limit of detection for batches made from hpDNA™. The examination of physical titers highlighted differences when testing different genome constructs, but overall similar titers between synthetic DNA vs plasmid DNA. Finally, transduction assays showed that rAAV particles made from plasmid or synthetic DNA were equally infectious.

While achieving similar viral genome titres and infectivity between the two production methods, we also demonstrated AAV vectors made from hpDNA™ were generally of better quality, which could greatly accelerate therapeutic development of gene therapy programmes.

316 Mechanistic Insights Enhance Multi-Serotype Production in the TruStable™ AAV Producer Cell Line

Sandhya Pande[1], Blake Engelbert[2], Anupama Lakshmanan[2]
[1]Shape Tx, Seattle, WA, [2]Shape Therapeutics, Inc., Seattle, WA

Adeno-associated virus (AAV) vectors are increasingly important for gene therapy applications, yet traditional production methods face significant limitations in scalability and consistency. We previously developed TruStable™, a fully stable AAV producer cell line, demonstrating robust and reproducible vector production of AAV5. Here, we report the expansion of this platform to additional AAV serotypes through mechanistic understanding of capsid mRNA production requirements. Systematic investigation identified a key viral helper factor essential for efficient capsid mRNA production across several AAV serotypes. Integration of this helper factor enabled high-titer production of multiple AAV serotypes beyond AAV5, significantly expanding the versatility of theTruStable™ platform. The robust process characteristic to TruStable™ enables detailed mechanistic interrogation of AAV biology to further enhance vector production and quality.

Challenges in Immunological Responses to Therapeutic Interventions

317 Potential for Potent Intrahepatic CD8$^+$ T Cell Responses Despite Lack of Peripheral Responses Following Systemic Muscle-directed Gene Delivery with AAV

Di Cao[1], Sandeep Kumar[2], Moanaro Biswas[3], Dongqi Liu, Maite Munoz[4], Dongsheng Duan[5], Weidong Xiao[6], Renzhi Han, Roland Herzog[7]*
[1]Indiana University, Fishers, IN, [2]Indiana University School of Medicine, INDIANAPOLIS, IN, [3]Indiana University, Indianapolis, Indiana, [4]Gene and Cell Therapy Group IU School of Medicine Department of Pediatrics, Indianapolis, IN, [5]Univeristy of Missouri, Columbia, MO, [6]Indiana University, Indianapolis, IN, [7]IU School of Medicine, Indianapolis, IN
**Corresponding Author*

Capsid-engineered adeno-associated virus (AAV) vectors are promising candidates for muscle-directed systemic gene delivery to treat neuromuscular disorders. However, therapeutic efficacy often necessitates high vector doses, which increase the risk of immunotoxicity. We recently found that intramuscular (IM) administration of $8x10^{12}$vg/kg of an AAV1 vector expressing chicken ovalbumin (OVA) from the CMV promoter induced a potent and destructive CD8$^+$ T cell response against OVA in C57BL/6 mice (with peak frequencies of 10-20% of CD8$^+$ T cells in peripheral blood at week 2) that was not be prevented by CpG depletion or other methods of disrupting innate immune pathways unless the vector dose was reduced or multiple pathways were targeted (Viruses 16:1507, 2024). Here, we packaged the identical expression cassette into AAVMyo, an AAV9-derived myotropic capsid with improved systemic muscle transduction (Nat Commun 11:5432, 2020). C57BL/6 mice (n=5/group) were intravenously injected with up to $1x10^{14}$vg/kg of AAVMyo-CMV-OVA. Surprisingly, circulating OVA-specific CD8$^+$ T cells were found only at ~10-fold lower peak frequencies and were the lowest (0.8%) at the highest vector dose. Frequencies further declined for the duration of the experiment (6 weeks). Transgene expression was detected by immunohistochemistry in the heart, diaphragm and limb muscle, accompanied by only very mild CD8$^+$ T cell infiltration (at 2 weeks, later time points pending), initially prompting us to conclude that systemic delivery elicited minimal CD8$^+$ T cell responses. However, a robust CD8$^+$ T cell response was unexpectedly found in the liver, with ~60% of intrahepatic CD8$^+$ T cells being OVA-specific and an overall increase in CD8$^+$ T cells in the liver at week 2. Tissue sections revealed substantial and wide-spread CD8$^+$ T cell infiltration of the liver parenchyma, despite undetectable OVA expression by immmunostaining. The liver also contained the highest vector copy numbers of all tissues examined, and significant elevation in serum ALT (3.2-fold) and AST (2.4-fold) levels were detected. Intrahepatic OVA-specific CD8$^+$ T cells expressed PD-1, 2B4, TIM3, and LAG3, exhibiting a phenotype of exhausted T cells, which may have limited liver damage. In our earlier IM administration study, we found that a vector containing a CpG-depleted transgene combined with a muscle-specific promoter (CK8e) and TLR9 inhibitory sequences (io2) elicited substantially lower responses against OVA (Viruses 16:1507, 2024). When AAVMyo-CK8e-OVA-io2-CpG$^-$ vector was given systemically, the intrahepatic CD8$^+$ T cell response was substantially reduced to on average ~9%, and only marginal CD8$^+$ T cell infiltration was observed. In conclusion, systemic delivery of AAV vectors has the potential to induce strong cellular immune responses in the liver that may not be detected in peripheral blood. Although the hepatic environment tends to limit T cell effector functions, this potential

for delayed liver damage by adaptive responses nonetheless constitutes a safety concern, as supported by liver toxicities seen several weeks after systemic AAV delivery in some patients. Our findings suggest that capsid modifications alone may not be sufficient to prevent liver-targeted immune responses, underscoring the importance of integrating vector genome engineering and other strategies to minimize off-target immune activation.

318 Intra-Ocular Delivery of the Bacterial Protease IdeS in Non-Human Primates: A Potential Strategy to Circumvent Pre-existing Immunity to Enable Successful AAV Gene Transfer to the Eye

Jennifer Sullivan[1], Bindu Nambiar[2], Christian Mueller[3], **Catherine O'Riordan[1]**, Suzanne Jacobs[4]
[1]Sanofi, Waltham, Massachusetts, [2]Sanofi, Framingham, MA, [3]Sanofi Genzyme, Waltham, MA, [4]Sanofi, Waltham, MA

Adeno-associated viral vector (AAV)-mediated ocular gene therapy has the potential to provide a long-term treatment for many genetic or acquired ocular diseases; however, neutralizing antibodies (nAb) to AAV vectors are highly prevalent in the human population and can be a major challenge to successful gene therapy in the clinic. Preclinical studies in non-human primates (NHPs) have shown that nAbs can negatively impact AAV transduction following intravitreal injection (IVT) of an AAV gene therapy vector, leading to reduced transgene expression. Furthermore, nAbs that are induced from a primary intravitreal AAV vector administration will likely pose a challenge for future re-administration, if ever needed. While the impact of nAb levels and AAV vector dose in the human eye are currently being evaluated in multiple clinical trials, there remains a need for improved protocols for AAV-mediated ocular gene therapy in AAV seropositive patients. Here, we explore the use of IdeS, a protease that specifically degrades IgG and is currently approved for use in kidney transplantation, as a strategy to enable successful ocular gene transfer in the presence of pre-existing neutralizing antibodies to AAV.

We evaluated the efficacy of IdeS in the eyes of non-human primates with pre-existing neutralizing antibodies to AAV.SAN024, a capsid with high tropism for the eye. NHPs seronegative or seropositive for AAV.SAN024 nAbs received a bilateral IVT dose of either PBS or IdeS three days prior to IVT administration of an AAV.SAN024-sFLT02 vector (2E10 vector genomes/eye). Vector genome and transcript levels in the retina and nAb titers in the serum, aqueous humor (AH), and vitreous humor (VH) were measured five weeks after vector administration to assess the impact of intravitreally delivered IdeS on ocular transduction and immune response.

AAV.SAN024-sFT02 vector genome and transcript levels in the retinas of PBS-treated seropositive NHPs were an order of magnitude lower compared to PBS-treated seronegative NHPs, demonstrating an impact of pre-existing nAbs on AAV transduction and subsequent transcript expression in the eye. In contrast, seropositive NHPs that received IVT IdeS treatment prior to AAV.SAN024-sFLT02 administration achieved levels of vector transduction and transcript expression comparable to the seronegative NHPs.

In seronegative NHPs, the majority of NHPs exhibited minimal increase in serum nAb titer and no increase in ocular fluid nAb titers five weeks after IVT AAV.SAN024-sFLT02 administration. In contrast, seropositive NHPs that received IVT PBS elicited a strong AAV nAb response to AAV.SAN024-sFLT02, which was detectable in serum, VH, and AH. However, seropositive NHPs that received IVT IdeS had lower levels of AAV.SAN024 nAbs in serum, AH, and VH compared to seropositive NHPs that did not receive IdeS, with the majority of IVT IdeS-treated eyes having undetectable AAV.SAN024 nAbs in the AH or VH at the end of the study. Overall, serum AAV.SAN024 nAb titers were higher than intraocular nAb titers within an individual animal.

These data demonstrate that intravitreal delivery of IdeS can improve the efficiency of AAV gene transfer in the presence of pre-existing immunity and suggest a potential safe and effective strategy for addressing this challenge in the clinic.

319 Immune Modulation Sustains Alpha Cell Reprogramming and Mitigates Immune Responses to AAV in a Diabetic Non-Human Primate Model

Introduction:
Diabetes mellitus is characterized by insufficient beta cell mass and inadequate endogenous insulin production. Gene therapy using recombinant adeno-associated virus (rAAV) has shown promise for curative therapy in diabetes mellitus in pre-clinical models. Retrograde intraductal infusion of rAAV6 to deliver Pdx1 and MafA, converting alpha cells into beta-like cells, reverses diabetes in mice. Direct infusion of AAV into the pancreatic duct for gene therapy has not previously been attempted in non-human primates (NHPs) and thus the immune response in this species is unknown. In clinical trials, anti-viral immunity to AAV can be a barrier to successful gene therapy. We evaluated the immune response to intraductal rAAV in NHPs with streptozotocin-induced diabetes.

Methods:
Diabetes was induced with streptozotocin (STZ) in cynomolgus macaques. NHPs received retrograde intraductal infusion of rAAV via laparotomy and duodenotomy for precise access to the pancreatic duct. rAAV capsids were chosen based on tropism for NHP pancreatic endocrine cells, and pre-existing neutralizing antibody titers (NAbs) were negative. Blood work including serum C peptide and IV glucose tolerance tests were serially obtained to monitor gene therapy efficacy. Immune response monitoring was performed for up to 4 months post-infusion and included serial NAbs, ELISpot assays, and immunophenotyping. Pancreatic tissues were analyzed using IHC and RNA-scope for beta cell markers and virus-encoded genes, as well as single-cell RNA transcriptomics.

Results:
One-month post-infusion, NHPs showed improved glucose tolerance and reduced insulin requirements. The AAV6 capsid with endocrine-specific promoters driving Pdx1 and MafA showed durable effects. ELISpot-positive cytotoxic T cells and neutralizing antibodies developed when steroids were absent. With steroid-sparing regimens, pancreatic B and T lymphocyte populations were noted on scRNA sequencing. Temporary immunosuppression (IS), using a combination of rituximab, rapamycin, and steroids, for a 3-month course is effective at preventing anti-viral immunity. Despite complete IS discontinuation at 3 months post-infusion, meaningful anti-viral immune response was not mounted up to one month after IS withdrawal, as evidenced by low NAb titers and negative ELISpot analyses. Additionally, rAAV gene therapy in these animals remained effective and glucose tolerance continued improving in the absence of immunosuppression.

Conclusion:
We developed a novel rAAV gene therapy approach and demonstrated that infusion of rAAV directly into the pancreatic duct of NHPs induces an anti-viral immune response. The anti-viral immune response in NHPs can be prevented by administration of a multi-agent IS and can allow for sustained therapeutic effects.

320 Co-Stimulatory Blockade Regimen Prevents anti-Transgene and anti-Vector Immune Responses for an Effective and Re-Dosable in vivo Gene Therapy for Hemophilia A.

Andrea Annoni[1], Michela Milani[2], Cesare Canepari[3], Silvia Iaia[4], Fabio Russo[4], Mauro Biffi[4], Luigi Naldini[4], Alessio Cantore[5]
[1]SR-TIGET, Milano, Milano, Italy, [2]SR-TIGET, Roma, Roma, Italy, [3]SR-TIGET, Rome, ITALY, Italy, [4]SR-TIGET, Milan, Italy, [5]SR-TIGET, Milan, Italy, Italy

Lentiviral vector (LV)-based in vivo gene therapy is attractive for its potential applicability to permanently correct monogenic diseases, even in childhood, with negligible limitations derived from pre-existing immunity towards the

parental virus. Although a single systemic LV administration has achieved stable transgene expression by hepatocytes in mice, dogs, and non-human primates, immunity towards transgene and vector may limit the therapeutic outcome and LV redosing.

In a mouse model of Hemophilia A (HA), LV-mediated factor VIII (FVIII) expression by hepatocytes revealed that multiple factors may contribute to the induction of T cell-dependent immune responses to FVIII, such as the protein structure, the proportion of transduced hepatocytes, the translation rate, and the protein half-life. A high dose of LV encoding for human (hu)FVIII (~$5X10^{10}$ TU/kg) in adult HA mice established stable expression of huFVIII (50% of normal) in absence of anti-FVIII immune responses in 80% of treated mice, by a combination of fasting and type-I interferon (IFN) signaling blockade (anti-IFNa receptor, aIFNAR) which allowed maximizing LV transduction efficiency and dampening innate immunity. Conversely, the administration of LV alone did not result in detectable huFVIII and induced anti-FVIII immunity. Comparable doses of LV encoding for half-life extended huFVIII.XTEN resulted in minimal and only transient FVIII expression in vivo, again abrogated by anti-FVIII immunity. To improve FVIII output in vivo at lower LV doses, the transgene sequence was codon-optimized (coFVIII), enabling 10-fold increased expression compared to huFVIII. This strategy allowed to obtain high levels of circulating FVIII produced by a limited proportion of hepatocytes but resulted in the induction of a strong anti-FVIII humoral and cellular immune response leading to clearance of LV-corrected hepatocytes. Therefore, we tested T cell-targeted immunotherapies to control anti-transgene immunity. We found that the administration of anti-IFNAR immediately before coFVIII-LV or coFVIII-XTEN-LV administration combined with the co-stimulation blockade regimen allowed stable huFVIII expression at 110% and 500% of normal, respectively, in HA adult mice by lower LV doses (~$2X10^{10}$ TU/kg). This immunotherapeutic regimen abrogated the induction of anti-FVIII antibodies and CD8+ T cells, allowing the persistence of LV-modified hepatocytes releasing FVIII in the absence of antibody-mediated neutralization, largely beyond the time of its administration.

Furthermore, we did not detect any neutralizing anti-VSV.G humoral response, typically induced by in vivo administration of VSV.G-pseudotyped LV, thus enabling an effective re-dosing of the same vector in case of a sub-therapeutic first dose. Interestingly, this immunotherapy was similarly effective also for re-administration of adeno-associated viral vectors. Overall, these data indicate that immunogenicity to therapeutic transgene can be controlled by i) increasing the proportion of transduced hepatocytes and lowering the amount of huFVIII produced per cell and ii) applying a co-stimulation blockade regimen to achieve stable FVIII expression at therapeutic levels, even increasing the rate of transgene translation in a reduced fraction of hepatocytes. Moreover, the latter strategy gives the opportunity to adjust transgene output by re-dosing in vivo gene therapy, thanks to the absence of immunity to transgene and vector particles.

321 Stimulation with Self Peptides Led to Interleukin-17 Secretion by Peripheral Blood Mononuclear Cells from an AAV-Treated Patient with Duchenne Muscular Dystrophy and Unexplained Fatality

Julie Crudele[1]*, Michelle Lorentzos[2], Frances Evesson[3], Michelle Petrasich[4], Sandra Cooper[5], Adam Bournazos[6], Gina O'Grady[7], Kristi Jones[8]

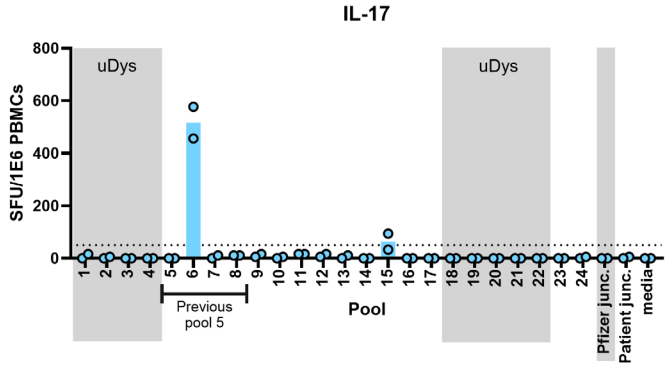
A 4-year-old boy treated with fordadistrogene movaparvovec had recurrent cycles of severe muscle pain, myoglobinuria and acute critical hyperCKaemia until his unexplained fatality 14 months following gene therapy. While another abstract at ASGCT (Lorentzos et al) focuses on his unusual clinical course, this abstract intends to present the findings from IFNγ/IL10/IL17 three-color FluoroSpots. The patient had a predicted in-frame deletion of *DMD* exons 45-48 accompanied by approximately 25-50% endogenous dystrophin expression by western blot and low-level immunofluorescent staining of endogenous dystrophin at the membrane on tissue sections. Despite this, he presented with a phenotype consistent with Duchenne muscular dystrophy (DMD). Peripheral blood mononuclear

cells (PBMCs) were isolated from whole blood at two time points during the course of the cyclical rhabdomyolysis events. The first blood collection occurred between crisis events, while the second occurred during an event. PBMCs were then used in a three-color FluoroSpot where cells were simulated with overlapping 15mer peptides spanning the patient's endogenous dystrophin (including the unique junction) and the transgenic microdystrophin (including unique junctions). Neither time point showed positive IFNγ or IL17 responses to peptides covering the microdystrophin. PBMCs from the first blood draw had a suggestive positive IL17 response to a peptide pool consisting of peptides contained only in the patient's endogenous dystrophin. This response was confirmed and the reactive peptides narrowed down with PBMCs from the second blood draw (see Figure). An additional pool of peptides covering only the patient's endogenous dystrophin was also identified as being weakly IL17 positive with PBMCs from the second blood draw (see Figure). While previous studies have shown patients with DMD to have IFNγ positive ELISpots upon stimulation of PBMCs with dystrophin peptides, we believe this is the first instance of IL17 responses being interrogated and documented in the same. The work described here was funded by Pfizer.



322 The Endosomal Recognition of AAV Genome is Critical for the Development of AAV Capsid-Specific Adaptive Immunity

Wei Zhan[1], Mengtian Cui[2], Yukiko Maeda[3], Jackson Mcgowan[4], Manish Muhuri[5], Nicholas Mustone[6], Jennifer Antonovitch[6], Phillip Tai[7], Katherine Fitzgerald[8], Guangping Gao
[1]University of Massachusetts Medical School, Worcester, MA, [2]Umass Chan Medical School, Worcester, MA, [3]Sanofi, Northborough, MA, [4]UMass Chan, Worcester, MA, [5]Voyager Therapeutics Inc, South Grafton, MA, [6]University of Massachusetts Chan Medical School, Worcester, MA, [7]UMass Chan Medical School, Worcester, Massachusetts, [8]UMass Chan Medical School

Adaptive immunity against the AAV capsid severely hampers vector transduction and prevents redosing, but the molecular mechanisms involved its development are not completely understood. In this study, we found that UNC93B1, a chaperone protein of endosomal toll-like receptors (TLRs)-3, -7/8, and -9, is critically involved in the development of both antibody responses and T cell responses against the AAV capsid. To demonstrate this, wild-type (WT) C57 mice or UNC93B1-knockout (KO) mice were administered 10^{14} vg/kg AAV vectors. Compared to WT mice, UNC93B1-KO mice presented markedly dampened antibody responses, characterized by delayed appearance and lower serum concentration of capsid-specific IgG. In contrast, the cytosolic DNA sensing STING-pathway did not affect the production of anti-capsid IgG. Similarly, UNC93B1-KO mice demonstrated significantly lower levels of capsid-specific T cell responses than WT mice, evidenced by fewer IFN-γ-releasing T cells following stimulation by AAV capsid peptide pool. The involvement of UNC93B1 was conserved across AAV8 and AAV9 and was independent of the encoded protein of the transgene. However, the presence of the AAV genome was required, since using empty capsids could partially, but not completely, reproduce the reduction of adaptive immune responses observed in UNC93B1-KO mice. Overall, we found that the endosomal recognition of AAV genome strongly promoted the development of adaptive immunity against the AAV capsid. As single TLR-7 or TLR-9 KOs did not show strong effects in reducing anti-capsid adaptive immune responses in previous studies, these results suggest that more than one endosomal TLRs, or additional UNC93B1-interacting partners, are involved in AAV genome detection. Furthermore, inhibiting UNC93B1 might be a possible route to reduce capsid-specific adaptive immunity.

323 Efficient Trafficking of AAV Encoded Protein from Hepatocytes to Hepatic Antigen Presenting Cells

**Corresponding Author*

The ability of adeno-associated viral (AAV) vectors to transduce antigen-presenting cells (APCs) remains controversial. To address this, we utilized the LoxP-Stop-LoxP-tdTomato cassette in Ai14 mice in conjunction with a hepatotropic AAV vector expressing Cre recombinase. This approach enabled mapping of AAV transduction patterns in various liver APCs. In AAV-transduced cells, Cre excises the LoxP-flanked stop codon, enabling sustained expression of the fluorescent reporter protein tdTomato (tdT). Using this approach, we previously demonstrated widespread tdT expression in various liver APCs (abstract #1588, ASGCT 2024). Notably, variable levels of tdT fluorescence intensity (tdTmid and tdThi) were observed across APC populations

We hypothesized that these distinct intensities might result from different mechanisms. Here, we intravenously injected Ai14 mice with 2×10^{11} vg/mouse of an AAV8-CMV-Cre vector and evaluated the AAV transduction profile by tracking tdT expression kinetics in liver cells at 2, 4, and 6 weeks post-administration (n=4/timepoint). Consistent with prior findings, two distinct tdT-positive populations emerged: tdTmid and tdThi. The tdTmid population constituted 10–30% of type-2 conventional dendritic cells (cDC2), plasmacytoid dendritic cells (pDCs), and $CD11b^+$ cells (including Kupffer cells/KCs, monocytes and neutrophils), with only 5% of tdTmid cells being type-1 conventional dendritic cells (cDC1). In contrast, the tdThi population predominantly consisted of cDC1 (40%), with 6–10% comprised of cDC2, pDCs, and $CD11b^+$ cells. Additionally, we flow-sorted tdTmid and tdThi cells to analyze recombination events and vector genome copy numbers. Molecular analysis revealed Cre-mediated recombination in tdThi cells, while no recombination was detected in tdTmid cells. Vector genome quantification indicated higher AAV vector load in tdThi cells compared to tdTmid cells.

AAV8 has strong tropism for murine hepatocytes. To further elucidate the source of tdTmid and tdThi signals in APCs, we modified the AAV-CMV-Cre vector by incorporating four copies of liver-specific miR-122 target sequences (miR-122T) into its 3′ untranslated region (UTR). MiR-122, a liver-enriched microRNA, binds to complementary sequences (miR-122T) in the 3′ UTR, leading to mRNA degradation in hepatocytes. Intravenous administration of the modified vector reduced tdT expression in hepatocytes from over 95% to less than 5% at all time points in Ai14 mice. This intervention completely eliminated the tdTmid APC population, while significantly reducing the proportion of tdThi APCs. However, the percentage of $CD11b^+$ cells with tdThi expression remained largely unchanged. Together with molecular evidence showing that tdTmid APCs lacked Cre recombination events, while tdThi APCs showed recombination, these findings suggest that tdTmid signals predominantly result from the trafficking of hepatocyte-derived tdT, whereas tdThi arise from hepatocyte-released Cre protein or mRNA. However, AAV may directly transduce a subset of $CD11b^+$ APCs, which we identified as KCs.

Altogether, our results demonstrate efficient trafficking of functional transgene product from hepatocytes to diverse APCs in the liver, resulting in a spectrum of antigen expression among hepatic APCs, most of which does not require direct transduction but likely plays a central role in the orchestration of antigen-dose dependent T cell priming and tolerance induction within the liver microenvironment.

CMC for AAV Vectors

324 Diving Deeper: Using a SYBR Gold Capsid Ejection Assay as an Orthogonal Method of Measuring Potency and VP1 Deamidation in AAV Drug Product Samples

Michaela Duffy[1], Alex Meola[1], Kelly Walsh[1], Amy You[2], Ifeyinwa Iwuchukwu[3]
[1]OXB, Bedford, MA, [2]Oxford Biomedica, Bedford, MA, [3]Oxford Biomedica Solutions, Bedford, MA

A recent paradigm shift in the gene therapy industry has placed significant importance on the accurate determination of viral vector potency as a key measure of both product quality and efficiency. The idea that potency should be a top priority during production is gaining traction; however, there are several challenges that come with developing a robust potency assay. The field currently faces a critical gap in reliable orthogonal methods to assess potency in a fast, high-throughput manner, leaving scientists to rely on costly, time-consuming, traditional cell-based assay methods, often with wide variability. Though an orthogonal approach may not replace conventional potency methods, it may compliment them by providing quick, preliminary results to aid in go or no-go decisions. This is especially useful when making important decisions surrounding process development and drug product formulation screening.

In our work, we have discovered a direct correlation between initial fluorescence readings- using a SYBR gold assay to detect DNA leakage- and significant potency loss in AAV drug product samples stored at 25°C and 40°C over time. This correlation has been validated across multiple independent studies, demonstrating robustness and consistency. Through our analyses, we also found that initial fluorescence directly correlates with VP1 deamidation, which we hypothesize to be an additional indicator of potency. These small changes in genome integrity may not be detected using traditional viral genome titer assays but are easily identified thanks to the sensitivity of the SYBR gold capsid ejection method. Further, we have demonstrated a linkage between increasing hydrophobicity using hydrophobic interaction chromatography with increased SYBR gold fluorescence. This powerful analytical method provides us with even more insight as to what is occurring at the capsid level as it undergoes thermal stress.

By deriving an equation linking initial fluorescence to relative potency and VP1 deamidation, we introduce a rapid and practical method for assessing drug product potency and relevant post-translational modifications without significant cost or lengthy turnaround times.

325 The Need for an Unbiased Assay to Detect and Quantify Replication Competent AAV in Clinical Vector Products

**Corresponding Author*

Replication-competent AAVs (rcAAV) are gene therapy product-related impurities that could have associated safety risks for patients. rcAAVs are conventionally detected in cell-based assays consisting of successive rounds of amplification in the presence of an adenovirus with a qPCR readout on viral gene sequences. The absence of rcAAV detection in 1E+08 vg has generally been used as an acceptance criterion.

Our data show that this cell-based method can generate significantly different results between testing facilities using different assay protocols. Moreover, we show that positive or negative results are highly dependent on the capacity of serotypes to infect the permissive cell line in vitro, which could be quite different from what is observed in vivo.

An analytical method that allows the unbiased detection and quantification of rcAAVs is thus needed. We have developed a method based on a multiplex digital PCR (dPCR) that targets 3 junctions specific to rcAAV genomes: ITR-Rep, ITR-Cap and Rep-Cap. It accounts for the presence of potential exogenous sequences and it takes advantage of the partitioning of the dPCR to isolate particles containing triple positive genomes. Several recombinant AAV vector batches of various serotypes, positive or negative for rcAAV in the cell-based assay showed similarly extremely low levels of triple positive genomes (less than 0.00008% of genomes quantified by qPCR) in comparison to wild type (wt)AAV. Interestingly the latter showed that only 3% to 7% of their genomes were triple positive. Results were independent of the HEK293/transfection manufacturing protocol. However, no

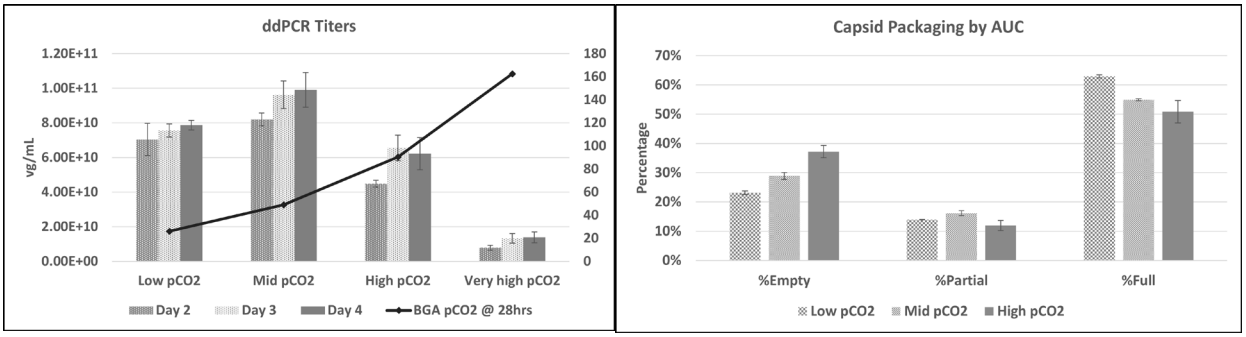
triple positive entities were found in baculovirus-generated preparations likely due to the modifications in constructs of the vector system.

Our data suggest that there are likely no HEK293/transfection-derived vector AAV preparations devoid of rcAAV genomes. In this context our efforts constitute the first step toward the goal of changing the way rcAAVs are detected and quantified. More results from other sponsors using AAV vectors are needed to solidify our preliminary data set and to engage in a field-wide discussion, including regulators, on how to generate specifications and acceptance criteria for this novel analytical method. This will help to better reflect on and provide mitigation strategies for potential safety risks associated with rcAAVs until means to eliminate them from vector batches have been identified.

326 pCO_2 Modulated Control of Recombinant AAV Production and Capsid Quality via Regulation of Pathways Linked to Rep and Cap Protein Expression

Nipun Goel[1], Madhuresh Sumit[2], Jeong Lee[3], Bruno Figueroa[4], Daniel Furey, Rachel Sun
[1]Genzyme, a Sanofi Company, Acton, MA, [2]Sanofi US Services Inc, Waltham, [3]sanofi, Waltham, MA, [4]Sanofi R&D Global CMC Development, Waltham, MA

Recombinant adeno-associated virus (rAAV)-based gene therapies have shown promise as a one-time treatment to cure genetic diseases by delivering the encapsidated vector genome as therapeutic agents. To produce cost-effective, safe, and potent therapeutics, it is essential to optimize cell culture processes for rAAV production, with a focus on controlling capsid quality (full, empty, and partial capsids). This requires a comprehensive understanding of process parameters and their impact on rAAV productivity and quality. In this study, we identified the partial pressure of carbon dioxide (pCO2) as a regulator in upstream processes that significantly affects AAV titer as well as capsid quality in producer cell lines (PCLs). To investigate this further, we maintained different levels of pCO2 in separate bioreactors for the first 48 hours of AAV production. Analysis of harvest samples revealed an optimal range near the lower end of the investigated pCO2 range, as determined by droplet digital PCR (ddPCR). Purified harvest samples from these experiments were analyzed for capsid quality by Analytical Ultra-Centrifugation (AUC), which indicated a correlation between an increase in pCO2 level and a decrease in % full capsid. Western blot analysis was also performed on the purified samples to analyze Rep and Cap protein expression, which are linked directly to AAV productivity. The results showed the highest expression of Rep and Cap proteins at the lowest pCO2 levels, which suggests an underlying mechanism linking pCO2 levels with Rep and Cap protein expression and subsequent modulation of AAV productivity. In conclusion, our work across different cell lines and AAV serotypes demonstrated that PCLs benefit from a lowpCO2 range, with the timing and levels contributing to high titers and good capsid quality. Application of these insights to AAV manufacturing process development can significantly reduce the cost of goods manufactured (COGM) and ensure high % full capsid to reduce the risk of high levels of empty and partial capsids being delivered to the patients.



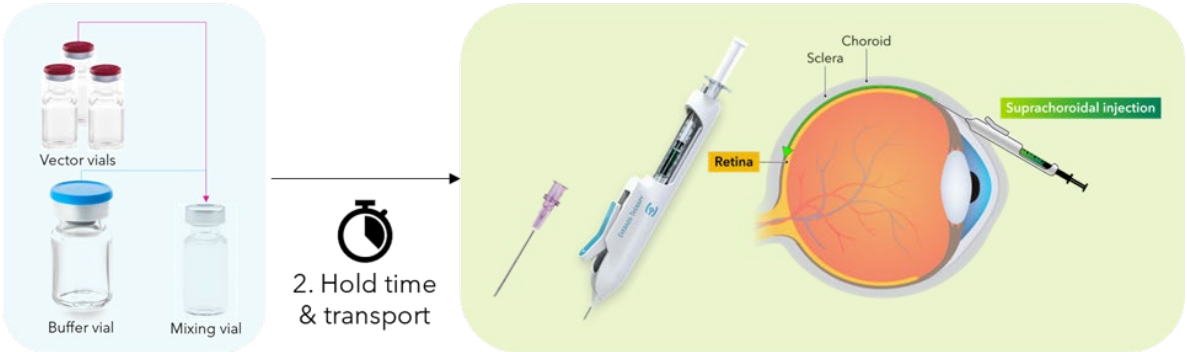
327 Stability of AAV2 Vector During Dose Preparation and Suprachoroidal Injection Using the Everads Injector

Robert Damitz[1], Kiley Coates[2], Rizalyn Golnar[3], Rachel Eclov[1], Hagay Drori[4], Wayne Yount[5]
[1]Kriya Therapeutics, Morrisville, NC, [2]Kriya Therapeutics, Durham, NC, [3]Kriya Therapeutics, Inc., Durham, NC, [4]Everads Therapy, Tel Aviv, HaMerkaz, Israel, [5]Kriya Therapeutics, Redwood City, CA

Kriya is pursuing a one-time AAV2-based gene therapy designed to block the complement pathway and reduce retinal lesion growth characteristic of geographic atrophy secondary to age-related macular degeneration. This therapy is to be delivered by suprachoroidal injection using a specialized device to better target the affected retinal tissues. As there is limited capacity for injection with any ophthalmic route of administration, drug products often must be diluted to prepare target doses. Ideally, dose preparations would occur as close to injection as possible. In practice, there is often a lag time between dose preparation in pharmacy and administration in clinic. Further, lubricants used in common syringes may challenge the strict subvisible particles safety limits for ophthalmic injections. It is thus critical to monitor product quality at all dose preparation and administration ranges proposed to ensure the doses patients receive are accurate, safe, and efficacious. A thorough in-use stability study was performed to establish stability of dose preparations and compatibility of our vectors with components to be used for preparation and administration.

A bracketed study design evaluated concentrations ranging from $1x10^{11}$ to $1x10^{13}$ vg/mL. The first part of the study assessed the accuracy and stability of dilutions prepared with lubricant-free syringes at refrigerated and room temperatures for up to 20 hours. The second part of the study evaluated loading and priming the Everads Injector, a novel suprachoroidal delivery device, with dose preparations stressed similarly to the first part of the study and then holding those doses for an additional 4 hours at room temperature before completing mock injections. Stability and compatibility were determined by comparing select product quality attributes (appearance, subvisible particles, vector genome titer, capsid titer, protein expression) to relevant controls or unstressed samples.

Concentrations of the high and low dose preparations were within expected variability of targets demonstrating target doses can be prepared accurately using syringe graduations. Mock doses achieved subvisible particle concentrations below USP <789> limits when 5µm filtered needles were used to extract prepared doses from compounding vials. No other notable product quality impact was observed from the use of filtered needles against unfiltered needles establishing their safety for use in clinical administration. No notable product quality impacts against respective controls were observed from the highest and lowest mock doses at the most strenuous conditions and durations evaluated. These results establish the stability of prepared dilutions for up to 20 hours at room temperature and stability of primed doses in delivery devices for up to 4 hours at room temperature allowing for flexibility between pharmacy and clinic. They also demonstrate that AAV2 vector is compatible with the components proposed (lubricant-free syringes and Everads Injector) to prepare and administer doses by suprachoroidal injection.



328 Development of a Flexible High Yielding, High Performing Process for Manufacturing of AFTX-201, a Novel Investigational AAV Gene Therapy for Treatment of BAG3 Dilated Cardiomyopathy

Michael DiBiasio-white[1]*, Matthew Bennett[2], Patrick Bresnahan[2], Rong Cong[2], Hanna Czeladko[2], Spencer Fielder[2], Graham Lilley[2], Shahrzad Parker[2], Lauren Sargent, Jordan Shufro[2], **Matt Edwards[3]***, Robert May[1]
[1]Affinia Therapeutics, Inc., Waltham, Massachusetts, [2]Affinia Therapeutics, Waltham, MA, [3]Affinia Therapeutics, Littleton, MA
**Corresponding Author*

Dilated cardiomyopathy (DCM) is defined as dilation and systolic impairment of the left ventricle and is the most common cause of heart failure (HF) in the young and most frequent indication for heart transplantation. More than 50% of patients with DCM have a genetic predisposition to the disease. B-cell lymphoma 2 (Bcl-2) associated anthanogene-3 (BAG3), a cochaperone that interacts with members of the heat shock protein (HSP) family, has been identified as a DCM-causing gene. BAG3-DCM represents a significant unmet medical need in this patient population with rapidly progressive cardiac dysfunction, and for whom no treatments targeting the underlying mechanism of disease exist. We are developing AFTX-201, an AAV-mediated gene replacement therapy to treat BAG3-associated DCM using a novel cardiotropic capsid with an improved safety profile.

The development of AFTX-201 required a flexible and scalable manufacturing process capable of handling diverse capsid-cargo combinations. To achieve this, we utilized Design of Experiment (DoE) studies to optimize the upstream process, resulting in high yields of >3e15 vg/L with >25% full particles at a 50L scale. To accommodate these yields, we developed a downstream process incorporating single-use chromatographic clarification, which increased throughput, reduced contaminants, and simplified setup. Affinity purification was optimized by focusing on capsid loading parameters rather than traditional viral genome loading, ensuring proper column sizing, reducing costs, and improving purity. A cesium chloride (CsCl) ultracentrifugation step was employed to achieve >90% enrichment of full particles. The process was successfully transferred to our CDMO partner, Forge Biologics, for toxicology material production, yielding high-quality vector with minimal host cell DNA, host cell proteins, and other common contaminants. The product has shown stability for over 6 months, with ongoing monitoring for extended time points. Additionally, the high yields enabled a reduction in Toxicology and Clinical lot production scale from 250L to 50L, resulting in significant cost savings without compromising quality.

329 Simplifying AAV Supply Chains: Demonstrating Equivalence of Long-Term Stability at -20 °C and -80 °C

Kiley Coates[1], Robert Damitz[2], Catherine Dial[2], Wayne Yount[3]
[1]Kriya Therapeutics, Durham, NC, [2]Kriya Therapeutics, Morrisville, NC, [3]Kriya Therapeutics, Redwood City, CA

Most AAV products use the ultra-cold chain (≤ -60 °C) for long-term storage and distribution. However, the ultra-cold chain is expensive, burdensome, and requires specialized equipment and dry ice for shipments. While this has been accepted for ultra-rare diseases where AAV has been successfully utilized so far, Kriya is pursuing AAV-based gene therapies for prevalent diseases with larger patient populations. Simplifying the supply chain and reducing the cost of goods is necessary to bring gene therapies to a broader population. However, storing AAV products cold (-15 °C to -25 °C) raises concerns about product instability. These temperatures may be above the systems' glass transition temperatures where products may not be completely frozen which could lead to degradation not observed at lower temperatures. We sought to investigate this by evaluating comparative long-term stability of our investigational products at cold and ultra-cold frozen conditions.

Engineering lots of multiple drug products comprised of various AAV serotypes were placed on stability at multiple frozen conditions (≤ -65 °C, -20 °C) as well as multiple stress conditions (5 °C, room temperature) with appropriately spaced durations. Select product quality attributes including appearance, subvisible particles, genome titer, capsid titer, aggregation, capsid purity, genome integrity, and protein expression were evaluated at each duration using stability-indicating analytical methods. Product quality differences were assessed across conditions to

determine if the temperature of frozen storage had a significant effect on product stability. Durations of stability studies ranged from 3 months to over 18 months at the time of this writing, and all studies are ongoing.

Although product quality was impacted from stress conditions as expected (i.e. aggregation, protein modifications, losses of potency), no significant product quality changes have been observed at frozen conditions across all products. Further, no significant differences in any product quality attribute have been observed when comparing cold and ultra-cold stability results. These results suggest that -20 °C may indeed be a viable long-term storage condition for AAV products which could greatly simplify distribution and reduce the cost of next-generation gene therapies.

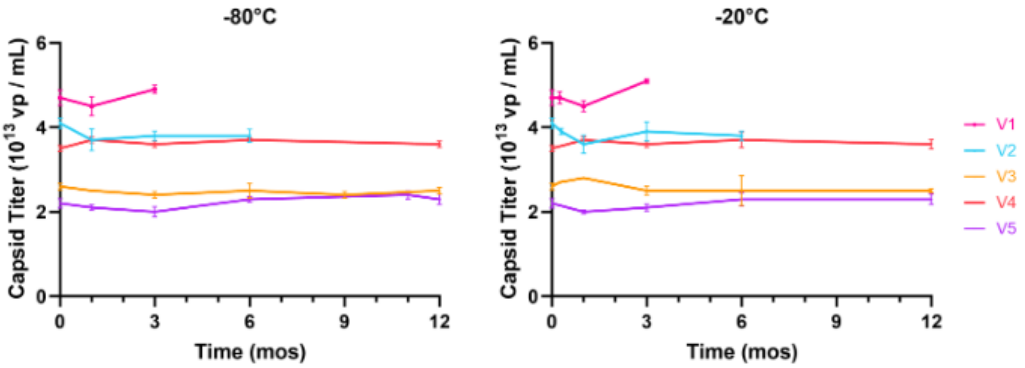


Figure 1: Capsid titer of different investigational AAV products stored at -80 °C and -20 °C over time.

330 Identifying AAV9 Degradation Pathways Caused by Stresses Encountered During the Product Lifecycle

Catherine Dial[1], Robert Damitz[1], Victoria Dowling[2], Wayne Yount[2]
[1]Kriya Therapeutics, Morrisville, NC, [2]Kriya Therapeutics, Redwood City, CA

Kriya Therapeutics Inc. is a fully integrated biopharmaceutical company developing gene therapies to address common diseases. AAV gene therapies are comprised of capsid (protein) and vector genome (DNA), both of which have multifaceted degradation pathways from stresses encountered during the product lifecycle that would be expected to impact product quality. To increase our understanding of these degradation pathways and resulting impact on potency, we completed a forced degradation study of AAV9.

AAV9 vector was subjected to physical and chemical stresses experienced during the product lifecycle, including acidic (pH 2, 4), alkaline (pH 8.5, 10), thermal (40°C), photooxidative (~2000 lux), chemical oxidative (1 – 3% H_2O_2), shear (up to 1.8 Pa), and room temperature control, for various durations. Vector quality attributes evaluated included appearance, protein expression (cell-based assay), vector genome titer (ddPCR), capsid titer (Gyros), aggregation (SEC, DLS, light obscuration), capsid charge distribution (AEX), capsid purity (CE-SDS), and genome integrity (CE), which we have previously shown to be impacted by stress.

Multiple distinct degradation pathways were observed from different stresses. Increased 60 – 2000 nm aggregate populations were observed after exposure to pH 2.0 and shear stress, while increased subvisible particle concentrations (≥ 2 µm) were observed after exposure to pH 10 and 3% hydrogen peroxide. Decreased capsid and genome titers were observed with increased vector aggregation. Chemical modifications of the capsid increased with exposure to alkaline (pH 10 and 8.5), chemical oxidation (1000 ppm and 3% H2O2) and thermal stresses, while capsid degradation resulted from exposure to pH 2, pH 10, and 3% H_2O_2. Stress conditions also impacted vector genome stability, with vector genome degradation resulting from exposure to pH 2, 1000 ppm and 3% H_2O_2 and

progressive genome ejection from capsids occurring from shear stress. Reductions of potency (protein expression) were also observed to different extents when these various degradation pathways occurred.

This forced degradation study demonstrated that stresses experienced during the product lifecycle can cause distinct product degradation pathways for both vector genome and capsid proteins. These AAV9 degradation pathways also reduced potency. Investigating product degradation early in development can better inform exposure limits and product control strategies to maximize product quality.

Duchenne muscular dystrophy (DMD) is a genetic disorder that causes muscle degeneration due to the absence of dystrophin protein. This leads to a continuous cycle of muscle degeneration and regeneration, eventually resulting in muscle weakness and atrophy. For many years, there was no effective cure for DMD. However, exon-skipping therapy, which uses antisense oligonucleotide (ASO) drugs to restore dystrophin expression, has recently gained significant attention. To date, the U.S. Food and Drug Administration (FDA) has approved four exon-skipping ASO drugs (eteplirsen, gorodilsen, biltrasen, and casimelsen) for the treatment of DMD. In addition, new exon-skipping drugs are still being developed. ASOs based on phosphorodiamidate morpholino oligomers (PMOs) are neutrally charged and stable, minimizing immune activation and toxicity, making them ideal for targeted exon-skipping therapy. However, significant challenges remain, including the short retention time of PMOs in the bloodstream and their limited delivery to the heart and diaphragm muscles. To overcome these challenges, PMOs were modified with lipids or peptides to enhance their blood retention and tissue permeability. Despite these advancements, the fundamental mechanism by which PMOs are delivered to skeletal muscle tissue remains unclear.

In this experiment, we aimed to investigate how PMOs are taken up in skeletal muscle. To achieve this, we first generated transgenic mice capable of monitoring exon skipping *in vivo*. Using these mice, we studied the relationship between exercise and PMO uptake. Specifically, PMO was administered to mice subjected to low-intensity eccentric contraction (ECC) training, significantly increasing exon-skipping efficiency. To understand the underlying mechanisms, we performed RNA sequencing (RNA-seq) using the muscles that had undergone low-intensity ECC training. The results identified several genes associated with inflammatory cytokines, indicating that inflammatory cells might contribute to the uptake of PMOs in skeletal muscles. To support this hypothesis, PMOs were systemically administered to DMD model mice in which the number of inflammatory cells had been reduced through TNFα inhibition. As a result, the efficiency of exon skipping was significantly reduced. Additionally, when PMOs were introduced into cultured monocytes and subsequently administered to DMD model mice, exon skipping was successfully induced in the muscles of these mice.

These findings suggest that some of the administered PMOs may be delivered to skeletal muscles through inflammatory cells. We will further investigate the regulatory mechanism by which PMOs are transported to skeletal muscle.

332 Alpha Synuclein Lowering by miRNA-Based AAV Gene Therapy for Synucleinopathies: Proof of Concept and Biodistribution Studies in Rodent Disease Models and Non-Human Primates

Seyda Acar-Broekmans[1], Meriem Bourajjaj[2], Charlot van Rooijen, Rhode Erbrink[2], Rudy de Laat, Mercedes Valls[3], Astrid Valles-Sanchez[4]
[1]UniQure Inc., Lexington, MA, [2]UniQure, Amsterdam, Noord-Holland, Netherlands, [3]UniQure Inc., Amsterdam, Netherlands, [4]UniQure, Amsterdam, NH, Netherlands

Synucleinopathies are clinically and pathologically heterogenous neurodegenerative disorders characterized by aggregation of alpha-synuclein protein (α-syn), encoded by the SNCA (Synuclein Alpha) gene. Pathological α-syn aggregates can be found in neurons and glia. Synucleinopathies are divided into two main groups: Lewy body (LB) diseases - Parkinson's Disease (PD) and Lewy Body Dementia - and Multiple System Atrophy (MSA). In PD, LB pathology originates in the brainstem and extends to midbrain and cortical regions with disease progression, in parallel with neurodegeneration of nigro-striatal dopaminergic circuits and other neurotransmitter systems. In contrast, MSA is characterized mainly by glial cytoplasmic inclusions (GCIs) in oligodendrocytes, with more extensive neuropathology including the olivopontocerebellar system. Only symptomatic therapies exist for PD. For MSA, symptomatic therapies are hardly effective. In both cases, there is a need for the development of disease-modifying strategies. Our hypothesis for a disease-modifying therapy is that lowering α-syn protein levels in relevant brain regions, i.e. putamen and midbrain, may reduce aggregation and degeneration, ultimately delaying disease progression.

We are developing an adeno-associated virus (AAV) gene therapy to deliver SNCA-targeting microRNAs (miSNCAs) engineered to decrease α-syn mRNA and protein levels. Here, we evaluate the potential phenotypic improvement by AAV5-miSNCA in two proof-of-concept studies in rodent PD and MSA models. Moreover, biodistribution and preliminary safety were evaluated in non-human primates.

In the PD study, adult rats received AAV1/2 overexpressing human A53T-α-synuclein ipsilaterally in the substantia nigra, at a dose known to cause neurodegeneration and PD-like motor phenotypes. Two weeks after AAV1/2-hA53T-α-synuclein administration, three different AAV5-miSNCA candidates were injected in the substantia nigra. All tested AAV5-miSNCA candidates showed correct microRNA processing and target engagement at both mRNA and protein levels. Moreover, dopamine metabolite deficiencies and motor deficits in hA53T-α-syn rats were corrected by AAV5-miSNCAs. Additionally, dopaminergic cell loss was rescued in the miSNCA-treated groups as compared to controls.

In the MSA study, a well characterized transgenic mouse model (MBP29) overexpressing wildtype human SNCA under the MBP promoter was used. Three different doses of our lead AAV5-miSNCA were administered at 2 months of age. At 9 months, dose-dependent target engagement at both mRNA and protein levels was observed. Moreover, myelin deficits were corrected, along with increased survival rate, in a dose-dependent manner.

Finally, we show safe and efficient delivery of AAV-miSNCA in non-human primates after MRI-guided intra-putamen bilateral injections. Furthermore, dose-dependent target engagement in putamen and midbrain were shown at both mRNA and protein levels. These results support the potential therapeutic value of α-syn RNAi-based gene therapy for disease modification in both PD and MSA.

333 ADAR-Mediated RNA Editing of *SLC10A1* (NTCP) as a Therapeutic Approach to Reduce Liver Bile Acid Re-Uptake in Cholestatic Diseases

Seda Yilmaz-Elis[1], Nicole Cnubben[2], Wouter Beumer[3], Francesco De Chiara[2], Marko Potman[2], Zlata Novalic[2], Tsinatkeab Hailu[4], van de Giessen Jeroen[2], Eva Coll[4], Tram Anh Do[4], Tessa Schoon[2], Marguerite Toros[1], Isabelle Bolt[5], Stan van de Graaf[5], Sjef de Kimpe[2], **Gerard Platenburg**[6]
[1]ProQR Therapeutics, Leiden, Noord-Holland, Netherlands, [2]ProQR Therapeutics, Leiden, Netherlands, [3]ProQR Therapeutics NV, NETHERLANDS, [4]ProQR Therapeutics, Leiden, Zuid-Holland, Netherlands, [5]Tytgat Institute for

Liver and Intestinal Research, Amsterdam UMC, Amsterdam, Netherlands, [6]ProQR Therapeutics B.V., Leiden, Zuid-Holland, Netherlands

Bile acid homeostasis is crucial for liver function, and the Sodium Taurocholate Co-Transporting Polypeptide (NTCP, *SLC10A1* gene) is integral in the hepatic re-uptake of bile acids. Dysregulation of this process, leading to toxic bile acid build up, is implicated in liver cholestatic diseases such as Primary Sclerosing Cholangitis (PSC) and Biliary Atresia (BA). These conditions currently lack effective therapies, leaving a significant unmet medical need. Innovative therapeutic strategies, grounded in human genetics, could selectively lower NTCP's function in bile acid re-uptake without affecting its other cellular roles. Sufficient NTCP modulation leading to a 2-fold bile acid increase in plasma, is expected to have a therapeutic effect. Axiomer, an RNA editing platform, uses chemically modified editing oligonucleotides (EONs) complementary to the *SLC10A1* mRNA to recruit and guide endogenous Adenosine Deaminase Acting on RNA (ADAR) to perform targeted A-to-I editing on the double stranded structure. This results in a single amino acid change in the protein sequence (NTCP Q68R), enabling alteration of the bile acid re-uptake function in NTCP. Here we present preclinical proof of concept data of the approach and the efficiency of Axiomer EONs in *in vitro* and *in vivo* studies.

In-silico 3D structural modelling of the NTCP Q68R variant demonstrated disruption of hydrogen bonds and contacts for Na+ binding which are essential for bile acid transport. In *in vitro* assessment, a plasmid expressed NTCP Q68R variant demonstrated a 7-fold reduction in bile acid uptake vs. wild-type with no impact on protein expression nor localization. EONs targeting *SLC10A1* RNA demonstrated a 20% RNA editing efficiency *in vitro*, and a dose-dependent bile acids uptake inhibition (40% decrease with the 50nM dose vs. control to a near complete inhibition with the 100nM dose vs. control).

In follow-up *in vivo* studies, ADAR mediated editing of NTCP resulted in a mean editing efficiency of 13.3% in humanized liver mice and 18.3% in NHP respectively (reaching up to 24% in NHPs). These EONs led to a mean change of 4.4-fold in plasma bile acids, above the 2-fold change therapeutic threshold. Correlation between plasma bile acids and EONs editing efficiency (linear regression $R_2 = 0.51$) was also reported. The observed change in plasma bile acids levels was associated with a change in bile acids profile, from an unconjugated (73%) / conjugated (27%) ratio to an unconjugated (13%) / conjugated (87%) ratio post treatment in NHPs. In safety analysis, EONs confirmed class safety, with no hepatotoxicity or immunostimulatory score.

ADAR-mediated editing of NTCP is a promising approach to address unmet medical needs in cholestatic diseases, such as PSC and BA. By decreasing bile acid re-uptake in the liver and increasing plasma bile acids leading to compensatory mechanism limiting bile acid production, the technology can potentially alleviate the bile acid toxicity in the liver. A clinical candidate, AX-0810, using GalNAc-mediated delivery and with enhanced potency (reaching up to 57% editing, representing a 5.5-fold increase over early generation) and stability profile, is being investigated in longer term *in vivo* studies and will be further investigated in clinical trials starting this year.

334 A First-in-Human Double-Blind, Placebo-Controlled Single and Multiple Ascending Dose Study (SAD, MAD) in Healthy Volunteers to Evaluate the Safety and Tolerability of an Investigational Antisense Oligonucleotide Therapy (CMP-CPS-001) for the Treatment of Urea Cycle Diseases (UCDs): Interim Safety Readout

Yuri Maricich[1]*, Daniel Tardiff[1], Gloria Wong[2], Elizabeth Brown[1], Ann Barbier[1], David Bumcrot[1]
[1]CAMP4 Therapeutics, Cambridge, MA, [2]Nucleus Network, Herston, Queensland, Australia
**Corresponding Author*

Introduction
UCDs are a group of 8 rare genetic diseases, each caused by a distinct autosomal recessive or X-linked defect in one of the 6 enzymes or 2 transporters in the urea cycle. The urea cycle is responsible for elimination of the noxious metabolite ammonia. The most common clinical characteristic of UCDs is episodes of hyperammonemia, triggered by increased protein intake or protein catabolism (e.g., during infection or overexertion). Symptoms include irritability, headache, vomiting, and ataxia in milder cases. Seizures, encephalopathy, coma, and death can occur in cases with ammonia levels >200 μmol/L (adult levels). Symptomatic treatment is comprised of reducing nitrogen

production (via a strict low-protein diet) and augmentation of nitrogen elimination (nitrogen scavengers) on a chronic basis. Liver transplantation is a treatment option, however it is usually limited to early-onset cases and comes with its own morbidity and mortality risks. Several approaches to correct or compensate for the underlying causes are in development, including gene and mRNA therapies for OTC-deficiency. CMP-CPS-001 is an antisense oligonucleotide that targets a regulatory RNA of the gene encoding carbamoyl phosphate synthetase 1 (CPS1), the initial and rate-limiting enzyme responsible for catalyzing ammonia to carbamoyl phosphate and coordination of the cycle's regulatory function across downstream enzymes. Thus, CMP-CPS-001 is a new and differentiated therapeutic strategy to restore urea cycle function for OTC deficiency and potentially other UCDs.

Methods
Phase 1 study CPS-101 evaluates the effect of CMP-CPS-001 administered subcutaneously in healthy participants in 2 parts (NCT06247670). Part A is a SAD with 4 sequential cohorts of 12 participants (3:1 ratio of active drug:placebo). After dosing, each participant was followed for 6 weeks. Part B is a MAD with 4 cohorts of 12 participants (same 3:1 ratio as Part A). Participants in Part B will receive 3 monthly doses of study drug with a 56-day follow-up post last dose. Part A and Part B include measures of ureagenesis via isotope-labeling as a pharmacodynamic marker to be reported in the future. Part A has been completed and blinded interim results are presented here. Part B is ongoing.

Results
Part A (SAD) enrolled 48 individuals (36 active:12 placebo) across 4 dose cohorts of 0.2, 0.6, 1.8, or 4.0 mg/kg . Twenty males and 28 females, with a mean age of 32.6 years (range 18-55) participated. A total of 40 treatment emergent adverse events (TEAEs) were observed, with 22 participants (46%) reporting at least one TEAE. All TEAEs were Grade 1 (mild) or Grade 2 (moderate). No treatment-emergent serious adverse events (SAEs) were observed. No participant discontinued the study due to an adverse event. The top 2 most common TEAEs across SAD cohorts were headache (N=6) and nausea (N=4). Four participants experienced TEAEs related to injection/administration at the site of injection (2 pain, 1 injection site reaction, 1 injection site erythema), all of which recovered/resolved. No clinically significant liver function or thrombocytopenia abnormalities were observed. CMP-CPS-001 was well tolerated and there is no indication of a maximum tolerated dose at the dose levels tested.

Conclusions
Overall single doses of CMP-CPS-001 from 0.2 mg/kg to 4.0 mg/kg were well tolerated. No SAEs were observed. The majority of TEAEs were Grades 1 and 2.

335 Targeting Regulatory RNAs with Antisense Oligonucleotides for the Potential Treatment of SYNGAP1-Related Disorders

Daniel Tardiff, Ali Al Abdullatif, Yeliz Yuva-Aydemir, Dale Guenther, Brynn Akerberg, Abeer Almutairy, Chelsea Bolmer, Eric Coughlin, Simrin Kapoor, Stephanie Lefebvre, Yuting Liu, Salome Manska, Andrew Masteller, Cécile Mathieu, Bryan Matthews, Shama Pilanker, Gokul Ramaswami, Preeti Sathe, Cynthia Smith, Scott Waldron, Brianna Unda, Shubh Roy, Alla Sigova, David Bumcrot
CAMP4 Therapeutics, Cambridge, MA

Regulatory RNAs (regRNAs) are long, short-lived, noncoding RNAs expressed from enhancers and promoters that act locally to regulate gene expression. This regulation is accomplished through the ability of regRNAs to bind transcription factors and increase their local concentration near a gene's promoter and enhancer elements. Our RAP Platformä enables the identification of regRNAs and antisense oligonucleotides (ASOs) targeting these regRNAs to modulate target gene expression. Here, we describe the development ASOs that target regRNAs of *SYNGAP1* to potentially restore its expression in patients with mutations that cause SYNGAP1 haploinsufficiency.

Truncation and loss of function mutations in the *SYNGAP1* gene cause SYNGAP1-related disorders, a group of devastating neurodevelopmental conditions characterized by a constellation of burdensome phenotypes, including intellectual disability, severe behavioral problems, seizures, motor abnormalities, and impaired communication. Mutations result in loss of expression of the affected allele, resulting in haploinsufficiency. Insufficient levels of SYNGAP1 in postsynaptic terminals results in increased insertion of AMPA receptor at the post-synaptic membrane

and increases neuronal activity. Hyperexcitability throughout development and life results in the aforementioned phenotypes.

Increasing SYNGAP1 protein levels in amounts sufficient to yield a therapeutic benefit is a potential therapeutic strategy for SYNGAP1-related disorders. We employed our RAP Platform to identify ASOs that target a *SYNGAP1* regRNA to increase *SYNGAP1* transcription and protein levels in multiple cell types, including patient-derived neurons. The impact of increased SYNGAP1 protein levels on SYNGAP1 haploinsufficiency is explored. A lead ASO was administered to a humanized SYNGAP1^{hu} knock-in/knock-out mouse through intracerebroventricular injection and shown to increase SYNGAP1 protein levels by up to ~2-fold. Critically, intrathecal administration of this lead ASO to cynomolgus monkeys resulted in a significant ~1.5-fold increase in SYNGAP1 protein.

These data demonstrate that targeting a *SYNGAP1* regRNA with an ASO increases *SYNGAP1* transcription *in vitro* and *in vivo*. Importantly, administration of the ASO by a clinical route of administration in these animal studies demonstrated a marked increase SYNGAP1 protein level, supporting the continued advancement of this program as a potential treatment for patients with SYNGAP1 haploinsufficiency.

336 Antisense oligonucleotides targeting toxic CGG-repeat expansion in primary ovarian insufficiency due to Fragile X premutation

Liubin Yang[1]*, Meaghan Donahue[2], Hugh Taylor[3], Yong-hui Jiang[4]
[1]Yale University, New Haven, CT, [2]Yale University, [3]Yale School of Medicine, New Haven, [4]Yale University School of Medicine, New Haven, CT
**Corresponding Author*

A common cause of primary ovarian insufficiency (POI) is Fragile X premutation (FXPOI), a genetic condition found in 1 in 148-291 women. This condition is caused by an expansion of the CGG trinucleotide repeat in the 5' untranslated region of the fragile X messenger ribonucleoprotein 1 (*FMR1*) gene, leading to toxic CGG-RNA and aberrant poly-glycine (polyG) protein buildup. FXPOI not only causes early menopause, but also infertility, increased risk of osteoporosis, cardiovascular disease, dementia, and adult-onset debilitating neurological disorders. Currently, there is no targeted treatment for individuals with FXPOI.

To address this unmet need, we designed three antisense oligonucleotides (ASOs) with varying chemistries and lengths. Together with previously published ASOs, these ASOs were tested in human granulosa cells (KGN line) that overexpressed 99 CGG repeats tagged with green fluorescent protein (GFP). Treatment significantly reduced CGG-GFP RNA and protein levels, as shown by qPCR, immunofluorescence, and flow cytometry. We also established primary cultures from human granulose cells isolated from the follicular fluid of patients undergoing assisted reproductive technology. After treating the cells with ASOs, we observed reduced CGG-protein levels. Notably, ASO treatment decreased oxidative stress (measured by MitoSox) without altering estradiol hormone production. To assess off-target effects, we performed bulk RNA-seq on treated versus untreated and control primary human granulosa cells. Differential gene expression analysis is ongoing.

For *in vivo* studies, we have a knock-in mouse that harbors 117 CGG repeats in the endogenous *FMR1* 5'UTR region. Preliminary data show that Cy3-labeled ASOs persist in ovarian tissue for several days after intraovarian injections and ongoing studies will determine the efficacy of ASO treatment in ovarian function including ovulation.

In conclusion, we have developed a novel RNA-based intraovarian therapy that directly targets the genetic cause of FXPOI. Our ultimate goal is to translate these findings into clinical trials, offering a much-needed gene-based therapeutic strategy for women with Fragile X premutation, paving the way for similar gene therapies in reproductive medicine.

337 Targeting Regulatory RNAs with Antisense Oligonucleotides for the Potential Treatment of Urea Cycle Disorders

Daniel Tardiff, Yun Joon Jung, Henry Moukheiber, Brynn Akerberg, Chelsea Bolmer, Eric Coughlin, Keerthana Gnanapradeepan, Dale Guenther, Yuchun Guo, Jiaqi Huang, Simrin Kapoor, Stephanie Lefebvre, Salome Manska, Bryan Matthews, Shama Pilanker, Cynthia Smith, Scott Waldron, Jenna Williams, Shubh Roy, Alla Sigova, David Bumcrot
CAMP4 Therapeutics, Cambridge, MA

Regulatory RNAs (regRNAs) are long, short-lived, noncoding RNAs expressed from enhancers and promoters that act locally to regulate gene expression. This regulation is accomplished through the ability of regRNAs to bind transcription factors and increase their local concentration near a gene's promoter and enhancer elements. Our RAP Platform™ enables the identification of regRNAs and antisense oligonucleotides (ASOs) targeting these regRNAs to modulate target gene expression. Using this platform, we successfully identified CMP-CPS-001, a clinical candidate targeting a regRNA of the gene encoding carbamoyl-phosphate synthase 1 (CPS1), the rate-limiting enzyme in the urea cycle.

The urea cycle is responsible for the elimination of ammonia from the body by its conversion to urea and subsequent excretion in urine. Mutations in enzymes of the urea cycle cause urea cycle disorders (UCDs), a group of rare disorders characterized by the toxic accumulation of ammonia that results in neurological symptoms and even death. At present, UCDs are inadequately treated, and a significant unmet need remains.

CPS1 is the first enzyme in the urea cycle that directly acts upon ammonia. We posited that increasing CPS1 activity could reduce ammonia levels by increasing metabolic flux through the urea cycle. We identified ASOs that target a human *CPS1* regRNA, as well as surrogate ASOs that target a mouse *Cps1* regRNA, and increase the expression of these genes. Increasing *Cps1* expression using a mouse surrogate ASO reduced plasma ammonia levels and increased urea production following an acute ammonia challenge in a disease-relevant mouse model carrying a mutation in ornithine transcarbamylase gene (*Otc*), a urea cycle gene mutated in ~60% of patients with UCDs. The clinical candidate – CMP-CPS-001 – increased *CPS1* gene expression *in vitro* in both wild-type and patient-derived primary hepatocytes, and reduced plasma ammonia levels in a humanized-liver mouse model. Finally, administration of CMP-CPS-001 resulted in increased ureagenesis in wild-type cynomolgus monkeys.

These preclinical data demonstrate that targeting a *CPS1* regRNA and increasing *CPS1* expression may directly ameliorate hyperammonemia, which is the key driver of symptomology in UCD patients. Moreover, the mouse model data show that increasing *Cps1* expression can lower ammonia and increase ureagenesis in the context of a mutation in *Otc*. CMP-CPS-001 is currently being evaluated in a Phase I clinical trial in adult healthy volunteers and is in development for the potential treatment of multiple urea cycle disorders.

Cell Therapy Product Engineering II

338 Feasibility of Manufacturing CARv3-TEAM-E T Cells for Intraventricular Injection in Recurrent Glioblastoma

Heather Daley[1], Diego Hernandez[1], Andrew Mason[1], Zankar Desai[2], Danielle Bernier[3], Lu Huang[4], Bryan Choi[5], William Curry[5], Elizabeth Gerstner[5], Matthew Frigault[5], Jerome Ritz[1], Kathleen Gallagher[5], Marcela Maus[6], **Sarah Nikiforow[7]***
[1]Dana-Farber Cancer Institute, Boston, MA, [2]Dana Farber Cancer Institute, Boston, MA, [3]Massachusetts General Hospital Cancer Center, Boston, MA, [4]Massachusetts General Hospital, Charlestown, MA, [5]Massachusetts General Hospital, Boston, MA, [6]Massachusetts General Hospital, Lexington, MA, [7]Dana-Farber Cancer Institute, Boston, Massachusetts
**Corresponding Author*

Background:
Promising Phase 1 clinical data in glioblastoma has been demonstrated following infusion of T cells transduced with a second-generation chimeric antigen receptor (CAR) targeting epidermal growth factor receptor vIII (EGFRvIII)

and secreting a T-cell–engaging antibody molecule (TEAM) against wild-type EGFR (Choi, NEJM 2024: INCIPIENT, NCT05660369). Feasibility of manufacturing CARv3-TEAM-E cells from glioblastoma patients for intraventricular delivery was a secondary study objective.

Methods:
The CliniMACs Prodigy® TCT program was used to generate a target of 6 doses of $10x10^6$ CAR T cells from autologous apheresis material over 7 days. Starting cell numbers and feeding schedule were optimized, with IL-2 used in expansion. Extensive validations were required to identify optimal cell concentrations and diluent solution to facilitate intraventricular delivery via Ommaya catheter and minimize amounts of cryopreservative and cellular debris.

Results:
CAR T manufacturing was successful for all 12 patients infused to date. Fresh starting material consisted of 12Ls apheresed (median 2.2 blood volumes, range, 1.9-3.5). Number of frozen doses for infusion achieved was median 8 per run (range, 4-11). CD3+ T cells comprised median 98.4% of the final product. Median CAR transduction efficiency was 22.4% (range, 15.6-28.1%), as assessed by flow cytometry detection of a CD19 epitope encoded on the CAR-containing viral vector. Median CD3+ T-cell fold-expansion over the course of culture was 20.8% (range, 13.2-25.1%). All sterility and PCR-based safety criteria were met (see Table). Median percent of CAR+ cells with secreted and then bound TEAM was 78.0% (range, 67.0-93.7%) compared to CAR negative cells with bound TEAM of median 3.0%. Notably, manufacturing characteristics of products derived from recurrent glioblastoma patients were similar to what we had observed in validation runs using cells from healthy donors. A feasible high concentration of total nucleated cells/mL was initially identified in normal donor validation studies to minimize amount of infused cryopreservative. For clinical runs this yielded frozen drug product volumes of median 0.45mL (range, 0.36-0.65mL). Thawing conditions and the diluent solution were optimized in normal donor validation studies for cell recovery and viability in the final 10mLs of diluted product to be administered intraventricularly.

Conclusions:
All intended autologous CARv3-TEAM-E T-cell products were successfully manufactured, yielding multiple doses. The manufacturing process of CAR transduction and expansion was consistent and reliable as reflected by low (two-fold) variability in T-cell expansion and transduction levels. Intraventricular delivery requires validation not just of manufacturing a CAR product but also of optimal cell concentration, freezing media and controlled rate freezing curves, and thawing conditions and diluent to ensure safe and effective delivery.

Table: CARv3-TEAM-E Drug Product Release Criteria

Release Criteria	Acceptable Values	Median	Range
Purity (%CD3+T cells of viable CD45+ cells)	≥ 90%	98.4%	96.4-99.2%
Transduction Efficiency (TE) (% CD19+ of viable CD3+CD45+ T cells)	≥ 10%	22.4%	15.6-28.1%
# Full Doses Frozen	Target 6 (Minimum 1)	8	4-11
Viability (Trypan Blue)	> 70%	95%	87-99%
Endotoxin	≤ 5 EU/kg/hr	<0.0013	<0.0009-0.0028
Mycoplasma (qPCR)	Absent	All Absent	N/A
Sterility (BacT)	NGTD at time of release (> 5 days in culture)	NGTD All negative at 14 days	N/A
VCN copies per transduced cell	0.2-10	2.0	1.5-2.4
RCL by qPCR	Decreasing and </= 100 copies/0.2ug DNA	Pass	N/A
EGFR-CD3 TEAM bound to EGFRv3 CAR+ Cells	≥ 5.0% CAR+ T cells with TEAM bound	78.0%	67.0-93.7%
EGFR-CD3 TEAM bound to EGFRv3 CAR- Cells	For Information Only	3.0%	1.9-6.6%

339 dnTGFβRII-Armored DLL3-Targeted CAR-T Cells Maintain TGFβ Resistance with Early Signals of T-Cell Exhaustion Modulation After Expansion in SCLC

Chuan Wang[1]*, Shuai Yang[2], Tao Zhao[2], Wang Zhang[2], Qiuchuan Zhuang[3], Laura Sun[4], Zhong Yun[5], Mythili Koneru[6], Paul Schwarzenberger[6], Sahista Vahora[6], Anqi Li[6], Jihong Dai[7], Dong Geng[8]

**Corresponding Author*

Introduction:
TGFβ promotes tumor growth through direct and indirect mechanisms by modifying the tumor microenvironment and inducing T-cell exhaustion. Lower TGFβ levels are linked with enhanced CAR-T efficacy. A dominant-negative TGFβ receptor (dnTGFβRII) was integrated into the DLL3-targeted CAR-T product LB2102, currently under phase 1 investigation (NCT05680922).

Methods*:*
Preclinical experiments utilized primary human T-cells from two independent donors, transduced with either the dnTGFβRII-armored DLL3-targeted CAR-T construct (LB2102) or the non-armored control (LCAR-T20). For clinical validation, LB2102 cells and endogenous lymphocytes were collected during CAR-T expansion from a phase 1 study participant who achieved a partial response.

Results*:*
LB2102 CAR VHHs demonstrated high specificity and no cross-reactivity to other DLL family members or unrelated proteins. LB2102 cells did not exhibit off-target killing in a panel of human primary cells (n=13). To assess whether dnTGFβRII expression confers resistance to TGFβ, LB2102 cells and unarmored LCAR-T20 cells were incubated with TGFβ1, and SMAD2 phosphorylation was assessed as a readout for TGFβ1-mediated signal transduction. SMAD2 phosphorylation was significantly inhibited in the armored LB2102 cells (Fig 1). Additionally, TGFβ1-induced expression of exhaustion markers was inhibited in the armored LB2102 cells, in contrast to that in the unarmored control cells.

In the patient-recovered LB2102 cells collected on Day 15 post-infusion, TGFβRII expression was observed in more cells and at a higher expression level in CAR+ T-cells (79.2%) compared to endogenous T-cells (5.61%). While baseline pSmad2 signaling remained low in both populations, ex vivo incubation with TGFβ1 induced SMAD signaling in the patient's endogenous lymphocytes but minimally in dnTGFβRII-armored LB2102 cells. Thus, the TGFβRII armoring effectively blocked TGFβ signaling upon exposure to TGFβ1 ex vivo (Fig 2). Notably, armored CAR+ T-cells also exhibited lower expression of exhaustion markers, specifically TIGIT expression was 22.9% in CAR-T cells compared to 50.8% in endogenous T-cells collected on Day 22 (Fig 3).

Conclusion and Discussion:
Recovered LB2102 CAR-T cells retained dnTGFβRII armor functionality, validating preclinical findings in a limited patient setting. This suggests that the phenotypic and functional stability of LB2102 CAR-T cells may be maintained after infusion and expansion in a patient with SCLC. Additionally, patient-recovered LB2102 cells exhibited reduced expression of exhaustion markers compared to the patient's wild-type lymphocytes. These findings support the hypothesis that dnTGFβRII armored CAR-T (LB2102) may counteract TGFβ-induced immunosuppression in this tumor, in part by reducing T-cell exhaustion. Despite limited data, the observed clinical response in this patient suggests that the armored CAR-T approach has the potential to enhance clinical efficacy.

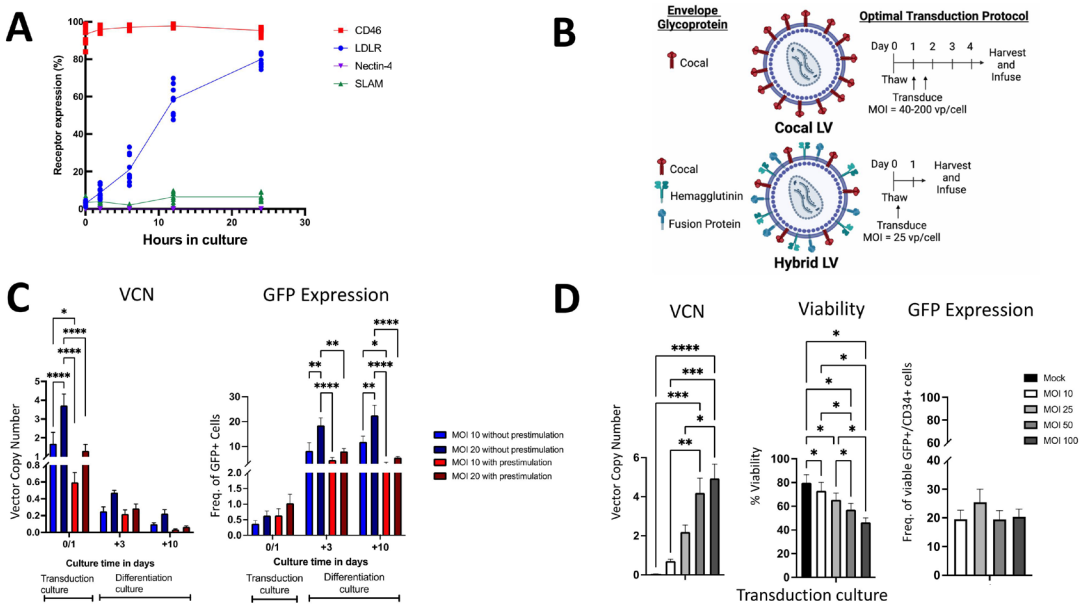
Hematopoietic stem and progenitor cells (CD34+) are promising targets for cell and gene therapies but their quiescent state limits transduction efficiency. A vector capable of transducing quiescent CD34+ cells could overcome these limitations. Vesicular stomatitis virus glycoprotein (VSVG)-enveloped lentiviral vectors (LV) are the current standard for CD34+ cell transduction but rely on the low-density lipoprotein receptor (LDLR), which is absent on resting CD34+ cells. Despite also displaying tropism for LDLR, we previously showed that cocal pseudotyped LV outperforms VSVG for transduction of CD34+ cells [Bayigga, L., ASGCT 2023]. Further, it is reported that LV pseudotyped with modified measles virus envelope glycoproteins, hemagglutinin (H) and fusion protein (F), utilize alternative receptors such as CD46 and SLAM to facilitate superior transduction in resting CD34+ cells [PMID: 29296856]. We assessed CD46, LDLR, SLAM and Nectin-4 expression in cryopreserved, G-CSF mobilized and purified primary human CD34+ cells (n=10 unique donors) over 24 hours in supportive culture for transduction (StemSpan SFEM II media + recombinant human cytokines). CD46 was consistently highly

expressed across all time points, whereas LDLR expression increased over time, reaching 58 ± 2% after 12 hours in culture (mean ± SEM). SLAM expression was minimal, while Nectin-4 expression was absent (Figure A).
We hypothesized that LVs incorporating both cocal and measles glycoproteins (hybrid LV) could enhance transduction of cryopreserved CD34+ cells at lower multiplicity of infection (MOI) to maximize vector batch yields (Figure B). Standard fourth generation LV preparation in 293T cells resulted in several formulations (F1, F4, F9, F11) with infectious titers ranging from 3.79E09 to 1.31E10 vector particles (vp)/mL. Of these, F4 demonstrated the highest transduction efficiency. Primary human CD34+ cells (n=4 donors) were transduced with cocal LV or F4 LV at MOI of 10 vp/cell as single hit transductions 24 hours following thaw with or without magnetically assisted transduction (MAT). MAT modestly increased transduction efficiency but was not statistically significant ($p > 0.05$). We next evaluated transduction timing by adding F4 LV at MOI of 10 or 20 vp/cell with or without 24-hour pre-stimulation culture (Figure C). Transduction was higher when vector was added immediately post-thaw (n=4 donors), suggesting preference for CD46 over LDLR. We further tested increasing MOI (10–100 vp/cell), with optimal transduction at MOI of 25 vp/cell (VCN: mean=2.2±0.3 copies/cell; %GFP+: 25.4 ± 4.5%), as higher MOI's were associated with reduced viability (Figure D). Clinical grade F4 LV (GFP- LV-158; titer = 1.4E09 vp/mL) was prepared for preclinical testing in a humanized NSG mouse model. CD34+ cells from four human donors were transduced immediately post-thaw (MOI of 25 vp/cell), cultured overnight and transplanted into mice following myeloablative total body irradiation at 1E06 viable cells/mouse (n= 8 mice/donor). The standard clinical transduction (24-hour prestimulation, 2- hit cocal
LV at MOI of 25 vp/cell) served as a positive control. Engraftment kinetics and transduction efficiency in peripheral blood are ongoing and will be presented. Our findings demonstrate proof-of-concept for a novel hybrid-envelope LV enabling low MOI, single-hit transduction of CD34+ cells immediately post-thaw, with no additional transduction enhancement required.



341 Biomaterials Manufacture and Deliver CAR T Cells In Vivo for Potent and Affordable Glioblastoma Treatment

Madelyn VanBlunk[1], Sharda Pandit[2], Pritha Agarwalla[2], Yevgeny Brudno[3]
[1]University of North Carolina, Chapel Hill, Cary, NC, [2]University of North Carolina at Chapel Hill, Chapel Hill, NC, [3]Cary, NC

Background

Glioblastoma (GBM) is the most common brain malignancy in adults with poor prognosis and no effective treatment. Chimeric Antigen Receptor (CAR) T cell therapy is a promising anti-cancer immunotherapy but suffers from expensive (~$500,000) and labor intensive (>2 weeks) manufacturing per dose. The lengthy ex vivo expansion

also deteriorates T cell quality as it encourages T cell differentiation. Previously, our lab has fabricated implantable dry, macroporous, alginate scaffolds (drydux) that efficiently mediate viral transduction and in vivo delivery of T cells. Drydux transduction is dependent on the hygroscopic nature of the biomaterial that allows drydux to absorb T cells and virus, causing these particles to collide for gene transfer. Drydux reduces CAR T cell manufacturing time to three days and improves the quality and potency of CAR T cells due to in vivo CAR T cell manufacturing **(Fig 1A)**.

Methods and Results

We performed in vitro cytotoxicity studies and an in vivo GBM resection model to determine antitumor efficacy of drydux-produced CAR T cells directed at the tumor-associated antigen B7H3. B7H3 is a type I transmembrane protein highly expressed in 60-70% of clinical GBM samples but limitedly expressed on healthy brain tissue. We have shown that drydux are capable of transducing T cells with B7H3-encoding retrovirus at transductions efficiencies above 80%, comparable to the conventional CAR T transduction method of spinoculating activated cells and retrovirus on RetroNectin-coated plates **(Fig 1B)**. To asses cytotoxic function in vitro, B7H3-specific CAR T cells made using drydux or conventional methods and U87 GBM cells were seeded together at different effector to target (E:T) ratios. After 5 days of coculture, cytotoxicity was analyzed using flow cytometry to measure the frequency of residual tumor cells. Inflammatory cytokine expression was analyzed 48 h after the start of coculture. At all E:T ratios, drydux-produced CAR T cells performed as well as conventionally-produced CAR T cells. All tumor cells were eradicated at higher E:T ratios. At 1:5, 1:10, and 1:20 ratios, about 90%, 70%, and 35% of tumor cells were killed, respectively **(Fig 2A)**. Drydux-produced CAR T cells produced similar or increased inflammatory cytokines compared to conventional CAR T cells. Non-transduced T cells did not produce any cytotoxicity. To evaluate antitumor efficacy in vivo, U87-GFP-FFLUC cells were injected intracranially into NSG mice. After tumor growth, ~96% of the tumor was resected. Drydux loaded with activated T cells and B7H3-specific CAR-encoding retrovirus were implanted into the resection cavity and compared to B7H3-specific CAR T cells created conventionally and directly injected into the resection cavity. Drydux loaded with activated T cells, but no retrovirus, were used as a negative control. 71% of mice in the drydux group had noticeably reduced tumor burden compared to only 50% in the conventional group and 0% in the negative control group, indicating the drydux may have enhanced antitumor efficacy **(Fig 2B)**.

Conclusions

These results demonstrate drydux-produced CAR T cells work as well as conventionally-produced CAR T cells at treating GBM, but with a significantly shorter manufacturing time. Biomaterials may provide the boost CAR T cell therapy needs to successfully treat GBM.

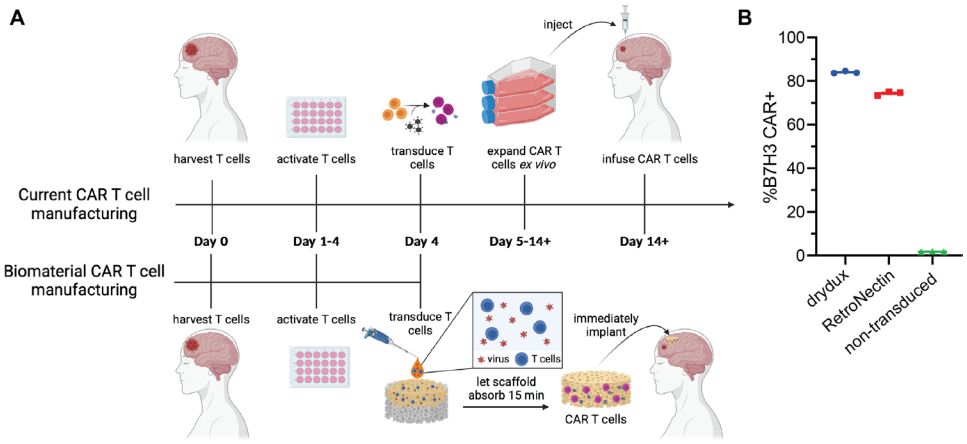


Figure 1. (A) Biomaterials (drydux) reduce the manufacturing time of CAR T cells to three days and can be implanted for *in vivo* manufacture and delivery. **(B)** Drydux transduces activated T cells with over 80% efficiencies, similar to spinoculation of RetroNectin-coated plates.

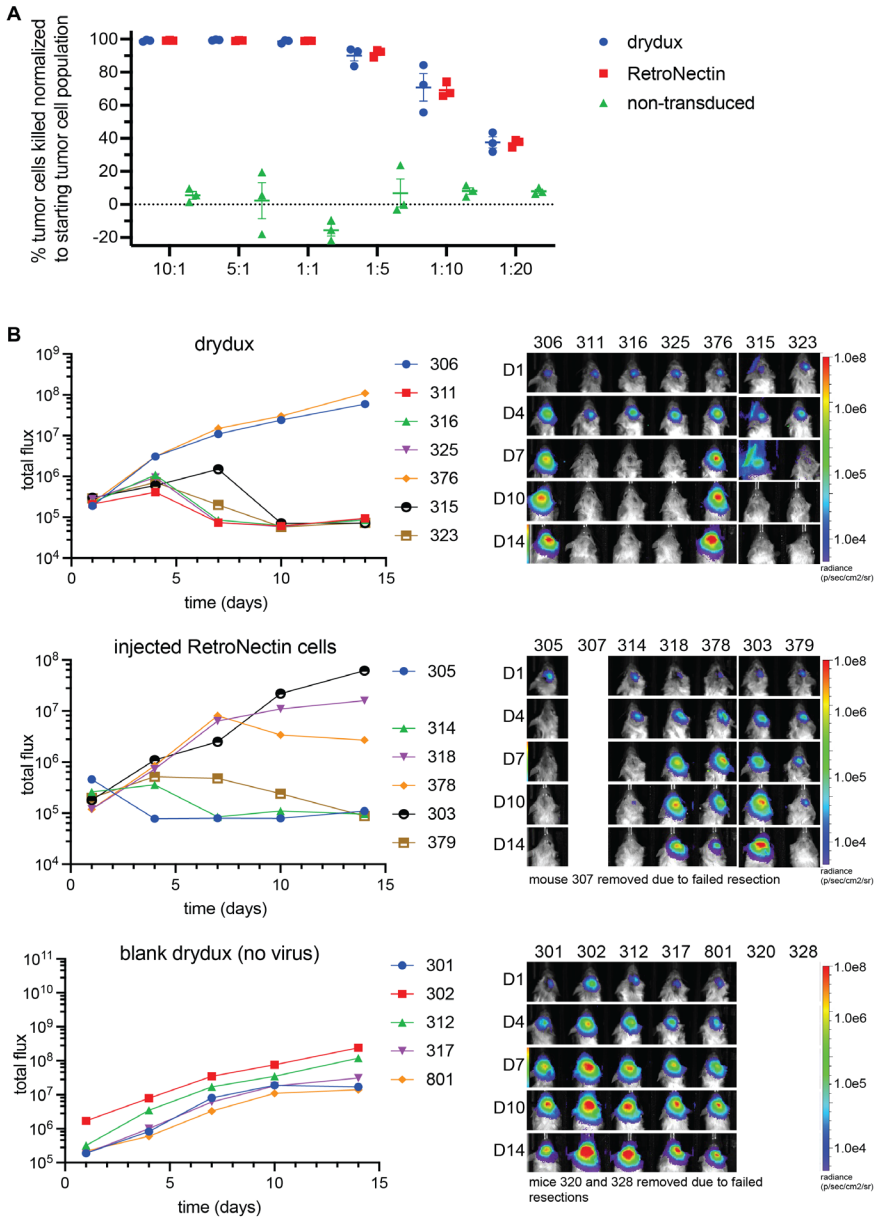

Figure 2. (A) B7H3-specific CAR T cells made using drydux or conventional methods and U87 GBM cells were seeded together at different effector to target (E:T) ratios. After 5 days of coculture, cytotoxicity was analyzed using flow cytometry. All tumor cells were eradicated at higher E:T ratios. At 1:5, 1:10, and 1:20 ratios, about 90%, 70%, and 35% of tumor cells were killed, respectively, by drydux and RetroNectin groups. No cytotoxicity was seen with non-transduced cells. **(B)** U87-GFP-FFLUC cells were injected intracranially into NSG mice and resected after growth. Drydux loaded with activated T cells and B7H3-specific CAR-encoding retrovirus were implanted into the resection cavity and compared to B7H3-specific CAR T cells created conventionally and directly injected into the resection cavity. Drydux loaded with activated T cells, but no retrovirus, were used as a negative control. 71% of mice in the drydux group had noticeably reduced tumor burden compared to only 50% in the conventional group and 0% in the negative control group.

342 Development of a manufacturing process for a Regenerative Macrophage Therapy to treat end-stage liver disease

Steven Howe[1]*, Damian Marshall[2]
[1]Resolution Therapeutics, London, Greater London, United Kingdom, [2]Resolution Therapeutics, London, London, United Kingdom
**Corresponding Author*

Macrophage-based regenerative therapies hold considerable potential for treating a variety of inflammatory and fibrotic diseases. Macrophages, as key regulators of tissue repair, not only mediate inflammation but also possess remarkable regenerative capacities, including tissue repair, resolution of inflammatory responses and immune modulation. We have advanced the manufacturing of a regenerative macrophage therapy (RMT), focusing on the optimisation of cellular engineering, scalability, and quality control in preparation for clinical application.

Clinical trials conducted previously by the University of Edinburgh demonstrated safety and efficacy of autologous RMT in liver cirrhosis patients (Moroni et al., 2019; Brennen et al, 2025]. We have further developed this approach through engineering cells to enhance anti-inflammatory and anti-fibrotic potency. Following manufacturing changes and optimisation, our lead asset, RTX001 is now entering Phase 1/2 clinical testing for treatment of end-stage liver disease in the UK and Spain.

We have further developed an *ex vivo* manufacturing platform to deliver multiple doses of a pro-regenerative macrophage therapy, ensuring functional consistency and potency across production batches. Process development has established a scaled GMP-compliant, robust protocol for the generation of autologous macrophages, integrating closed processing and optimised culture conditions to achieve high yields of macrophages with enhanced regenerative properties. We have developed a method of gene delivery to express IL-10 and MMP9 to boost the anti-fibrotic and anti-inflammatory activity of macrophages. A robust supply chain and the ability to provide multiple doses has been enabled through the development of cryopreservation and implementation of GMP-compliant storage and logistics systems.

Our process includes rigorous monitoring and quality control measures at every stage, from receiving input leukapheresis material through to final product release. Development of a comprehensive analytical package allows testing for safety, identity, quantity, purity, and potency to ensure that our final product meets regulatory standards. We have also built and incorporated a matrix of extended characterisation techniques which will enhance product understanding as we progress through clinical evaluation.

The application of process and quality controls minimises the risk of contamination and ensures the consistency of product quality.

In conclusion, our proprietary process for manufacturing a regenerative macrophage therapy has enabled us to initiate clinical testing against end-stage liver disease. By combining advanced cell engineering, scalable manufacturing, and rigorous quality control, we are creating a robust therapeutic platform with the potential to deliver transformative outcomes for patients. As we move into clinical trials and investigate the application of RMT in other fibrotic and inflammatory disease areas including, but not limited to, pulmonary fibrosis and graft-versus-host disease, we will continue to refine our processes for successful delivery of this next-generation regenerative therapy.

343 Continued Clinical Scale Process Development to Enable Safe and Effective Homology Directed Repair Gene Edited Hematopoietic Stem and Progenitor Cells for Sickle Cell Disease

Jason Skowronski[1], Kirby Wallace[1], Dana Duan[1], Premanjali Lahiri[2], Daniel Lord[2], Meet Shah[3], Yue Yuan[4], Angelica Garcia[4], Joshua Thomas[2], Annalisa Lattanzi[1], Valentin Barsan[5], Jerry Cacia[5], Matthew Porteus[5]
[1]Kamau Therapeutics, South San Francisco, CA, [2](Former) Graphite Bio, South San Francisco, [3](Former) Graphite Bio, Portland, OR, [4](Former) Graphite Bio, South San Francisco, CA, [5]Kamau Therapeutics, South San Francisco

Nulabeglogene autogedtemcel (nula-cel) is a phase I/II investigational drug product (NCT04819841), consisting of ex-vivo gene corrected, plerixafor-mobilized CD34+ HSPCs to cure Sickle Cell Disease (SCD). High-fidelity Cas9 is precomplexed with chemically modified gRNAs to induce innate Homology Directed Repair (HDR) mechanisms

via a recombinant AAV6 DNA donor template containing the wild-type *HBB* gene. This cell therapy directly corrects the disease-causing variant, simultaneously reducing sickle hemoglobin (HgbS) production and restoring physiologic adult hemoglobin (HgbA) levels.

Previously, a single patient (P1) was treated with cells manufactured using a first-generation process (V1.0). While P1 has done clinically well and met pre-defined safety and efficacy endpoints, including <10% HgbS at T24 months, the engraftment of red blood cells and platelets was delayed, requiring transfusions up to D+263 and eltrombopag to temporarily boost HSC growth. In addition, in the first phase of engraftment at T6 months, the level of gene corrected HDR alleles decreased from 33% in the drug product to 5-6% in the myeloid output from the bone marrow.

We address the delayed engraftment and low HDR correction with significant manufacturing process improvements. Here we describe the qualification of a V2.0 manufacturing process to improve nula-cel and address P1 observations. We switched to the Maxcyte GTx electroporator and initially increased %HDR from 39% to 47% and further tested an additional process change from culture bags to the G-Rex® bioreactor. The average from independent runs (n=5) showed: 1) a further increase in %HDR alleles to 59%±1.3% (mean±SEM); 2) an increase in cell yields from 112%±18% to 173%±26% despite a 1-day reduction in culture time. To better preserve HSCs, we shortened manufacturing to 3 days. We reduced the p53-mediated stress response by lowering the AAV6 MOI coupled with addition of a 53BP1 inhibitor HDR Enhancer peptide to favor HDR. We achieved a 4x AAV6 MOI reduction from 2500 to 625, while consistently achieving >50%HDR with no detectable increase in genotoxicity. A process comparability study (n=3) demonstrated that the above changes resulted in improved critical quality attributes including: increased HDR (36.6%±4.0% to 51.5%±6.7%); increased monoallelic/biallelic HDR events (39.7%±6.8% to 74.7%±7.4%); increased the LT-HSC marker profile by 49%±14%; improved viability via Annexin-V/7-AAD staining (76.3%±1.7% to 88.5%±0.7%); improved CFUs relative to an RNP only control without AAV6 (82.0%±14% to 110%±10%); while maintaining >100% cell yields despite a 2-day shorter manufacturing process.

The V2.0 process was successfully replicated at a CDMO in three independent clinical scale engineering runs. Comparability study results were maintained with 125%±8.3% cell recovery, 94.3%±0.7% cell viability, 97.0%±0.6% CD34+ purity, 53.7%±2.5% HDR correction and 101%±15% CFUs relative to an untreated control without editing. We also performed an *in vivo* long-term engraftment study in NSG mice and noted an average of 4-5 fold improvement in hCD45 engraftment in the bone marrow relative to prior studies using the V1.0 process. In conclusion, we demonstrated the clinical readiness of an improved V2.0 nula-cel product, with continuing FDA clearance for phase I/II clinical trial implementation.

344 Scalable Production of Hematopoietic Stem Cells and Microglia from iPSCs Using Stirred Tank Bioreactors for Consistent Cell Therapy Manufacturing

Joao Cotovio[1], Pieter van Loenen[2], Stefan Braam, **Mariana Argenziano***
[1]Ncardia, LEIDEN, Netherlands, [2]Ncardia, LEIDEN, Zuid-Holland, Netherlands
Corresponding Author

Hematopoietic stem cells (HSCs) and microglia are critical for the development of blood, immune, and central nervous system (CNS) cells, offering immense potential for cell therapy and the treatment of various hematological and neurodegenerative conditions. The manufacturing of HSCs and microglia from human induced pluripotent stem cells (hiPSCs) with consistent quality and at scale is essential for their integration into therapeutic applications. However, achieving this goal is challenging due to the complexity of the differentiation process. Ncardia, with extensive experience in iPSC innovation, has developed robust protocols for HSC and microglia differentiation, ensuring large batch consistency and scalability.

We adapted HSC and microglia differentiation processes originally developed in small-scale 2D adherent culture into 250mL stirred tank bioreactors, with the goal of scaling up to 1L and 3L bioreactors. A Design of Experiments (DoE) approach was employed to systematically evaluate critical process parameters (CPPs) such as dissolved oxygen, agitation speed, and inoculation density. Parallel testing of multiple differentiation protocols was conducted

to establish proof of concept. In-process monitoring, combined with comprehensive data science analysis, enabled a robust understanding of critical quality attributes (CQAs). This methodology ensured quick optimization and high consistency of the differentiation process.

These protocols successfully yielded high-quality HSCs and microglia characterized by their ability to self-renew and differentiate into various functional cell types. The hiPSC-derived HSCs exhibited typical morphology, expressed key markers (>90% CD34, CD45, and CD43), and demonstrated potential for differentiation into multiple immune cell lineages, including natural killer (NK) cells, macrophages and microglia, highlighting their applicability in cell therapy and immunotherapy. Similarly, hiPSC-derived microglia, known as Ncyte® Microglia, exhibited the expression of typical markers (>80% IBA1, TMEM119, and CX3CR1) and functional properties such as phagocytosis and cytokine secretion in response to inflammatory stimuli. The ability to co-culture microglia with neurons and other CNS cell types further enhances their potential applications in drug discovery and toxicity testing.

Ncardia's innovative use of stirred tank bioreactors for HSC and Microglia differentiation from hiPSCs addresses the critical need for large batch consistency and scalability in cell therapy and research applications. By combining expertise in stem cell biology with advanced bioreactor technology, Ncardia ensures high-quality, reproducible production of HSCs and microglia. This capability not only accelerates the development of cell therapies but also enhances the potential for generating diverse immune and neural cell types for therapeutic use. Ncardia's comprehensive approach positions them as a leading partner in the advancement of iPSC-derived HSCs and microglia for clinical, research, and regenerative medicine applications, facilitating new opportunities in immunotherapy and neurodegenerative disease treatment.

Across Platforms for Hematopoietic Disorders

345 Long-term Inflammatory manifestations post lentiviral hematopoietic stem/progenitor cell gene Therapy for Wiskott Aldrich syndrome

Corresponding Author

Introduction:
Wiskott-Aldrich syndrome (WAS) is a complex X-linked disorder caused by loss-of-function mutations of the WAS gene encoding to the WAS protein (WASp). WASp is a crucial regulator of the actin cytoskeleton in hematopoietic cells. WASp deficiency typically results in characteristic microthrombocytemia and lymphoid-myeloid dysfunction, with severity often correlating with residual WASp expression and function levels. However, emerging evidence highlights that WASp also plays a role in modulating autophagy and inflammasome activity.

Context:
In our open-label, non-randomized ex vivo gene therapy (GT) with LV-w1.6 WASp self-inactivating lentiviral vector clinical trial, which involved eight patients treated at Necker-Enfants Malades Hospital (Paris, France), and Great Ormond Street Hospital (London, UK), inflammatory manifestations emerged as a notable post-treatment issue. This study focuses on the inflammatory manifestations observed in the French cohort (NCT02333760).

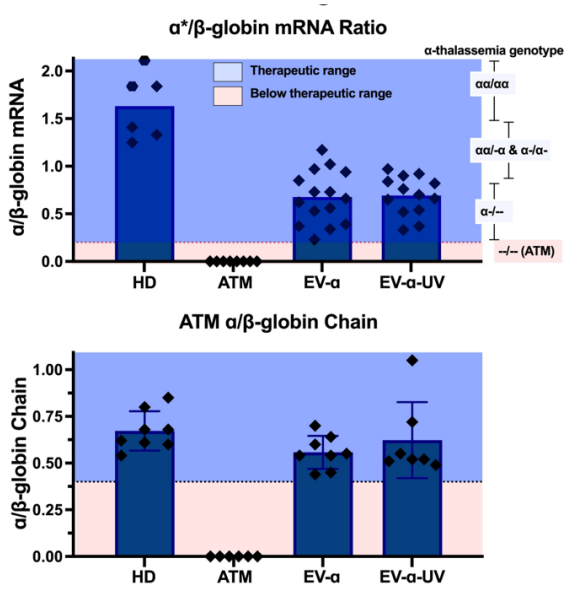
Results:
All patients improved their inflammatory phenotype for four years, with normalization in inflammatory cytokine expression profiles. Despite overall improvement after GT treatment, three out of four patients from the French cohort developed inflammatory clinical manifestations ranging from grade 1 (N=2) to grade 2 (N=1) despite successful engraftment of gene-corrected Hematopoietic Stem and Progenitor Cells (HSPCs) expressing WASp and effective T-cell immune reconstitution. Interestingly, gene-corrected cells' engraftment depended on selective lineage and was particularly low in CD14+ and CD15+ cells (range 0.04; 0.43 copies/cells). One patient experienced a worsening of the lower extremity vasculitis that had been improving since the GT, requiring grade II analgesics for pain management ten years after the transplant. Two patients also developed late-onset oligoarthritis (one of whom had minimal vasculitis involvement) without systemic inflammation or specific auto-antibodies. All biological tests indicated a dysregulation of the innate immune system and impaired inflammasome activation, with elevated levels of IL-1 β, TNF-α, and IL-18 secretion. These findings were closely linked to the gene-corrected myeloid engraftment. All inflammatory symptoms responded well but only transiently, to immunoglobulin therapy. Two cases, including the most severe one, were successfully treated with a human interleukin-1 receptor antagonist, indicating that targeting the IL-1β pathway may be a viable therapeutic approach for managing inflammation after and potentially before gene therapy for Wiskott-Aldrich syndrome (WAS).

Conclusions:
This data highlights the importance of myeloid-corrected cells and emphasizes the need to closely monitor inflammation biomarkers and inflammasome activity to develop targeted immunotherapy for patients with WAS.

346 Lentiviral Vectors for Hematopoietic Stem Cell Gene Therapy for Alpha Thalassemia

Eva Segura Gensler[1], Beatriz Campo Fernandez[2], Kevyn Hart[3], Frederic Bushman[4], Tippi MacKenzie[5], Donald Kohn[6]
[1]UCLA, Los Angeles, CA, [2]Kohn Lab at UCLA, Los Angeles, CA, [3]Los Angeles, CA, [4]University of Pennsylvania School of Medicine, Philadelphia, PA, [5]University of California, San Francisco, California, [6]Unversity of California, Los Angeles, CA

Alpha thalassemia major (ATM) is an inherited blood disorder caused by the absence of all four α-globin genes (*HBA2/1*), resulting in severe anemia from deficiency in hemoglobin production with lifelong dependence on blood transfusions and chelation therapy. While allogeneic hematopoietic stem cell transplant (HSCT) offers a potential cure, donor availability remains a significant challenge. Here, we present a novel gene therapy approach for autologous HSCT, utilizing lentiviral vectors (LVs) to deliver the *HBA2* gene under the regulation of optimized β-globin locus control region (LCR) enhancers, effectively restoring α-globin chain production in red blood cells (RBCs). The best performing LVs, EV-α and EV-α-UV, demonstrated 90-100% transduction efficiency in human hematopoietic stem and progenitor cells (HSPCs) transplanted into immunodeficient mice, achieving optimal vector copy numbers (<5) and a safe integration profile. Bone marrow-derived HSPCs from an ATM patient, treated with EV-α or EV-α-UV LVs, exhibited normalized α/β-globin mRNA and chain ratios (~1.0), recapitulating healthy RBC profiles. Furthermore, treated HSPCs derived from multiple cell sources across three ATM donors restored hemoglobin levels in RBCs by 50 to 100%. These findings establish the safety, efficacy, and translational potential of EV-α and EV-α-UV LVs, offering a promising autologous stem cell gene therapy for the treatment of ATM.



347 Lentivector Gene Therapy Mediates Reduction of Induced Inflammation in a Mouse Model of Deficiency of Interleukin-1 Receptor Antagonist

Alex Cho[1], Uimook Choi[2], Amanda Lawson[3], Raphaella Goldbach-Manksy[4], Paul Bryson[5], Du Jiang[6], Harry Malech[7]
[1]NIH - National Institute of Allergy and Infectious Diseases, Bethesda, MD, [2]NIH, NIAID, Bethesda, MD, [3]NIAID, Bethesda, [4]NIH - NIAID, Bethesda, [5]Pasadena, CA, [6]CSL Behring, Pasadena, [7]NIH/NIAID Laboratory of Clinical Immunology and Microbiology, Bethesda, MD

Deficiency of Interleukin-1 Receptor Antagonist (DIRA) is a severe inherited autoinflammatory disease. IL-1Ra regulates inflammation by competing with IL-1α and β for binding to IL-1 receptor. Daily injections of Anakinra, recombinant hIL-1Ra, are used to treat DIRA. Significant injection site reactions, development of focal anakinra amyloidosis in some patients, breakthrough symptoms upon discontinuation, and the high cost of life-long treatment provide rationale to explore development of a single-treatment lentivector-based gene therapy for DIRA. We designed a SIN lentivector containing MND promoter, human wild-type IL-1Ra cDNA, modified WPRE and 650bp 5′-HS4 chicken β-globin insulator. Preliminary studies demonstrated secretion of functional hIL-1Ra after transduction. Here, we report promising results using this gene therapy to reduce inflammation in a DIRA mouse (B6.129S-Il1rntm1Dih/J) gastrointestinal inflammation challenge model.

DIRA mice lack spontaneous autoinflammation. We used a 7-day 2% Dextran Sulfate Sodium (DSS) water challenge to cause colitis in DIRA versus C57BL/6J mice that is associated with a marked rise in Serum Amyloid A (SAA) inflammation marker. SAA was similarly low at baseline (pre-DSS challenge) in B6 versus DIRA mice (~18-26 ug/ml), but increased to 199 versus 832 ug/ml, respectively (4-fold greater inflammation in DIRA versus B6 mice) post-DSS challenge. We established an Anakinra versus saline subcutaneous pump treatment regimen, demonstrating that continuous treatment of DIRA mice with 4 mg/kg/day Anakinra (continuous blood level of 195 ng/ml) during the 7-day DSS water challenge reduced the rise in SAA to less than observed in B6 mice saline pump controls (DIRA saline 1310 ug/ml, DIRA Anakinra 262 ug/ml, B6 saline 341 ug/ml).

DIRA mouse c-kit-positive HSCs transduced with hIL-Ra lentivector (120 MOI with LentiBOOST®), achieved VCN 6.1 with 96% of HSC colonies transgene positive and flow cytometry demonstrating expression of hIL-1Ra in ~36% of cultured cells. Five recipient DIRA mice conditioned with 900 cGy were transplanted with transduced DIRA HSCs. At 9 wks post-gene therapy serum hIL-1Ra averaged 253 ng/ml, about 30% higher than achieved with the Anakinra pump. When these gene therapy treated DIRA mice were subjected to the 7-day DSS water challenge, SAA levels rose to only 100 ug/ml, half of the SAA level seen with DSS challenged B6 mice and 8-fold less than

observed with DSS challenged naïve DIRA mice, demonstrating that this gene therapy treatment provided profound protection from DSS challenge gastrointestinal inflammation.

At 12 weeks DIRA mice were sacrificed to assess gene marking. In bone marrow, spleen and peripheral blood, VCN averaged 2, 1 and 4, respectively. Flow cytometry demonstrated hIL-1Ra expression in 15-35% of B cells, T cells and myeloid cells of bone marrow, spleen and blood. Our study demonstrates a novel lentiviral vector-based gene therapy for treating the DIRA mouse model. This gene therapy approach was well tolerated and demonstrated both superior IL-1Ra expression and superior reduction of inflammation from DSS gastrointestinal inflammation challenge, even compared to Anakinra pump, supporting further exploration of its potential as a long-term treatment for DIRA patients.

348 Functional Restoration of Immune Defects in STAT1 Gain-of-Function Immunodeficiency Following Gene Editing

Robert Torrance[1], Kate Orf[2], Nathan White[3], Alexander McKenna[4], Claire Booth[5], Adrian Thrasher[6], Thomas Fox[7], Pietro Genovese[8], Siobhan Burns, Emma Morris[9]
[1]University College London, LONDON, London, United Kingdom, [2]UCL, LONDON, London, United Kingdom, [3]University College London, LONDON, United Kingdom, [4]University College London, [5]UCL Great Ormond Street Institute of Child Health, London, London, United Kingdom, [6]UCL Institute of Child Health, LONDON, United Kingdom, [7]UCL, [8]Boston Children's Hospital, Boston, MA, [9]University College London, United Kingdom

Hypothesis:
Gain-of-function (GOF) mutations in the *STAT1* gene result in a rare, combined immunodeficiency with a severe clinical phenotype. The only curative treatment option is allogeneic haematopoietic stem cell (HSC) transplantation (allo-HSCT) which carries high risks of morbidity and mortality for STAT1 GOF patients. Autologous gene therapy may be curative without the immunological complications associated with allo-HSCT. We hypothesise that gene editing of STAT1 GOF mutations in patient T cells and HSCs will restore normal STAT1 function.

Methods:
Guide RNAs specifically targeting the p.T385M mutation were electroporated into T cells and HSCs derived from peripheral blood (PB) in conjunction with mRNA encoding an adenine base editor. The degree of editing was determined by Sanger sequencing of target site amplicons. Functional analyses were performed in edited cells using flow cytometry to assess total STAT1, phosphorylated STAT1 (pSTAT1) and IL-17 production before and after stimulation. Real time quantitative PCR (RT-PCR) was used to measure transcript levels of key interferon stimulated genes (ISGs). Multiplexed digital droplet PCR was used to characterise on-target, unintended outcomes.

Results:
Base editing of p.T385M STAT1 GOF patient T cells resulted in 100% $\pm$ 0% (n=4) reversion of the patient mutation to the wild-type sequence, with an associated statistically significant ($p<0.01$) restoration of total STAT1 and pSTAT1 to healthy control levels, and a concurrent rescue in ISG expression. Up to 95% allelic correction was achieved following base editing of PB-HSCs from p.T385M STAT1 GOF patients. Levels of editing were maintained in HSC-derived monocytic progeny and corresponded to functional correction of total STAT1 and pSTAT1 in these cells. Importantly, initial experiments indicate that base editing does not induce any unintended on-target DNA aberrations, and that base edited PB-HSCs retain engraftment potential as measured by colony forming unit and phenotyping assays.

Conclusions & Future Directions:
Here, we show functional restoration of STAT1 gain-of-function following gene editing in patient T cells and HSCs. To our knowledge, this is the first case of base editing being used to successfully correct gain-of-function mutations causing inherited immunodeficiency. Future work will include off-target genotoxicity studies, as well as experiments utilising artificial thymic organoids to assess functional rescue in edited HSC-derived T lymphocytes. *In-vivo* chimerism experiments in a validated STAT1 GOF murine model are also underway.

With thanks to the MRC for funding this project (**MR/N013867/1).**

349 Site-Specific Gene Integration Strategies for IL7Rα-SCID Hematopoietic Stem Cell Gene Therapy

Ralph Valentine Crisostomo[1], Jack Reid[1], Ashley Huh[1], Delaram Zare[2], Aditi Kumar[1], Rebecca Chu[3], Marian Navarrete[1], Zulema Romero Garcia[1], Donald Kohn[1]*

Interleukin 7 Receptor subunit alpha Severe Combined Immunodeficiency (IL7Rα-SCID) is a rare inherited monogenic disorder that results in improper immune function because the patient cannot produce T cells, a group of immune cells that play a critical role in our adaptive immune response. The only approved treatment is an allogeneic stem cell transplant where the patient receives functional cells from an HLA-matched healthy donor. With limited donor availability, autologous hematopoietic stem cell gene therapy (HSCGT) using CRISPR/Cas9 is being developed by our group as a potential long-term treatment for IL7Rα-SCID. Previous work in IL7RA$^{-/-}$ mice that were treated with gammaretrovirus containing a constitutive promoter resulted in splenomegaly and neutrophilia, while an attempt to use alpharetrovirus with a lymphoid-restricted promoter in IL7RA$^{-/-}$ mice did not develop mature T cells *in vivo*. These results highlight the importance of maintaining the endogenous IL7Rα gene regulation for appropriate T cell development. In our strategy, we performed targeted gene editing in human CD34^{+} hematopoietic stem and progenitor cells (HSPCs) to insert the therapeutic IL7Rα transgene in the IL7RA locus through Homology-Directed Repair (HDR) and restore its function. Here, we evaluated three potential IL7Rα donor delivery methods: double-strand DNA (dsDNA), adeno-associated virus serotype 6 (AAV6), and integrase-deficient lentivirus (IDLV). After editing the HPB-ALL (IL7Rα-KO) cell line, all donor delivery methods restored IL7Rα expression using flow cytometry with mean fluorescence intensity similar to wild-type levels. A major challenge in HSPC gene editing is achieving high levels of HDR while minimizing toxicity observed from these donor delivery methods. We tackled this issue by adding AZD7648, a potent DNA-PK inhibitor, to influence DNA repair further towards the HDR pathway while adding lower amounts of the donor template. The addition of AZD7648 treatment increased HDR rates by 2-fold, and we achieved as high as ~50% with IDLV, ~71% with AAV6, but still ~1% with dsDNA *in vitro*. We further investigated the impact of gene editing combined with IDLV or AAV6 using downstream assays. Upon Colony-Forming Unit assay, we observed a higher clonogenic potential with IDLV (72% of Mock) than AAV6 (58% of Mock) even after using a lower dose of AAV6. Interestingly, we observed a slightly better outcome for both delivery methods with AZD7648 treatment. We also transplanted edited-HSPCs into immunodeficient NSG mice to investigate engraftment potential. After 16 weeks, we analyzed cells from the bone marrow and achieved higher total engraftment on HSPCs edited with IDLV (43% and 62%,+/-AZD7648) compared to AAV6 (38% and 23%,+/-AZD7648). More importantly, HDR% decreased by 3 and 2-fold in AAV6 (+/-AZD7648, respectively) treated cells, while HDR% increased by 1.5-fold in both IDLV conditions. Our results highlight the development of using site-specific gene integration with CRISPR/Cas9 for IL7Rα-SCID HSCGT; and suggest potential long-term advantages of using IDLV over AAV6. We are currently confirming lineage-specific expression and investigating the ability of HDR-edited HSPCs to become mature T cells using various *in vitro* differentiation protocols towards multiple lineages of the immune system. Crucially, we are also looking into sequence fidelity of the integrated transgenes due to reports of IL7Rα gain-of-function mutations in Leukemia patients.

350 Restore in vivo functions of mouse Fancc$^{-/-}$ hematopoietic stem cells using the CRISPR/Cas9 system.

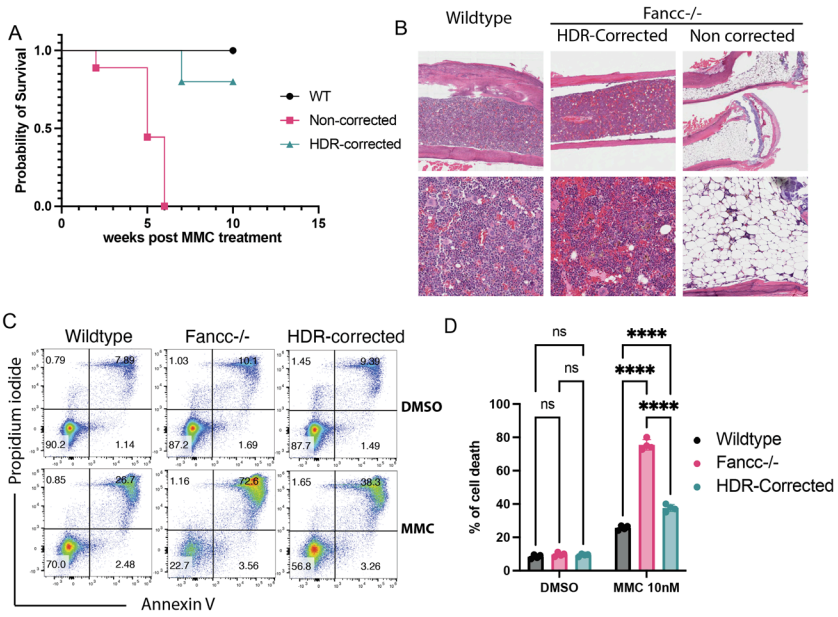
Fanconi Anemia (FA) is an incurable recessive disease caused by mutations in any members of the FA pathway. FA Complementation group C patients (FANCC), one of the most common subtypes, exhibit typical, but more severe symptoms than other subtypes. Gene therapy to repair mutated genes in autologous FA patient-derived hematopoietic stem/progenitor cells (FA-HSPCs) can permanently rescue FA-mediated bone marrow failure (BMF) and overcome the limitations of allogeneic bone marrow transplantation. FA-deficient cells are known to defect in the homologous recombination (HDR) pathway. However, we demonstrated an efficient HDR in mouse HSPCs using a reporter system, proving that the HDR pathway is active in Fancc-/- cells. Thus, CRISPR/Cas9- HDR is feasible for restoring functions of Fancc-/- HSPCs in vivo. We established a CRISPR/Cas9/AAV6-HDR system to integrate Fancc cDNA into the endogenous Fancc promoter. Of note, along with the reestablished expression of Fancc, corrected HSPCs restored the colony-forming ability and the resistance to mitomycin C (MMC) treatment. We assessed the functions of corrected HSPCs in vivo by transplanting these cells into irradiated Fancc-/- mice. 3 months later, we induced the BMF by MMC treatment. We found that mice transplanted with non-corrected HSPCs developed BMF and died after 5 doses of MMC injection, supported by the hypocellular structure of bone sectioning. However, mice transplanted with corrected HSPCs survived and did not develop BMF. Bone sectioning of survivors showed normal cellular structure. Collectively, we demonstrate that CRISPR/Cas9-HDR rescued functions of Fancc-/- HSPCs both in vitro and in vivo. Although, we can rescue the BMF in Fancc-/- mice, we observed significant cell death after the gene editing, as Fancc-/- cells are susceptible to secondary DNA damage caused by the CRISPR/Cas9. To improve the functions of corrected HSPCs, we are exploiting our established Spacer-Nick approach in Hypoxia that barely introduces double-stranded breaks and DNA damage. Spacer-Nick demonstrated improved functions of corrected HSPCs compared to the conventional CRISPR/Cas9 system. We are currently validating the functions of Spacer-Nick-corrected HSPCs in vivo.



351 *In vivo* HSC Transduction in Humanized Mice Mediated by Novel Capsid-modified HDAd Vectors

We have developed an *in vivo* HSC gene therapy approach consisting of HSC mobilization and intravenous injection of HDAd vectors. While we have demonstrated safety and efficacy of the approach in CD46-transgenic mice and rhesus macaques, studies in mice with a humanized hematopoietic system could facilitate its potential clinical translation for the treatment of hemoglobinopathies and HIV. Here, we generated an Ad6-based vector containing

fibers from Ad3 (HDAd6/3) with enhanced affinity to DSG2. *In vitro* studies showed greater transduction of primitive HSCs ($CD34^+CD38^-CD90^+$) cells and colony forming cells by HDAd6/3-GFP compared to HDAd5/35-GFP. This was also confirmed *in vivo* in humanized NSGW41 mice. NSGW41 mice engraft cryo-preserved human $CD34^+$ cells in the bone marrow (BM) without preconditioning. However, human chimerism in peripheral blood (PB) is usually low, and mobilization of human cells by G-CSF/AMD3100 is inefficient. We showed that low-dose total body irradiation (100 Rad) or busulfan treatment (12.5 mg/kg) increases the percentage of human $CD45^+$ cells in PB two- and five-fold, respectively. In the low-dose busulfan treated mice, G-CSF/AMD3100 mobilization resulted in >20,000 human $CD34^+$ cells in the periphery, 40 min after AMD3100 injection (15% of human $CD45^+$ cells were $CD34^+$). At the peak of mobilization, humanized mice were injected with HDAd5/35-GFP or HDAd6/3-GFP vectors, followed by O^6BG/BCNU-*in vivo* selection to expand transduced HSPCs. At end of the study, HDAd6/3-treated mice showed significantly higher percentages of human $CD45^+GFP^+$ cells compared to HDAd5/35-treated mice (41.12±10.62% vs 22.38±8.17%, p=0.0338, respectively). This was also reflected by the percentage of GFP-expressing $CD45^+$ cells in the bone marrow (BM) and spleen. A similar pattern of increased GFP expression was found in the human $CD45^+$ cells in the BM of the secondary recipients of cells isolated from the BM of HDAd6/3-treated primary mice. Moreover, we tested G-CSF-free mobilization regimens, the CXCR2-inhibitor tGroβ together with AMD3100, or AMD3100+tGrob together with the VLA4 inhibitor WU-106, as G-CSF/AMD3100 mobilization has some limitations. The percentages of human $CD45^+CD34^+$ and $CD45^+CD34^+CD90^+$ cells in PB were measured at 15 min, 1, 2, 3, 6 hours, and 3 days after injection. The peak of G-CSF/AMD3100 mobilization was at ~1 hour, while the peaks for tGrob+AMD and tGrob+WU106+AMD3100 were at 15min post injection. Importantly, mobilization of $CD34^+CD90^+$ with tGrob+AMD3100 was significantly more efficient than G-CSF/AMD3100 at their corresponding peaks. HDAd6/3-transduction of HSCs mobilized with the different mobilization schemes followed by O^6BG/BCNU selection resulted in stable increase of GFP in peripheral blood with comparable GFP expression pattern in human $CD45^+$ cells within the BM of the different groups. Finally, we also tried to improve the HDAd5/35 vector platform by targeting the virus to a second HSC receptor, a_6b_1/CD49f (HDAd5/35_lam). *In vivo* transduction of human HSCs in humanized NSGW41 mice showed >20% transduction of $hCD34^+CD38^-CD90^+$ three days after the virus injection. In summary, our data in humanized mice show that human HSCs can be efficiently mobilized with G-CSF/AMD3100 or G-CSF-free regimens and *in vivo* transduced with HDAd vectors resulting in high GFP marking rates, which, theoretically, should be curative for hemoglobinopathies and HIV.

Gene Therapy Trials - In-Vivo Gene Therapy Modification

352 Initial safety data from ELIMINATE-B, the first clinical trial of a gene editing treatment for chronic hepatitis B

Mark Sulkowski[1], Alina Jucov[2], Alex Vogel[3], Emily Harrison, Andrew Van Cott, Neil Leatherbury[3], Brittany Zick[4], Daniel Nazarenko[3], John Fry[3], Jeff Smith[5], Cassie Gorsuch, Murray Abramson[6]
[1]Division of Infectious Diseases Johns Hopkins Bayview Medical Center, John Hopkins University & Medicine, Baltimore, [2]ARENSIA Research Clinic, Chisinau, Moldova, [3]Precision BioSciences, Durham, NC, [4]Precision BioSciences - Durham, NC, Durham, NC, [5]Precision BioSciences, Inc., Durham, NC, [6]Precision BioSciences, Durham

Chronic hepatitis B virus (cHBV) infection affects approximately 300 million patients world-wide and is responsible for 1.1 million deaths annually. Premature death in patients is predominantly due to complications of cirrhosis, portal hypertension, and hepatocellular carcinoma even with current standard of care therapies. Currently there is no curative therapy for cHBV infection. ELIMINATE-B is an ongoing, global trial to evaluate PBGENE-HBV, a first-in-class gene editing therapy in patients with cHBV infection with the intent to cure. PBGENE-HBV consists of an ARCUS nuclease-encoding mRNA that is formulated in a lipid nanoparticle and optimized for safety and potency. PBGENE-HBV is designed to eliminate covalently closed circular DNA (cccDNA), the source of replicating virus, and inactivate integrated HBV DNA. Part 1 of ELIMINATE-B evaluates multiple ascending doses in HBeAg-negative patients controlled on nucleos(t)ide analogs. Initial data from the first cohort comprising 3 participants receiving their first dose administration of 0.2 mg/kg of PBGENE-HBV demonstrated the treatment was well-tolerated with no serious adverse events, including no clinically significant laboratory abnormalities. More

specifically, AST/ALT and platelet count have remained within normal limits for all dosed participants. The initial safety data supports continued evaluation of a finite course of dose administrations across multiple dose levels of PBGENE-HBV. Comprehensive datasets of the tolerability and efficacy of multiple administrations are being collected and will be analyzed on full dosing of cohorts.

Preclinical efficacy models across multiple species including nonhuman primates (NHPs) demonstrated that PBGENE-HBV eliminates cccDNA and inactivates integrated HBV DNA, resulting in durable reductions of HBV DNA and HBsAg. PBGENE-HBV demonstrated cumulative editing at three dose levels tested in an NHP HBV model, achieving 99% viral inactivation after two doses. Preclinical toxicology data indicated that PBGENE-HBV was well-tolerated after multiple dose administrations in NHPs at all dose levels evaluated. Consistent with other nonclinical studies utilizing systemic administration of LNPs, clinical chemistry findings in NHP included non-adverse, transient elevations in liver transaminases fully normalizing between 7 and 14 days. No adverse effects were observed in any parameter, including hematology, coagulation, immune function, or macroscopic/microscopic tissue evaluations after multiple dose administrations in NHPs. PBGENE-HBV distributed primarily to the NHP liver and showed no evidence of biodistribution to germ cells. In culmination, the initial clinical safety data discussed above demonstrates the translatability of the NHP model and supports the continued evaluation of multiple administrations and dose levels of PBGENE-HBV with the goal of cure.

353 Direct image-guided convective perfusion of the bilateral thalami offers a consistent approach to CNS dosing: first-in-human experience with gene therapy for frontotemporal dementia.

Russell Lonser[1], Matthew Rabon[2], Mirek Zabek[3], J. Bradley Elder[4], **David Cooper[5]**
[1]OSU Wexner Medical Center, Columbus, OH, [2]ClearPoint Neuro, Solano Beach, CA, [3]Interventional Neurotherapy Center,, Warsaw, Poland, [4]Department of Neurological Surgery, Columbus, OH, [5]AviadoBio, LONDON, London, United Kingdom

Background:
Nervous system gene therapy delivery methods, including cerebrospinal fluid (CSF) or systemic administration, are limited by lack of target specificity, immune response/exposure and/or the blood-brain barrier. Convection-enhanced delivery (CED) overcomes these obstacles and permits for the direct, targeted, homogeneous, reliable and safe delivery of high concentration of viral vectors for transgene expression. Moreover, the use of real-time magnetic resonance (MR)-imaging allows for the precise monitoring of vector distribution during convective target perfusion. The current study exploits the properties of CED to deliver AVB-101 (recombinant adeno-associated virus serotype 9 (AAV9) encoding the human granulin (*GRN*) gene) to treat frontotemporal dementia (FTD) associated with progranulin deficiency. While large animal studies have demonstrated the safe and effective administration of AVB-101 into the thalamus, it has not been explored in humans previously.

Objective:
To define the properties of MR-guided intrathalamic convective gene therapy delivery, we analyzed findings in patients with FTD associated with a *GRN* mutation (FTD-*GRN*) that underwent administration of AAV9 expressing *GRN* as part of the ongoing ASPIRE-FTD Phase 1/2 study (NCT06064890).

Methods:
FTD-*GRN* patients underwent real-time MR-guided convective co-infusion of the bilateral thalami with AVB-101 and gadolinium (1 mM). A protocol-defined volume was divided equally between anterior/posterior thalamus, delivered as two pairs of simultaneous bilateral infusions.

Results:
Three consecutive patients (mean age 53.0 ± 18.2 years) underwent a total of 12 thalamic infusions with mean follow-up of 3 to 9 months to date. Real-time MR-imaging demonstrated increasing tissue volume of distribution (V_d) with increasing volume of infusion (V_i) that was consistent across patients. Infusion shaping by varying infusion rate and cannula position permitted in target distribution with mean 87.2% of perfused area within thalamus. Consistent with the expected variability in segmented thalamic size (5.4 to 8.4 cm^3), mean thalamic

coverage was 39.1 (range, 28.7 to 47.6%). There was no significant perivascular loss or leakback along the cannulae. There was no evidence of complication on imaging or clinical safety assessments. To date there have been no serious adverse events nor any adverse events related to the product or procedure reported in the follow-up period.

Conclusions:
First-in-human experience with real-time MR-guided convective delivery provides new insights into the consistency of thalamic gene therapy perfusion properties. The isotropic tissue composition, low propensity for perivascular leakage and its broad interconnectedness makes the thalamus an ideal gene therapy target for a wide variety of neurologic disorders.

354 RGX-202, an Investigational Gene Therapy for the Treatment of Duchenne Muscular Dystrophy: Interim Clinical Data

Olivier Danos[1]*, Amy Harper[2], Susan Iannaccone[3], Nancy Kuntz[4], Carolina Tesi-Rocha[5], Aravindhan Veerapandiyan[6], Nidal Boulos[7], Stacey Curtiss[1], Michele Fiscella[1], Michelle Gilmor[1], Stephen Pakola[8], Hiren Patel[1], Dawn Philips, Catherine Wilson, Jahannaz Dastgir[1]

Introduction:
Duchenne is a severe, progressive, degenerative muscle disease caused by mutations in the *DMD* gene which encodes for dystrophin, without which muscles degenerate and become weak, eventually leading to loss of movement and independence, required support for breathing, cardiomyopathy, and premature death. RGX-202 is an investigational, one-time AAV gene therapy designed to deliver an optimized microdystrophin gene that encodes for a novel microdystrophin protein that includes the C-Terminal (CT) domain found in naturally occurring dystrophin. In preclinical studies, the CT domain has been shown to protect muscles from contraction-induced stress and to improve muscle repair.

Methods:
AFFINITY DUCHENNE®, a phase I/II/III multi-center, open-label trial of a one-time intravenous administration of RGX-202 at two dose-levels (DL1, $1x10^{14}$ or DL2, $2x10^{14}$ genome copies/kg body weight) is enrolling ambulatory boys aged one and above with Duchenne to evaluate safety, tolerability, and clinical efficacy.

Results:
As of November 8, 2024, RGX-202 has been well tolerated in the Phase I/II portion (n=11) with no serious adverse events in boys aged 1-11 years old. Participants demonstrated robust RGX-202 microdystrophin expression three months following RGX-202 administration at DL1 (10.4 – 83.4%; n = 3) and DL2 (20.8-77.2%; n = 6). Functionally, RGX-202 participants demonstrated mean improved function on the North Star Ambulatory Assessment (NSAA) and time function tests at DL1 (12 months follow-up; n = 3) and DL2 (9 months follow-up; n = 2). These participants also exceeded available external natural history controls matched for age and baseline function.

Conclusion:
In the Phase I/II patients, RGX-202 has been well tolerated and demonstrated both robust RGX-202 microdystrophin expression and functional improvements.

355 Long-Term Functional Outcomes and Safety Following Delandistrogene Moxeparvovec Treatment in DMD: EMBARK 2-Year Results

Introduction:
Delandistrogene moxeparvovec, an rAAVrh74 vector-based gene therapy approved in the US and other select countries, delivers a transgene encoding delandistrogene moxeparvovec micro-dystrophin, an engineered, functional form of dystrophin that stabilizes or slows Duchenne muscular dystrophy (DMD) progression. EMBARK (NCT05096221), a Phase 3, randomized, double-blind, placebo-controlled, two-part study, assesses delandistrogene moxeparvovec in DMD.

Methods:
EMBARK enrolled ambulatory males with DMD aged ≥4─<8 years (Mendell. *Nat Med*. 2024). Patients received delandistrogene moxeparvovec (single intravenous dose 1.33×10^{14} vg/kg) or placebo in Part 1 (52 weeks) and crossed over in Part 2. Due to the crossover, 2-year functional outcomes from patients treated with delandistrogene moxeparvovec in Part 1 were compared with a cohort of external controls (EC), matched using prespecified propensity-score-weighted analyses based on baseline prognostic factors that impact DMD progression.

Results:
At 2 years, patients treated with delandistrogene moxeparvovec in Part 1 (N=63) demonstrated statistically significant and clinically meaningful functional benefit versus EC (N=113–115, dependent on functional assessment). Mean change from baseline was 2.63 versus –0.25 points on the North Star Ambulatory Assessment total score (between-group difference: 2.88 points); 0.65 versus 2.71 seconds on the Time to Rise (between-group difference: –2.06 seconds), and –0.04 versus 1.32 seconds on the 10-meter Walk/Run (between-group difference: –1.36 seconds); all $P<0.01$. There were no deaths, discontinuations, or clinically significant complement-mediated adverse events (AEs). Between Weeks 52 and 104, 15 (23.8%) patients experienced 34 treatment-related treatment-emergent AEs. One patient experienced two treatment-related serious AEs of rhabdomyolysis; both resolved.

Conclusions:
2-year results indicate favorable treatment effect of delandistrogene moxeparvovec on disease progression versus a well-matched EC. Stabilized functional outcomes, prognostic for delaying loss of ambulation, demonstrate durability of treatment. Safety was consistent with prior experience.

356 Safety and Efficacy of AAV9-Mediated Gene Therapy GC301 in ERT-Stabilized Infantile-Onset Pompe Disease: An Open-Label, Single-Arm Study with Over 12 Months of Follow-Up

Xinting Liu[1], Yingying Mao[2], Xiaodong Wang[3], Linyan Hu, Shuangqing Yu[4], Wenhao Ma[3], Wen He[5], Xiaoyan Dong[6], Xiaobing Wu[7], Guang Yang[5]*

**Corresponding Author*

Introduction
Pompe disease, a lysosomal storage disorder resulting from mutations in the GAA gene, triggers glycogen accumulation in various tissues. Enzyme replacement therapy (ERT), currently the standard treatment, requires lifelong administration and exhibits variable efficacy. In contrast, gene therapy has emerged as a promising approach to address the underlying genetic defects. This study aims to assess the safety and efficacy of adeno-associated virus serotype 9 (AAV-9) mediated gene therapy GC301 in patients with infantile-onset Pompe disease (IOPD) whose condition has been stabilized with ERT.

Methods
From April 18, 2023 to November 9, 2023, six IOPD patients who had been receiving ERT were recruited for this study. Each patient received a single-dose intravenous injection of the GC301 gene therapy at a dose of 1.2E+14 vg/kg, after which ERT was discontinued. Follow-up for all six patients has continued for over a year. Safety observations include monitoring adverse events and immunogenicity. Efficacy endpoints were frequently assessed, focusing on survival status, cardiac function, exercise ability, and GAA enzyme activity in both blood and muscle tissue. Echocardiography was utilized to evaluate cardiac function. The GMFM-88 scale was employed to evaluate motor function.

Results
A total of 6 subjects were enrolled in this study. One subject withdrew due to personal reasons 60 days after administration. Prior to enrollment, all participants had undergone ERT once or twice a month, with an average duration of 29.7 months (range: 5.0 - 49.9 months). The average time interval between the last ERT and gene therapy was 10.5± 6.1 days. Following the administration of GC301, no serious adverse events (SAEs) related to the gene therapy have been observed. Treatment-related adverse events (TRAEs) in grades 1-2 were reported, with transient fever and liver injury being the most common. Anti-GAA antibodies remained negative during the follow-up period. During the follow-up, five patients did not use ERT for an average of 525.60 ± 60.43 days. The left ventricular mass index (LVMI) was stable compared to baseline, left ventricular ejection fraction (LVEF) remained within the normal range (>55%) (Fig.1 A). Among the six subjects, three patients demonstrated significant improvements in their motor developmental milestones including 3 subjects achieving the milestone of independent walking (Fig.1 B), and their GMFM-88 scores also improved (Fig.1 C). Three subjects voluntarily underwent muscle biopsy, and their muscular GAA enzyme activities and GAA protein significantly increased after GC301 administration compared to pre-treatment levels (Fig.1 D and E).

Conclusion
This study provides evidence regarding the efficacy and safety of AAV-9 gene therapy GC301 for treating IOPD patients who have achieved disease stabilization via ERT. Throughout the follow-up period, we observed that gene therapy enables to reduce the use of enzyme while maintaining stable or improved survival rates, heart function, GAA enzyme activity, and motor function. This study suggests that AAV gene therapy has the potential to become a new therapeutic approach for IOPD.

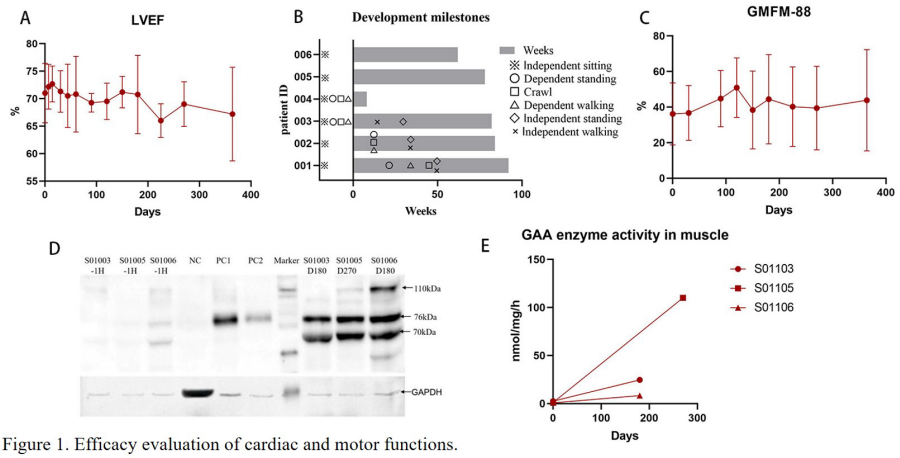

Figure 1. Efficacy evaluation of cardiac and motor functions.

A. The trend of LVEF changes in the subjects (average±SD). B. The motor developmental milestones obtained by six subjects from GC301 administration to now. C. The trend of GMFM-88 changes in the subjects (average±SD). D. Western Blot detected an increase in the expression of GAA protein after treatment. E. After administration, the GAA enzyme activities in muscle tissue significantly increased.

357 ART001: Development and Interim Clinical Outcomes of a CRISPR-Based In Vivo Gene-Editing Therapy for Hereditary ATTR

Yasi Jiang[1], Lei Huang[2], Songyuan Li[3], Leqi Liao[2], Huanle Liu[2], Han Qiu[4], Xinchao Xia[2], Ye Chen[5], Jialin Tao[6], **Yongzhong Wang**[7], Rui Chen[8], Yonggang Hao[9]

Accuredit Therapeutics 2024

Hereditary transthyretin-mediated amyloidosis (ATTR) is a progressive disease caused by misfolded transthyretin (TTR) protein, leading to amyloid deposits in tissues and organ such as peripheral nerves or the heart. Current treatments, including TTR-stabilizing agents and RNA-based therapies, require long-term administration and primarily delay disease progression. ART001 is a novel CRISPR-based in vivo gene editing therapy designed for single-dose, long-lasting treatment by knocking out the wild-type or mutant TTR gene in hepatocytes, using a lipid nanoparticle (LNP) system. ART001's **regulatory approval for phase I clinical trials in both the United States and China** further underscores its global significance, as it is one of only two in vivo gene-editing therapies authorized for clinical trials targeting ATTR in US. In cynomolgus monkeys, ART001 demonstrated sustained, dose-dependent reductions in TTR levels by 85%, 97%, and 99% at doses of 1, 2, and 3 mg/kg, respectively, maintained for up to 360 days. Crucially, comprehensive genomic analyses detected **no off-target editing at as much as 79 times EC90, with only minimal large genomic alterations, such as large indels or translocations.** These results supported an open-label, single-center investigator-initiated trial (IIT) to evaluate ART001 in 10 patients with hereditary ATTR. Patients aged 31–65 years were enrolled across six dose cohorts (0.05–1.0 mg/kg) and received ART001 intravenously. ART001 exhibited an exceptional safety profile, **with no infusion-related reactions (IRRs), serious adverse events (SAEs), or significant immune toxicities reported. No elevations in liver enzymes beyond Grade 1** or evidence of liver toxicity was observed, reinforcing ART001's safety advantage. Adverse events were limited to mild and transient occurrences, such as hypertriglyceridemia, limb pain, and weight gain, with all resolving within the follow-up period. Efficacy results from this IIT trial have been equally impressive, with ART001 achieving dose-dependent reductions in serum TTR protein levels **at 48 weeks: 78%, 83%, and 93% in the 0.5 mg/kg, 0.7 mg/kg, and 1.0 mg/kg** cohorts, respectively. These reductions far exceeded

the clinically meaningful threshold of 60%, highlighting ART001's potential as an effective single-dose therapy for long-term disease management. ART001 represents a major advancement in gene editing, achieving sustained TTR protein knockdown with a single administration and minimal adverse effects. With regulatory approvals and promising, 48-weeks, interim clinical results, ART001 holds the potential to revolutionize ATTR treatment, reduce treatment burden, and significantly improve patient outcomes.

358 Safey and Efficacy of ATSN-201 Dose Escalation in Patients with X-linked Retinoschisis (XLRS)

Shannon Boye[1], Lesley Everett[2], Aaron Nagiel[3], Byron Lam[4], Andreas Lauer[5], Audina Berrocal[4], Ninel Gregori[4], Sanford Boye[6], Laura Pardon[7], Dan Yoon[7], Christine Kay[8], Kenji Fujita[9]
[1]Division of Cellular and Molecular Therapy, Department of Pediatrics, University of Florida, Gainesville, FL, Gainesville, Florida, [2]Casey Eye Institute, Oregon Health & Sciences University, Portland, OR, [3]Children's Hospital Los Angeles, Los Angeles, CA, [4]Bascom Palmer Eye Institute, Miami, FL, [5]Oregon Health & Science University, [6]Powell Gene Therapy Center, University of Florida, Gainesville, FL, Gainesville, Florida, [7]Atsena Therapeutics, Durham, NC, [8]Vitreoretinal Associates, Gainesville, FL, [9]Atsena Therapeutics, Millburn, NJ

X-linked retinoschisis (XLRS) is associated with mutations in the RS1 gene and is a leading cause of juvenile macular degeneration in males that currently has no approved treatment options. XLRS is characterized by schisis, or abnormal splitting of the retinal layers, which causes impaired visual acuity that is not correctable with glasses and leads to progressive vision loss and ultimately blindness. Despite being a secreted protein, RS1 needs to be secreted from photoreceptors in order to properly function. The only effective route of administration for efficient AAV-mediated gene delivery to photoreceptors is subretinal injection. The presence of schisis cavities in the central retina poses a challenge to safe and effective delivery of AAV-RS1 to XLRS patients. The novel AAV.SPR capsid laterally spreads well beyond the margins of the subretinal injection (SRI) bleb, providing a means to perform peripheral SRI (without detaching the fovea and avoiding schisis cavities) and effectively deliver RS1 to both the peripheral and central retina. The goal of this phase 1/2 dose escalation study is to evaluate the safety and preliminary efficacy at 3 dose levels of ATSN-201, a laterally spreading subretinal gene therapy, in patients with XLRS. Nine adult patients received unilateral subretinal injections of ATSN-201. Three cohorts (N = 3 each) were treated with ATSN-201 [Cohort 1: 1.5 x 10^{10} vg/eye (low dose), Cohort 2: 5.0 x 10^{10} vg/eye (high dose), and Cohort 3: 3.0 x 10^{10} vg/eye (mid dose)], delivered in 2 or 3 blebs while avoiding foveal detachment. The primary endpoint is the incidence of dose-limiting toxicities (DLTs) and treatment-emergent adverse events (TEAEs), and key secondary endpoints include changes in retinal thickness and microperimetry (MP). Data are reported through a data cutoff date of 25 November 2024. All subjects were followed through at least Month 1 and up to Month 12 post-treatment. A total of 66 TEAEs were observed, 43 of which were related to the surgical procedure. No DLTs have been reported, and one serious TEAE that was unrelated to ATSN-201 or study procedures was reported. All 3 subjects in Cohort 2 developed TEAEs of subretinal deposits and associated retinal thickening that improved following extended steroid treatment; as a result, the dose was de-escalated to an intermediate dose in Cohort 3. All 3 subjects in Cohort 3 developed TEAEs of retinal thickening which resolved in two subjects and is resolving in one patient as of the data cutoff. One subject also experienced subretinal deposits that improved following extended steroid treatment. Of subjects with at least 3 months of follow-up, 5 of 7 subjects demonstrated closure of foveal schisis in the treated eye at the most recent visit. No untreated eyes showed foveal schisis closure. Treated eyes with structural improvements also generally demonstrated improvements in MP average threshold. In conclusion, ATSN-201 is a promising treatment approach for patients with XLRS, a disease for which no treatments currently exist.

AAV Preclinical and Proof-of-Concept Studies

359 *In Vivo* Mosaic Screens Uncover Novel Gene Therapies for Age-Related Diseases

Martin Borch Jensen[1], Neety Sahu[2], Naoto Muraoka[2], Gavin Pharaoh[2], Chase Bowman[2], Shengping Wang[3], Carmen Le[3], Smitha Shambhu[2], Alex Araki[2], Hikaru Miyazaki[2], Jingshu Chen[3], Dimitry Popov[2], Vinay Kartha[2], Lianna Fung[2], Chris Carrico[4], Ian Driver[2], Linda Chio[5], **Chris Towne[5]***, Francisco LePort[2]

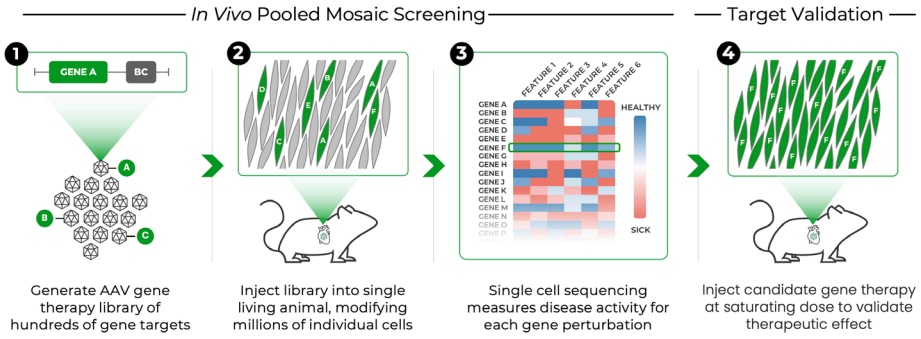
Background:
The complexity of age-related diseases, such as osteoarthritis (OA) and heart failure (HF), demands innovative strategies for therapeutic discovery. Here, we present an *in vivo* pooled mosaic screening platform that enables the identification of multiple therapeutic candidates in relevant disease models.

Methods:
Our *in vivo* drug discovery process consists of two key phases (see figure): 1) *In Vivo* Pooled Mosaic Screening – AAV delivery of barcoded therapeutic candidates into disease models, followed by single-cell sequencing and transcriptomic analysis to identify promising interventions. 2) Target Validation – Functional assessment of nominated targets in human patient samples and rodent disease models to confirm therapeutic potential.

Results:
Osteoarthritis: We screened 154 therapeutic interventions in the fetlock joints of thoroughbred horses (n=9) diagnosed with OA. Fibroblast Growth Factor 18 (FGF18), a best-in-class anabolic agent, served as a positive control, with non-targeting gene sequences as inert controls. Twenty-four top candidates were prioritized based on transcriptomic shifts indicative of therapeutic activity and were subsequently tested in ex vivo co-culture systems derived from OA patient chondrocytes and synovial cells. Four novel gene therapies demonstrated a 2.6-fold increase in glycosaminoglycan (GAG) content compared to FGF18, alongside reduced inflammatory and matrix-turnover biomarkers. The top two candidates were then administered intra-articularly into two preclinical mouse models of OA, namely, >2-year-old C57Bl6/J mice with spontaneous OA (n=16 joints per group) and monoiodoacetate (MIA) mice with inflammatory joint pain (n=10 joints per group). After six weeks, histological analysis revealed significant improvement in cartilage degeneration scores in the aged mice for both treatments, confirming structural modification potential. In the MIA pain model, both AAV gene therapies significantly restored weight bearing on the affected limb, indiciating reduction in pain.
Heart failure: A total of 151 therapeutic candidates were screened in 16-week-old female ZSF1 obese rats, a gold-standard model of heart failure with preserved ejection fraction (HFpEF). The screen incorporated positive control genes with established relevance to HF pathways or ongoing preclinical/clinical development. Transcriptomic analysis identified ten lead candidates, which were subsequently administered intravenously in two independent models of HF, namely, ZSF1 obese rats (n=12 per group) and the high-fat diet + L-NAME mouse model (n=20 per group). Here, at least one of the chosen interventions improved parameters of diastolic dysfunction on echocardiography, such as e' and E/e', and showed a reduction in hypertrophy. Further assessment was conducted using treadmill tests and pressure-volume loops to measure phenotypic improvements by the therapeutics.

Conclusions:
These findings demonstrate that *in vivo* pooled mosaic screening can uncover multiple therapeutic interventions for complex age-related diseases such as OA and HF. Several of these candidates are now progressing through IND-enabling studies. This platform is now being applied to additional indications, including Idiopathic Pulmonary Fibrosis (IPF), Metabolic Dysfunction-Associated Steatohepatitis (MASH), and obesity, further highlighting its potential for broad therapeutic impact.



360 Optidys: a Dual-AAV Gene Therapy Strategy for Duchenne Muscular Dystrophy

Sonia Albini[1]*, Louna PILI[2], Laura PALMIERI[3], Laurine Buscara[4], Tanguy Corbel[5], Nathalie Danièle[6], Isabelle Richard[7]*
[1]GENETHON, EVRY, france, France, [2]Genethon, Evry-Courcouronnes, Essonne, France, [3]GENETHON, EVRY, Paris, France, [4]GENETHON, Evry, Essonne, [5]genethon, evry, France, [6]Généthon, Evry, France, [7]GENETHON, EVRY, Essonne, France

Duchenne Muscular Dystrophy (DMD) is a still incurable severe muscle wasting disease, leading to wheelchair dependence and premature death. DMD is caused by X-linked mutations in the dystrophin gene that result in a total lack of dystrophin, a crucial protein required for the preservation of muscle integrity following mechanical stress. Although DMD is a suitable disease for gene replacement therapy, the extent of Dystrophin transcript size exceeds by far the AAVs cargo capacity and only short versions of dystrophin can be accommodated. Several forms of microDys are currently being investigated in clinical trials. However, while the therapeutic effects are unequivocally met in the animal models, results from clinical trials highlighted an insufficient correction of the disease and unexpected adverse immunogenic events triggered by AAV delivery. This evidence supports the necessity to identify strategies to face the challenges of safety and efficacy.

It is still unclear to which extent microdystrophins can replace the full-length dystrophin function in human patients, as short versions lack structural and signaling domains important for the optimal function of the protein. We then generated a larger version of dystrophin (quasidystrophin-qDys EP2020/05837) including key domains for signaling protein and cytoskeleton organization, by a dual-AAV system based on homologous recombination. We evaluated the efficiency and safety parameters of our system by employing a ddPCR-based methodology demonstrating that our Dual AAV approach, systemically administered in the severe D2-mdx mice model, led to high transgene reconstitution efficiency and negligible ITRs-dependent concatemerization. This phenomenon led to remarkable protein restoration in muscles where lower fibrosis and higher muscle force strength were obtained compared to mice expressing a similar amount of microdystrophin protein.

We explored the therapeutic efficacy of our gene candidate in both DMD mouse and rat models, by employing LICA, our newly generated proprietary capsid with higher muscle tropism and liver detargeting confirmed in NHP, which allows superior efficiency in delivery and consequently the use of lower, thus safer, doses. In particular, both D2 mdx mice and DMD rat model (delEx45) treated with LICA-qDys (OPTIDYS) led to outstanding expression levels of the reconstituted dystrophin form in all muscles and to global improvement of muscle pathology and function. Moreover, the therapeutic efficacy and safety of Optidys are currently being investigated in our DMD rat model that shows a severe cardiac phenotype to evaluate the effect and safety on heart function.

In conclusion, OPTIDYS has the potential to safely increase the correction of the disease at a higher level than the current microDys approaches, keeping in mind that supportive strategies might be needed to further improve first-generation gene therapies and are currently under investigation.

361 Hepatocyte Tropism of a Bioengineered AAV3B Capsid Variant in a Machine-perfused Normal and Steatotic Human Liver

Wenjun Zhang[1], Sandeep Kumar, Maite Munoz[2], Moanaro Biswas[3], Sergei Zolotukhin[4], Ype De Jong[5], Chandrashekhar Kubal[1], Roland Herzog[6]*
[1]Indiana University School of Medicine, Indianapolis, IN, [2]Gene and Cell Therapy Group IU School of Medicine Department of Pediatrics, Indianapolis, IN, [3]Indiana University, Indianapolis, Indiana, [4]University of Florida, Gainesville, FL, [5]Weill Cornell Medicine, New York, NY, [6]IU School of Medicine, Indianapolis, IN
**Corresponding Author*

The liver is an important target for adeno-associated virus (AAV)-mediated gene therapy not only for the correction of liver diseases but also for systemic delivery of therapeutic proteins, for example in treatment of hemophilia. Further advancing hepatic AAV gene transfer is hindered by the limitations of pre-clinical models in predicting the

transduction of human liver cells and by variability in the human population. For example, steatotic liver disease has become highly prevalent while limited data are available on the impact of steatosis on hepatocyte (HC) transduction. Previously, we identified a potential candidate for human liver gene transfer, AAV3B-v4, which was selected from a combinatorial capsid library. This capsid demonstrated enhanced transduction efficiency in mouse passaged primary human HCs as well as in humanized liver chimeric mice when compared to other AAV3B variants (Hum Gene Ther 34:289-302, 2023). To further characterize and define the transduction pattern of this vector in human liver, we administered scAAV3v4-CB-mScarlet vector to a normal and a steatotic human liver maintained on normothermic machine perfusion.

Two donor livers were sourced from the Indiana Donor Network. Donor 1, a 38-year-old Caucasian male (BMI 22.0), provided a non-steatotic liver categorized as donation after circulatory death (DCD). Donor 2, a 58-year-old African American male, provided a steatotic liver categorized as donation after brain death, exhibiting 30-40% macrovesicular steatosis with F2-3 bridging fibrosis and moderate portal inflammation. Both livers were declined for transplantation due to slow lactate clearance. To evaluate transduction, 1×10^{13} viral genomes (vg) of scAAV3v4-CBA-mScarlet were infused via the portal vein after 14 hours (donor 1) and 11 hours (donor 2) of perfusion, once lactate levels dropped below 3.0 mmol/L and HCs were analyzed at the completion of the experiment.

Liver viability was sustained for 110 hours (donor 1) and 60 hours (donor 2), evidenced by recovery in lactate clearance, glucose metabolism, pH, and bile production. Perfusion continued until lactate levels began to rise, after which the livers were harvested. Vector clearance was assessed by measuring AAV genome copies in the perfusate. For donor 1, 2.8×10^{7} vg/mL (~0.5% of total infused virus) were detected 4 hrs post-infusion, declining to 4.2×10^{6} vg/mL by the end of the perfusion. For donor 2, 6.8×10^{7} vg/mL (~1% of the total virus) were detected 2 hrs post-infusion, peaking at 1.8×10^{8} vg/mL at 17 hours before declining. Flow cytometry showed mScarlet transgene expression in ~40% of HCs in donor 1 and ~21% in donor 2, which was confirmed by fluorescent microscopy of freshly isolated HCs (with persistent expression observed during a 16-day culture period). Interestingly, mScarlet expression was minimal in non-parenchymal cells (NPCs), such as endothelial and Kupffer cells (~0.1%) in donor 1 but was higher in $CD45^{+}$ NPCs (~5%) in donor 2. The extended perfusion period for donor 1 (~4.5 days versus ~2.5 days for donor 2) likely contributed to the higher transduction of HCs (~40% vs. ~21%). Despite this, hepatocytes in the steatotic liver showed substantially brighter transgene expression. These findings are consistent with our observations in primary human HCs models that show enhanced transduction in steatotic HCs.

362 Interfering with CUG toxic repeats using AAV.U7snRNA rescue myotonia and splicing defects in myotonic dystrophy type 1

Nicolas Wein[1], Camila Almeida[2], alex Brinkman[3], Charlie Wendt[4], anton blatnik[4], andrea delgado[3], Liubov Gushchina[5], David Arnold[6], Robert Weiss[7], Arthur Burghes[8]
[1]Center for Gene Therapy - Nationwide Children's Hospital, Columbus, OH, [2]Nationwide Children's Hospital, Columbus, OH, [3]abigail wexner research institute at nationwide children's hospital, columbus, [4]the ohio state university, columbus, [5]The Ohio State University and Nationwide Children's Hospital RI, Columbus, OH, [6]University of Missouri, Columbia, MO, [7]The University of Utah Department of Human Genetics, [8]Ohio State Universoty

Myotonic dystrophy type 1 (DM1) is the most common form of muscular dystrophy in adults affecting the skeletal muscle, heart, and brain. It is caused by a CTG repeat expansion in the 3'UTR of the *DMPK* gene. The CUG repeats aggregates with muscle-blind proteins (MBNLs) in nuclear *foci*, leading to the impairment of several mRNA processing functions, including alternative splicing. The reversal from an adult to a fetal splicing profile alters or abrogates the function of a myriad of proteins, resulting in dysfunction in multiple organs. Currently, there is no treatment available for DM1 patients. Antisense oligonucleotides (ASOs) aiming to knock down *DMPK* expression or bind to the CUG repeats and release MBNL have been explored, with promising results in animal models. Unfortunately, a clinical trial with these drugs, while safe, failed to show improvement in patients, probably due to intrinsic limitations of ASOs. To overcome this limitation, we designed modified U7 small nuclear RNAs containing a promoter and antisense sequences targeting the 3'UTR region to promote *DMPK* knockdown or steric hindrance of the CUG repeats. We used patient-derived cell lines to test our approach, and the effect of the treatment was evaluated using RNA FISH combined with MBNL1 immunostaining for *foci* quantification and MBNL1

localization. Gene expression and splicing profiles were assessed by RNAseq and selected candidate genes were confirmed by RT-PCR. The AAV treatment reduced the *foci* number, released MBNL1 from the CUG *foci*, and shifted the splicing profile. Based on the *in vitro* results, we selected one vector candidate to test *in vivo*. We injected AAV1.U7snRNAs in the tibialis anterior (TA) and gastrocnemius (Gas) of HSA^{lr} mice, which express CTG repeats in skeletal muscles only. Eight weeks post-injection, we submitted the animals to muscle torque and electromyography (EMG) tests and collected the muscles for further analysis. The functional tests revealed reduced mechanical myotonia (a major phenotype in DM1 muscles) and even the absence of electrical myotonia in individual muscles. RNA FISH quantification showed a reduced number and intensity of *foci* in TA and Gas. The reduction in *foci* led to improved splicing of *Serca1, Mbnl1, Ldb3,* and *Clcn1* transcripts. In conclusion, U7snRNAs that interfere with the CUG-expanded mRNA can reverse DM1 pathology with the restoration of molecular features *in vitro* and *in vivo*, accompanied by significant amelioration of muscle physiological properties. This work will provide the basis for testing the first AAV-based gene therapy for DM1 in humans.

363 Insulin Replacement Gene Therapy Using a Novel Glucose- and Drug-Inducible Adeno-Associated Virus

Aleksandra Maciejczuk[1], Stefan Hargett[1], Igor Correia-Rocha[2], Iuliia Vitko[1], Jun Xie[3], Guangping Gao[3], Thurl Harris[1], Edward Perez-Reyes[1]*

Objective:
To develop AAV-based gene therapies that can be activated by the FDA-approved drug doxycycline (Dox). We present proof-of-concept studies using diabetic mice that show effective delivery and pharmacological regulation of an insulin gene replacement therapy.

Methods:
Glucose-inducible promoters have been developed by incorporating the DNA sequences that bind the carbohydrate response element binding protein, ChREBP. We developed a novel promoter with multiple repeats of ChREBP binding motif 1 and motif 2 (Jeong et al., 2011). For Dox regulation we engineered a single AAV to contain both components of the 3G Dox-on system (Clontech): 1) the reverse tetracycline transactivator (rtTA), whose expression is controlled by the glucose-inducible promoter; and 2) the tet operator, where the rtTA binds in the presence of Dox to induce the expression of recombinant insulin. Recombinant AAV8 pseudovirions were injected into the tail vein of diabetic mice (streptozotocin model). Blood glucose levels were monitored after a 4 hour fast and after an intra-peritoneal glucose tolerance test (GTT). Insulin production was monitored using serum samples and an ELISA directed against the human C-peptide produced by the rAAV. Expression of recombinant insulin mRNA was also validated using RT-qPCR. AAV delivery was confirmed by qPCR on liver DNA.

Results:
Design of the AAV targeting plasmid was guided by in vitro studies measuring the expression of the fluorescent reporter, Fusion Red. In vitro experiments showed 4-fold regulation of expression by glucose and robust regulation by doxycycline with a large dynamic range (1,000-fold). All in vivo experiments were blinded and included 4 groups of mice (C57Bl/6, n=5 each): Group 1 were control (CTRL) mice (not diabetic, no AAV); Group 2 was a negative control (diabetic, null AAV); while Groups 3 and 4 tested variations of the rAAV-Insulin gene therapy. Baseline studies established that STZ-treated mice lost their ability to control blood glucose. Strikingly, administration of Dox normalized glucose handling in groups 3 & 4 to similar levels as observed in the naive group. We also performed dose response studies varying the concentration of Dox in the chow (Figure 2.). Very high doses of Dox (100 mg/kg) actually lowered blood glucose below levels observed in CTRL. Titration down to 10 mg/kg Dox in chow restored blood glucose in diabetic mice to the control level.

Significance:
The human insulin replacement market has been estimated at $42 billion dollars. Most commonly used strategies rely on the patient monitoring of their blood glucose and daily subcutaneous injections of recombinant insulin. The

present research suggests that a one-and-done pharmacologically inducible insulin gene replacement strategy can be developed.

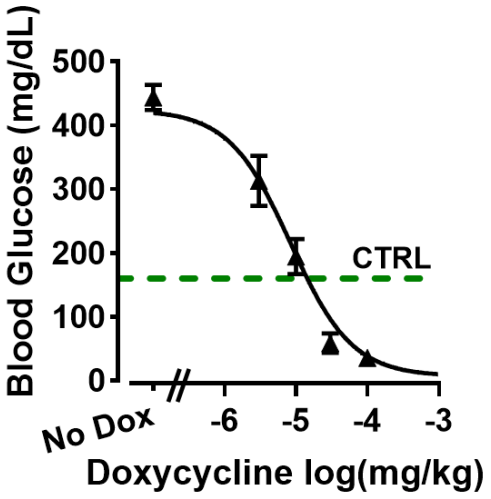

Fig. 2 Blood glucose levels in response to Dox concentrations in chow.
Titration down to 10 mg/kg Dox in chow restored blood glucose in diabetic mice to the control level.

364 Endoscopic Ultrasound-Guided Delivery of Human Glucagon-like Peptide-1 Pancreatic Gene Therapy: Safety and Feasibility in a Porcine Model

Timothy Kieffer[1], Jacob Wainer[1], Michael Biasella[1], Lindsay Schulman[1], Nicole Picard[1], Jessica Von Stetina[2], Rebecca Reese[1], Alice Fitzpatrick[2], Emily Cozzi[3], Shimyn Slomovic[4], Jay Caplan[2], Harith Rajagopalan[5]
[1]Fractyl Health, Inc., Burlington, MA, [2]Fractyl Health, Burlington, MA, [3]Fractyl Health, Attleboro, MA, [4]Fractyl, Arlington, MA, [5]Fractyl Health, Lexington, MA

Introduction:
Glucagon-like peptide-1 (GLP-1) is a key hormone regulator of metabolism, and GLP-1-based therapies are now an important mainstay of obesity and type 2 diabetes (T2D) care. Yet, treatment discontinuation is frequent and typically results in near-complete weight regain and loss of metabolic benefits for patients, which underscores an urgent unmet need for long-term therapeutic durability. We have developed a novel AAV-based pancreatic gene therapy (PGTx) platform with an endoscopic ultrasound (EUS)-guided delivery system to enable durable, nutrient-responsive, beta-cell-driven GLP-1 production (Smart GLP-1) toward this unmet need. In proof-of-concept murine models of metabolic disease, GLP-1 PGTx treatment improved hyperglycemia, lowered body weight, and sustained weight loss after semaglutide withdrawal. Here, we aimed to establish the feasibility and safety of delivering RJVA-001 (GLP-1 PGTx candidate for T2D) via an endoscopic transgastric route of administration (ROA) in Yucatan pigs.

Methods:
To directly target the pancreas with gene therapy, an echoendoscope with a proprietary automated fluid delivery system was inserted into the porcine stomach and a custom 27G needle was used to transgastrically infuse RJVA-001 [AAV9 vector encoding a human insulin (hINS) promoter and GLP-1 transgene, 6e13 total vector genome (VG)] into the splenic lobe of the pancreas under EUS guidance (N=5). Serum lipase and neurofilament light chain (Nf-L) were evaluated from baseline through study termination as markers of pancreatitis and dorsal root ganglia (DRG) toxicity, respectively. Pigs were necropsied at 5 weeks post-procedure and pan-pancreatic biopsies (up to 20 per pig) were assessed to establish vector copy number (VCN), transgene RNA and protein expression as indicators

of transduction efficiency and RJVA-001-driven GLP-1 production. Dual hINS/GLP-1 immunofluorescence was employed to assess beta-cell promoter specificity. Histological assessments of tissues including the pancreas, liver, heart, and DRG were carried out to evaluate inflammation.

Results:
All animals successfully underwent EUS-guided RJVA-001 delivery with correct pancreatic needle placement confirmed by ultrasound and no behavioral indicators of distress or discomfort observed. Mean lipase levels remained in the normal range [3.5±0.5 U/L standard error of the mean (SEM)] post-procedure, and no elevations in Nf-L were detected across all timepoints evaluated, with levels remaining below 10 pg/mL. Mean pancreatic VCN and RJVA-001 RNA levels were positively correlated ($r=0.85$, $p<0.0001$). Likewise, mean RNA levels correlated with RJVA-001-driven GLP-1 protein levels ($r=0.85$, $p<0.0001$). Active mean GLP-1 protein expression was five-fold higher in treated vs. endogenous levels in untreated controls (185±32 vs. 36±9 ng/g total protein SEM, $p<0.02$). GLP-1 positive immunofluorescence was observed in pancreatic islets, and co-localized with insulin, demonstrating beta-cell transduction and promoter specificity. No inflammation above background findings was observed in the pancreas, liver, heart, and DRG.

Conclusions:
Taken together, these data suggest that RJVA-001 can be safely and reproducibly delivered transgastrically to the pancreas leading to local, beta-cell specific production of GLP-1. These findings represent a major stride forward toward advancing this PGTx delivery procedure and candidate toward T2D first-in-human studies.

365 Gene Therapy of Computationally Designed IL-10 in DSS-induced Colitis Mouse Models

Jordan Stokes[1], Sihong Song[1]*, Clive Wasserfall[1], Allison Bayer[1], Li Chenglong[1], Iram Hyder[2], Peter Ramdhan[1], Zhihang Shen[1]
[1]University of Florida, Gainesville, FL, [2]University of Flordia, Gainesville, FL
**Corresponding Author*

Interleukin-10 (IL-10) is an immunoregulatory cytokine that can mediate both anti-inflammatory and pro-inflammatory effects. We aimed to develop IL-10 mutant drugs that have anti-inflammatory function, but no or minimal pro-inflammatory effect for the treatment of inflammatory bowel disease (IBD), which is associated with IL-10 deficiency. Using structure-based computational-design approach, we have designed several IL-10 mutants and generated recombinant adeno-associated virus (rAAV) vectors expressing wild type (IL-10W) or mutant IL-10 molecules (IL-10A, B and C). To test the therapeutic effect of these vectors, we employed dextran sodium sulfate (DSS) induced colitis mouse models. In DSS-induced acute colitis model (4% DSS in drinking water for 5 days), we showed that our rAAV8 vectors ($1x10^{11}$vg/mouse) mediated high levels of IL-10 in circulation. We observed that the expression levels decreased after DSS treatment suggesting the increase of consumptions of IL-10 during the disease development. Clinical evaluations showed the disease activity index (DAI) in IL-10C on the 7th day after DSS-induction was significantly lower than that in IL-10W group. In addition, the spleen weight in IL-10C group was significantly lower than that in IL-10W group. Flowcytometry analyses showed that our mutants have significantly lower activities in stimulating NK cells than IL-10W, while maintaining similar effects to IL-10W on monocytes indicating the mutants have reduced-pro-inflammatory effects and retained-anti-inflammatory effects. To test the long-term effect of IL-10 mutants, we performed IL-10 mutant gene therapy ($5x10^{10}$ or $1x10^{10}$ vg/mouse) in DSS-induced chronic colitis mouse model (3 cycles of DSS-induction). The results from this study showed that the cumulative DAI (AUC) of IL-10C group was significantly lower that of IL-10W. In summary, computational designed IL-10 mutants have improved function in regulating inflammation. Gene therapy of these mutants may provide a novel therapy for inflammatory bowel disease (IBD) and other chronic inflammatory diseases.

Translational Approaches: Gene Therapy of Neurological Diseases in Large Animal Models

366 Four year follow up of AAV-mediated gene replacement therapy in a large animal model of Krabbe disease.

Allison Bradbury[1], Steven Gray[2], Ernesto Bongarzone[3], Charles Vite[4]
[1]Nationwide Children's Hospital, Columbus, Ohio, [2]University of Texas Southwestern Medical Center, Dallas, Texas, [3]University of Illinois at Chicago, Chicago, IL, [4]University of Pennsylvania

Krabbe disease commonly presents as a devastating, early-onset disease with rapid progression and premature death by 2 years of age. We are uniquely experienced with an invaluable large animal model of Krabbe disease. The canine model of Krabbe disease closely recapitulates the genetic, biochemical, and physiological disease in humans and provides translational advantages for evaluation of genetic therapies.

AAV9-mediated gene therapy administered directly into the cerebrospinal fluid (CSF) at the cisterna magna of 2-week-old presymptomatic Krabbe dogs increased GALC enzyme activity, normalized psychosine concentration, improved myelination, and attenuated inflammation in both the CNS and PNS in our initial reporting up to one year post-treatment (Bradbury AM et al. *Krabbe disease successfully treated via monotherapy of intrathecal gene therapy*. Journal of Clinical Investigation 2020; 130). We now report that long term follow up demonstrated that this gene replacement therapy mitigated clinical neurological dysfunction, allowing dogs to live beyond 3.5 years of age (predefined study endpoint), more than 11 times longer than untreated dogs. In two dogs, megaesophagus warranted euthanasia that was distinct from traditional Krabbe disease neurological disease progression. We speculate that the gene therapy did not completely correct the autonomic nervous system in these animals, as has been shown in other large animal models of lysosomal storage disorders. In a subset of the remaining treated dogs which lived >3.5 years of age, postmortem analysis revealed emergence of pathology in select brain regions including globoid cell accumulation, axonal degeneration, and white matter gliosis in the centrum semiovale, internal capsule, and corona radiata. While other brain regions, including the cerebellum, showed complete correction of disease pathology and intact myelination. We quantified GALC activity, psychosine levels, and inflammatory markers including GFAP for astrocytosis and CD68 for microgliosis in numerous brain regions. We corroborated these findings with clinically relevant readouts, including MRI and nerve conduction velocity testing, and longitudinal biomarker analyses of serum and CSF psychosine levels. We hypothesize that irreversible myelin loss was already present at the early 2 week treatment time point and coupled with reactivation of the disease process due to adult myelin remodeling and exhaustion of local gene correction in these focal lesions. This data will provide critical insight to both the necessary timing of treatment and the durability of AAV gene therapy, particularly for white matter diseases, using an invaluable large animal model that closely recapitulates human disease.

367 Evaluating delivery methods for treatment of neurodegenerative disease in large animal models.

Neurofibromatosis 1 (NF1) is a neurocutaneous syndrome characterized by the development of tumors in the central or peripheric nervous system (CNS and PNS respectively), that affects 1 in 2500-3000 births. NF1 is caused by dominant mutations in the NF1 gene that encodes a protein, neurofibromin, that is a negative regulator of Ras/Raf/MEK-pathway and therefore has as a tumor suppressor activity. The loss of neurofibromin results in tumorigenesis in the skin, nerves, brain but also results in neurological signs like Autism spectrum disorder or attention deficit disorder. The lack fo Ras regulation leads to excessive cell growth provoking the development of tumors in a large verity of tissues all over the body. Examples include neurofibromas, and plexiform neurofibromas. The appears in late childhood and increase in number with age. The fibromas can vary in number form few to thousands. They can cause pain, disfigurement, local compression and loss of function of the affected area which result in a gravely affected quality of life and decreasing life expectancy. Genetically, neurofibromas are developed when the normal copy of the NF1 gene is lost in Schwann cells, a genetic mechanism known as loss-of-

heterozygosity (LOH). Gene therapy using viral vectors such as adeno-associated virus (AAV) is a promising approach for NF1 as it allow to correct the underlaying genetic defect though transporting the therapeutic gene directedly to the affected tissues. Our team has developed a NF1 minigene that halts tumor progression in NF1 mice. Given the multisystem involvement of NF1 we conducted large animal studies to determine optimal route of injection, biodistribution and safety for future human clinical trials. Cranial sub-leptomeningeal injection (Fig. 1A) of MRI contrast agent was far superior to CSF delivery, with strong enhancement of deep brain structures including the striatum and thalamus (Fig. 1B). Therefore, we tested sub-leptomeningeal injection of AAV and compared it with CSF delivery. We treated pigs and sheep with high dose AAV ~1-2 E14vg by leptomeningeal injection and compared it with cisterna magna injection or combination of multiple CSF routes (bilateral ICV, CM and lumbar intrathecal; (Fig 1C-F). Sub-leptomeningeal injection showed high vector expression in the parietal cortex near the injection site when compared to CSF injection, and therapeutically relevant delivery in deeper areas of the brain[JG1] (thalamus, striatum, parietal cortex) that were on par with the CSF delivery methods (Fig. 1C&D). This was corroborated with immunohistochemistry which showed striking staining throughout the parietal cortex and into the white matter approximately a 4mm deep from the surface of the brain near the injection site (Fig. 1F). The meninges adjacent to the injection site showed extraordinarily high vector genomes in all treatment groups with a 2x increase in the leptominengial injection. Interestingly, with sub-leptomeningeal injection we did not observe transuducion (add numbers) of the liver as compared to CSF injection (add numbers) (Fig 1E). Altogether, our data indicate that leptomeningeal injection far surpasses the cortical biodistribution of cisterna magna within the gyrus containing the injection site, with diffusion of viral particles to other brain areas similar to the CSF injection groups. In conclusion, sub-leptomeningeal injection is a promising therapeutic AAV delivery method for treatment of NF1.

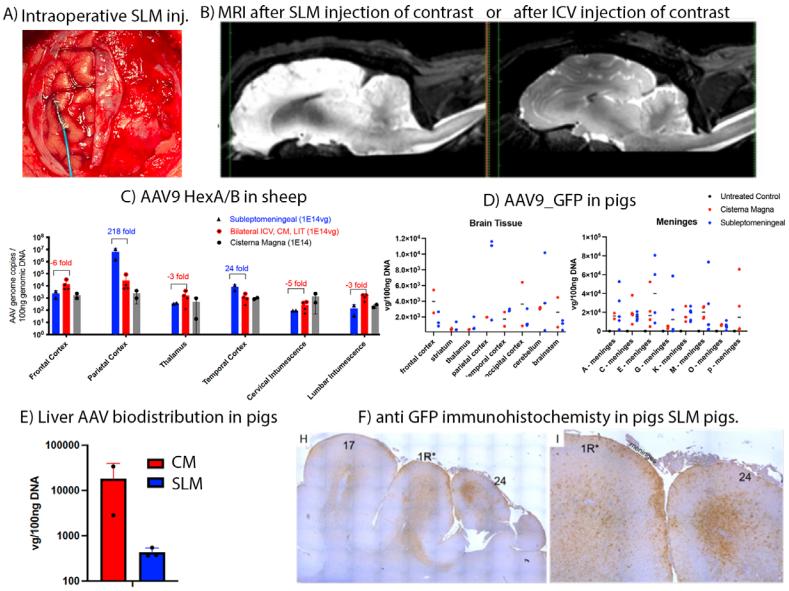

Figure 1. Sub-leptomingeal injection (SLM) compared to CSF injection delivery routes. A) Interoperative image of a pig recieving a subleptomeninges injection over the parietal cortex. B) MRI after SLM injection compared to intracerebroventricular (ICV) injection. C) vector genomes in the brain and spinal cord after SLM injection or combined bilateral ICV in sheep with 1E14vg AAV9. D) Vector genomes in the brain of pigs after 1.6E14vg of AAV9-GFP adminstered by SLM injection. E) liver biodistribution after SLM or cisterna magna (CM) injection. F) GFP immunoreactivity in the parietal cortex of pigs after 1.6E14vg AAV9-GFP.

368 AAV gene therapy for GBA-PD and Gaucher Disease

Swathi Ayloo[1]*, Jae Ryu[2], Shih-Ching Chou[3], charles miller[4], Lydia Blatnik[4], Erik Wischhof[2], Jie Bu[2], Lilu Guo, Mahmud Hossain[2], Dhiman Ghosh[4], William McCarty[1], Yao Chen[2], Ann Byrne[4], Lilly Chai[4], Bradford Elmer[5], Christian Mueller[6], Shyam Ramachandran[6]

Mutations in the *GBA1* gene, which encodes the lysosomal enzyme glucocerebrosidase (GCase), are a common genetic risk factor for Parkinson's disease (PD) and causative for Gaucher Disease (GD), a rare lysosomal storage disorder. Both diseases converge on GBA1-driven lysosomal dysfunction, leading to impaired lipid metabolism and cellular toxicity. Here, we report the development of an AAV-mediated *GBA1* replacement therapy for treating GD and GBA-PD through a one-time infusion delivered intra-CSF intravenously (for GD Type 1) or intra-CSF (for GBA-PD). We engineered human *GBA1* to be readily secretable to facilitate cross-correction across multiple tissues. We packaged our payload in AAV.GMU01, a capsid with superior biodistribution and transgene expression in both the central nervous system (CNS) and peripheral tissues. In pharmacology and efficacy studies using conduritol ß-epoxide (CBE)-induced lipid flux models in both mice and non-human primates (NHPs), our lead candidate SS3-GBA1 demonstrated robust secretion, efficient lipid clearance, and significant cross-correction. Importantly, huGBA1 protein levels in SS3-GBA1 injected NHP brain tissues reached ~50% of levels observed in healthy human donor brain tissues. Given that GBA-PD patients are carriers of heterozygous mutations in GBA1, our data indicate near-physiological restoration of GBA1 protein that is required for clinical efficacy. Intravenous dosing of SS3-GBA1 promoted effective lipid clearance across multiple peripheral tissues including liver, spleen, bone marrow and muscles, key target tissues in GD Type 1. Effective lipid clearance in the bone marrow is a notable advantage of our approach for GD Type 1 when compared to the enzyme replacement therapies (ERTs), which lack bone marrow penetration. Importantly, across all our studies, AAV.GMU01-SS3-GBA1 is well tolerated with no adverse findings, demonstrating a favorable safety profile. These findings establish AAV.GMU01 SS3-GBA1 as a promising therapeutic candidate capable of addressing the unmet needs of both GD and GBA-PD patients through a single gene therapy product. By restoring GBA1 protein levels to physiological levels and enabling effective lipid clearance across both CNS and peripheral tissues, this strategy offers a transformative approach to treating lysosomal dysfunction in these genetically defined populations.

369 AAV-mediated Delivery of an Engineered Zinc Finger Lead to Selective and Potent Repression of Nav1.7 in Human Sensory Neurons and Nonhuman Primates DRG Nociceptors Following Intrathecal Injection

Mohammad Samie[1], Toufan Parman[2], Mihika Jalan[3], Jisoo Lee[3], Patrick Dunn[4], Jason Eshleman[5], Yonghua Pan[4], Marina Falaleeva[1], Sarah Hinkley[6], Tammy Chen[7], Sumita Bhardwaj[8], Michael Trias[8], Anthony Chikere[7], Madhura Som[1], Yanmei Lu[9], Sandeep Yadav[10], Kathleen Meyer[4], Bryan Zeitler[3], Amy Pooler[3]

Idiopathic small fiber neuropathy (iSFN) is a type of chronic neuropathic pain that is caused by severe and permanent damage to peripheral sensory neurons. iSFN has an estimated prevalence of at least 43,000 patients in the U.S. and manifests as severe pain in lower extremities, which leads to a major impact on quality of life. Current pain medications for iSFN are inadequate; effective pain reduction occurs in less than 50% of the patients and the medications are often associated with severe side effects. In humans, the Nav1.7 sodium channel, which is encoded by *SCN9A* gene, is involved in a spectrum of inherited pain-related disorders and has emerged as a promising target for analgesic drug development. However, the development of a selective Nav1.7 inhibitor has been challenging in part due to structural similarities among other Nav channels. We have developed an engineered zinc finger repressor (ZFR) targeting *SCN9A* with high potency and selectivity as a potential treatment for iSFN. *In vitro*, adeno associated virus (AAV)-mediated delivery of the ZFR (AAV-ZFR) in human iPSC-derived GABAergic and sensory neurons resulted in a 90% reduction of *SCN9A* over a wide-dose range with no detectable off-target activity as measured by global transcriptomics analysis. Microelectrode array (MEA) recordings in human sensory neurons showed a significant decrease in the average neuronal firing rate in response to noxious heat following AAV-ZFR treatment, illustrating reduced Nav1.7 activity. In NHPs, four weeks after a single intrathecal (IT) injection of AAV-ZFR, a dose-dependent repression of *SCN9A* was observed in bulk DRG tissue at three different levels (lumbar, thoracic, and cervical). While up to 60% repression of *SCN9A* was observed across different DRG levels, other Nav channels, such as *SCN8A* (Nav1.6), *SCN10A* (Nav1.8), and *SCN11A* (Nav1.9), were not affected, demonstrating the selectivity of AAV-ZFR toward *SCN9A* in NHPs. Additionally, single-cell analysis using RNAscope revealed potent *SCN9A* repression in CGRP-positive nociceptors in lumbar DRG following IT injection. The treatment was well tolerated in NHPs, with no dose-limiting findings observed four weeks following the treatment. The results

demonstrate the potency and selectivity of a AAV-ZFR in NHPs and support further development of ST-503, an investigational therapy for the treatment of intractable pain due to iSFN.

370 Development and validation of an intravenous AAV gene therapy for mucopolysaccharidosis type IIIB in mouse and dog model of the pathology

MPSIIIB is an autosomal recessive lysosomal storage disorder, caused by alpha-N-acetylglucosaminidase (NaGlu) enzymatic deficiency leading to accumulation of Heparan Sulfate Oligosaccharides (HSO) in tissues including the central nervous system (CNS). Patients manifest with early developmental delays followed by severe behavioral abnormalities, progressive neurodegeneration, and death before the age of 20 years. To date, there are no curative therapies for MPSIIIB. We have previously conducted an AAV5 phase I/II intracerebral gene therapy trial that has shown promising results in four MPSIIIB patients with best results being obtained in the youngest patient (18 months-old). However, disease progression in tissues as important as meninges, brain capillary walls, and choroid plexus was presumably not stopped. Therefore, treatment of patients younger than 2 years and the delivery of NAGLU both within and outside the brain was concluded.

We recently described a novel AAV gene therapy using AAVPHP.eB-CAG-NaGlu vector with intravenous delivery in mouse model and combine intracerebral and intravenous delivery in dog and non-human primates. We demonstrated a good efficacy but some local inflammation at the injection site in the brain.

We thus improved our therapeutic strategy by using last generation AAV, a serotype able of large Blood brain barrier crossing after intravenous delivery notably in large animals. We demonstrate a large CNS transduction of the vector in mouse and NHP after intravenous delivery as well as supra physiological NAGLU expression and activity and a perfect tolerance of the AAV on all tissues. Efficacy and safety studies are currently ongoing in the dog model of the pathology and data will be presented.

371 Vagus Nerve Delivery of AAV9/GAN Is Required After Intrathecal Administration for a Full Rescue of Autonomic Nervous Dysfunction in Giant Axonal Neuropathy

Nanda Regmi[1], Matthew Rioux[2], Xin Chen[3], Yuhui Hu[4], Rachel Bailey, Steven Gray[5]*
[1]UTSW, Coppell, TX, [2]University of Texas Southwestern Medical Center, Dallas, TX, [3]UT Southwestern Medical Center, Dallas, TX, [4]UT Southwestern, Dallas, [5]University of Texas Southwestern Medical Center, Dallas, Texas

Giant axonal neuropathy (GAN) is a pediatric progressive neurodegenerative disease caused by homologous loss-of-function mutations in the gene encoding gigaxonin. GAN patients manifest clinical symptoms related to the loss of function of the central nervous system, the peripheral nervous system, and the autonomic nervous system (ANS). A Phase 1 clinical trial (NCT02362438) evaluating intrathecal (IT) administration of AAV9/GAN has shown partial rescue benefits in GAN patients (Bharucha-Goebel et al., NEJM, 2024). A notable therapeutic gap from the IT administration is suboptimal targeting of key ANS neuronal populations, leading to ANS dysfunction and additional clinical unmet need. Although IT administration of therapeutic agents is widely used and has a wider applicability, IT injection of AAV9/GAN alone was insufficient to rescue the altered ANS functions in GAN model rats (ASGCT-

2020, Abstract #936). In that pilot study, a combination of IT and vagus nerve (VN) mediated AAV9/GAN delivery (same day injection) was observed to be effective compared to IT alone. Additional studies were carried out to identify an appropriate vg dose via the VN route to maximize transduction of ANS targets, and optimize the use of an FDA-approved and compatible tracking dye to monitor VN injection fidelity (ASGCT-2023, Abstract#1270). In the present study, we report a complete rescue benefit of ANS parameters in GAN rats with a combination of IT and VN administration. Notably, the IT and VN injections were spaced apart in this study, modeling a redosing scenario where patients that previously received an IT injection of AAV9/GAN would receive a later VN injection. First, at ~6.5 months old, GAN homozygous KI rats were treated IT with 20 µl of AAV9/GAN (3.6 E11 vg/rat), while GAN heterozygous KI rats (controls) were treated IT with 20 µl of vehicle. Two months following the IT injection, all rats treated with AAV9/GAN were randomly subdivided into four different subgroups: Only IT, IT+VN low dose (LD, 6.7E10 vg/rat), IT+VN middle dose (MD, 2.0E11 vg/rat), and IT+VN high dose (HD, 6.0E11 vg/rat). All subgroups, except the "Only IT" group, then received an injection of AAV9/GAN into the left VN at the cervical region. All groups of rats received a telemetry sensor implantation at 17 months old to record the ANS parameters (temperature, heart rate, blood pressure, and respiratory rates). Upon 1 mg/kg pilocarpine stimulation, all groups of rats with IT+VN (LD, MD, and HD) showed normalization of temperature, heart rate, and respiration rate compared to the "Only IT" group. No abnormal blood pressure phenotype was observed in any of the animals, compared to het control rats. These results indicate that IT administration of AAV9/GAN alone is not enough to rescue GAN ANS dysfunction, but a subsequent delivery of AAV9/GAN via the VN can rescue these deficits. Pivotal GLP toxicology studies were carried out in normal canines, which received an IT injection of AAV9/GAN followed by a VN injection of the vector or vehicle 9 weeks later. Animals received an immunosuppressive regimen matching the GAN clinical trial protocol, consisting of prednisone and rapamycin. Biodistribution to key ANS neuronal populations was achieved. No adverse effects related to AAV9/GAN were observed in dogs and rats. In January 2025, IND #31180 was cleared by the FDA to proceed, to evaluate VN administration of AAV9/GAN in GAN patients that previously received an IT injection of AAV9/GAN.

372 Sub-motor Cortex Convection-enhanced Delivery of AAV5-GDNF – a Novel Treatment Strategy for Amyotrophic Lateral Sclerosis

Neil Barua[1], Ali Bienemann[2], Sharon Kane[3], **Steven Gill[4]**
[1]Neurochase Limited, Bristol, Bristol, City of, United Kingdom, [2]University of Bristol, Bristol, United Kingdom, [3]Neurochase, Glasgow, United Kingdom, [4]Neurochase Ltd, BRISTOL, Bristol, City of, United Kingdom

Introduction
Gene therapies hold significant promise for the treatment of neurological disorders. However, achieving widespread gene expression at therapeutic concentrations in conditions characterised by degeneration of brain and spinal cord remains a significant challenge. Amyotrophic Lateral Sclerosis is characterised by degeneration of the motor pathway from cortex to spine. Extensive pre-clinical data indicate that delivery of the neutrophic factor Glial cell-line derived neurotrophic factor (GDNF) to the entire motor pathway could ameliorate symptoms and promote survival and regeneration of motor neurons. We describe an innovative method of achieving gene expression in brain and spinal cord using sub-motor cortex convection-enhanced delivery (CED) in a large animal model.

Methods
Bilateral sub-motor cortex CED of AAV5-GDNF at 2 infused titres ($2x10^{13}$ and $4x10^{13}$ Vg/mL) was performed with MRI guidance in 4 sheep using a novel acute cannula system. AAV5-GDNF was infused through a cannula targeted to the sub-motor cortex white matter through a posterior-anterior trajectory. A second more ventral cannula was inserted parallel, through which artificial CSF was infused in order to "drive" the test article into overlying motor cortex. Outcomes included MRI analysis of distribution, neurotoxicity and GDNF expression in brain and spinal cord.

Results
Gadolinium co-infusion allowed MRI-confirmation of distribution to motor cortex in all animals. No adverse surgical events were identified. No behavioural change, loss of appetite or weight loss over the 3 month study period was seen. GDNF ELISA confirmed expression at clinically-significant concentrations throughout the motor cortex of all animals. However, only the test subject receiving the lower infused titre showed GDNF expression throughout

the spinal cord. Immunohistochemical evidence of a mild immune response was identified in the high titre cohort, which was absent in the low titre test subject.

Conclusions
Sub-motor cortex CED was safe and effective, and at the lower titre achieved GDNF expression throughout the motor cortex and spinal cord at 3 months following a single infusion. This finding confirms the potential of this novel strategy for the treatment of neurological diseases characterised by widespread degeneration, with spinal cord gene expression dependent on the infused titre.

Upstream Manufacturing for AAV Vectors 1

373 Achieving Continuous Production of Recombinant Adeno-Associated Virus with Baculovirus Expression Vector System

John Joseph[1], Francesco Destro[2], Paul Barone[3], Anthony Sinskey[3], Richard Braatz[4]*, Stacy Springs[5]*
[1]Massachusetts Institute of Technology, Boston, MA, [2]Cambridge, MA, [3]Massachusetts Institute of Technology, [4]Massachusetts Institute of Technology, Cambridge, Massachusetts, [5]MIT Center for Biomedical Innovaiton, Cambridge, MA

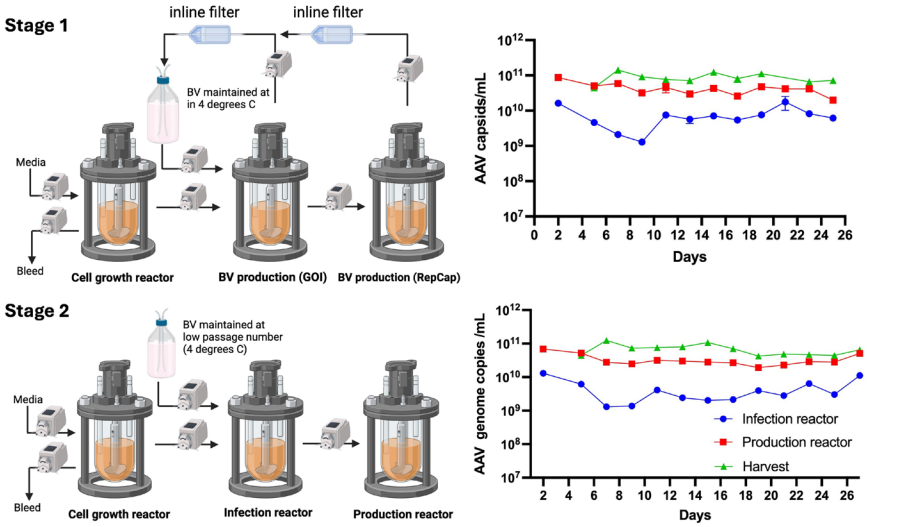
Continuous production processes offer significant advantages for biotherapeutic manufacturing, including increased productivity, improved product quality, reduced facility footprint, and decreased process turnaround time. Despite these benefits, continuous adeno-associated viruses (AAV) manufacturing has been limited due to the *in situ* formation of defective interfering particles (DIPs), which hinders continuous AAV production. This study addresses the challenge of reducing DIP propagation through the infusion of standard recombinant baculovirus and the compartmentalization of early- and late-stage infected cells, resulting in stable AAV production. AAVs were continuously produced in a series of cascading reactors, comprising a feeder reactor, an infection reactor, and a production reactor. The transfer dynamics of the inoculum across the three reactors were optimized based on the production kinetics of baculovirus and AAV derived from our mechanistic model. AAV packaging occurred in the baculovirus-infected Sf9 cells, primarily within the production reactor, which was maintained at an average residence time of approximately 60 hours. This study demonstrates the successful implementation of a continuous AAV production process, yielding over 5E10 vg/mL for 25 days. This work represents the first reported continuous AAV production process utilizing the Sf9/BEVS platform and establishes a foundation for overcoming manufacturing challenges associated with recombinant AAV (rAAV)-based gene therapies.



The schematic illustrates the continuous production of AAV using a series of cascading reactors. In Stage 1, insect cells from the growth reactor are infected with recombinant baculovirus encoding the gene of interest and AAV genes to produce a baculovirus stock. The budded baculovirus is harvested and stored at 4°C before continuous infusion into the infection reactor to maintain an MOI greater than 1 PFU/cell at Stage 2. The graphs depict successful AAV capsid and genome production in the continuous run.

374 Optimizing the TESSA® Platform for Enhanced rAAV Production

Chloã© Fustinoni[1], Tsz Chow[1], Louise Montgomery[1], Francesca Bennett[2], Siobhan Clerkin[2], Matthew Peckett[1], Mohine Alam[1], Michal Fleszar[2], Danuta Lisiecka[2], Amy Lennon[2], Adam Dooner[2], Robert Leydon[3], **Weiheng Su[4]**
[1]Oxford Genetics Limited, UNITED KINGDOM, [2]OXGENE, Oxford, United Kingdom, [3]OXGENE (Oxford Genetics), Oxford, United Kingdom, [4]OXGENE, OXFORD, Oxfordshire, United Kingdom

Efficient and scalable production of recombinant adeno-associated virus (rAAV) vectors remains a significant challenge for AAV gene therapy, particularly in meeting preclinical and clinical demands. To address this, we developed the TESSA® platform, a self-silencing helper adenoviral system that delivers all the necessary components for efficient rAAV production in HEK293 cells. The system also self-inhibits expression of late adenoviral structural proteins, effectively eliminating adenoviral contamination during rAAV manufacturing.

The TESSA® platform enables rAAV production through two distinct approaches, offering flexibility for different gene therapy applications. The key difference between these models lies in how the gene of interest (GOI) is introduced into HEK293 cells:

TESSA® Duo model: A TESSA® vector encoding Rep and Cap is combined with a second TESSA® vector carrying the AAV GOI transfer genome.

TESSA® Pro model: A TESSA® vector encoding Rep and Cap is co-infected with an AAV GOI seed stock.

Previously, we demonstrated that the TESSA® platform enables cost-effective and scalable rAAV manufacturing, achieving up to a 20-fold increase in AAV vector production with productivities exceeding 1E+6 vector genome copies (GC) per cell and >1E+17 total GC from a 200L bioreactor.

To further enhance the TESSA® system, we implemented genetic engineering strategies focused on optimizing AAV Cap expression through promoter screening and evaluated hybrid AAV Rep proteins to improve rAAV yield and quality. Our assessment of rAAV9 production using both the TESSA® Pro and Duo models demonstrated vector genome titers of >2–3E+12 GC/mL of cell culture, representing a ~5-fold improvement over first-generation TESSA® RepCap vectors and a >30-fold increase compared to the conventional triple-transfection method. These

results highlight the significant impact of the TESSA® platform in overcoming key manufacturing bottlenecks in AAV gene therapy. Further optimization, including advanced promoter engineering, holds the potential to drive even greater efficiencies in rAAV production.

375 Next-Gen Recombinant Adeno Associated Virus Processes: Boosting Productivity & Quality via Process Intensification & Optimized Triple Transfection for All Common Serotypes

Pouria Motevalian[1], Angela Andaluz[2], James Fasano[2], Amy Correia[1], Kevin Vera[2], Ivan Gajic[2], Junyan Zhang[2]
[1]Thermo Fisher Scientific, Plainville, MA, [2]Thermo Fisher Scientific, Plainville

Recombinant adeno-associated viruses (rAAVs) are widely used as gene therapy vectors. With the expansion of new indications, achieving higher titers and reducing manufacturing costs have become increasingly critical. In suspension-based transient transfection, low viable cell density (VCD) and fixed bioreactor volumes limit productivity. Furthermore, the absence of serotype-specific upstream optimization for transfection results in low yields and elevated levels of product- and process-related impurities, which pose significant challenges for downstream purification.

To address these limitations, perfusion using was implemented to increase cell density before triple transfection. Additionally, high-throughput process development technologies, such as Sartorius AMBR15 and AMBR250, were employed to optimize process parameters for all common rAAV serotypes (rAAV2, AAV5, AAV6, AAV8, and AAV9), enhancing overall productivity and product quality. This approach was further integrated with high-throughput analytical testing methods to assess product strength and characterize process- and product-related quality attributes post-production.

Incorporating perfusion into the upstream process led to at least a 5-fold increase in productivity and a significant reduction in the cost of goods while maintaining acceptable levels of process- and product-related impurities. Additionally, high-throughput optimization based on Quality by Design (QbD) principles significantly improved upstream titers and percent full capsids (up to 40%) for a gene of interest near the AAV vector's packaging limit (4.8 kbp). This approach provides a rapid, scalable, and cost-effective strategy across multiple serotypes, addressing the increasing demand for high-titer rAAV vectors in gene therapy. An rAAV production titer of ~1E12 vg/mL with over 40% full capsids was achieved.

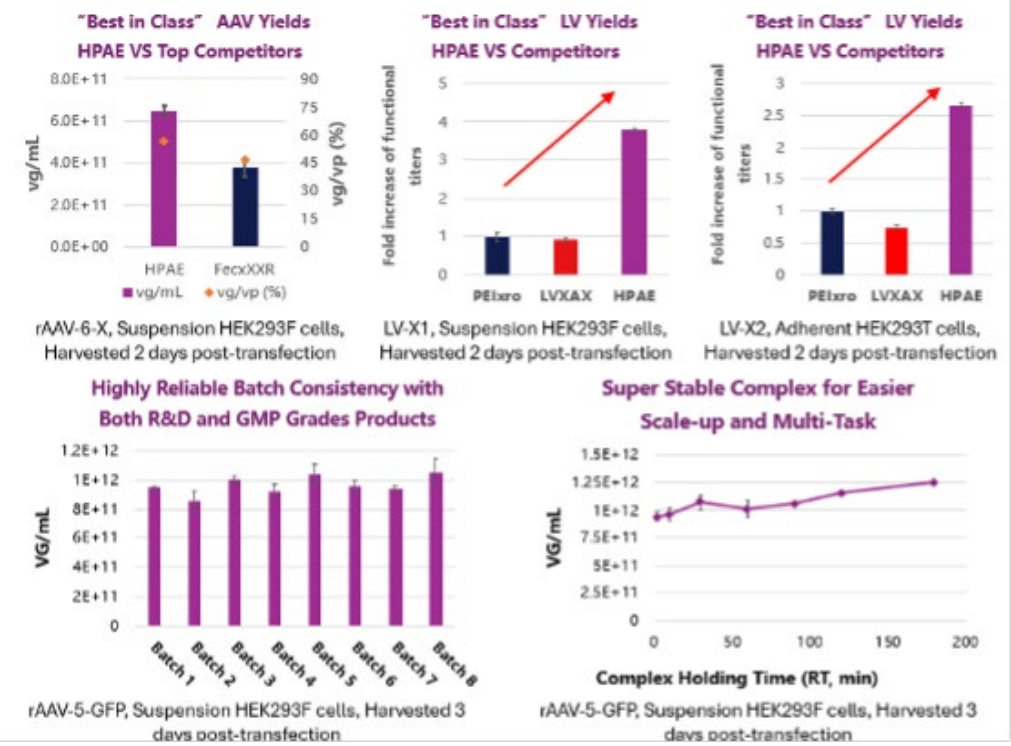
376 Revolutionizing Viral Vector Production: Biodegradable Hyperbranched Poly (β-amino ester)-Based Transfection Technology Boosts Yields and Efficiency

Liang Yao[1], Zhonglei He[2], Xi Wang[3], **Hongyun Tai**[4]*, Wenxin Wang[5]*
[1]University College Dublin, Dublin, Dublin, Ireland, [2]Branca Bunus, IRELAND, [3]Branca Bunús Ltd, Dublin, Ireland, [4]Branca Bunús Ltd, Dublin, Dublin, Ireland, [5]University College Dublin, IRELAND
**Corresponding Author*

Traditional viral vector production has long relied on cationic liposomes or polyethyleneimine (PEI) as transfection reagents, despite their inherent limitations such as low efficiency, high cytotoxicity, and cumbersome scaling up processes. This study introduces a groundbreaking non-viral gene delivery platform based on hyperbranched poly (β-amino ester) (HPAE), an advancement over linear poly (β-amino ester), which presents a promising alternative to conventional transfection technologies [1,2].

The transfection reagents derived from this platform exhibit several pivotal advantages over traditional methods, including (1) Enhanced potency for efficiently transfecting large plasmid DNA (>12 kb); (2) Reduced cytotoxicity with a fully degradable polymer that leaves no residue; (3) Simplified scalability due to the stability of transfection complexes for at least 3 hours at room temperature; (4) cost-effectiveness with significantly reduced reagent consumption (＜25% of PEI); and (5) highly consistent polymer weight distribution and efficacy suitable for GMP-compliant production of viral vectors.

We demonstrate the superior effectiveness of HPAE-based transfection reagents in the production of viral vectors, including adeno-associated viruses (AAV) and lentiviruses (LV), achieving markedly higher viral yields and superior batch consistency compared to commercially available alternatives. Moreover, the versatility of the HPAE platform extends beyond viral vectors, enabling the efficient delivery of mRNA, siRNA, and CRISPR-Cas9 RNP complexes, offering a comprehensive solution that holds great potential for advancing gene therapy and cell therapy research and development [3-7].



377 Late-stage Development and Upstream Process Characterization of UX701 AAV Gene Therapy for Wilson Disease

Jun Li[1], Benjamin Hanson[1], Tiego Bezerra[1], Jan Panteli[2], Patrick Hossler[1], James Warren[2]
[1]Ultragenyx Pharmaceutical Inc., Woburn, MA, [2]Ultragenyx, Novato, CA

Introduction:
Wilson Disease (WD) is caused by mutations in the copper-transporter gene *ATP7B* which leads to toxic accumulation of copper primarily in the liver and brain. Copper chelators are the current standard of care but can result in significant side effects, do not address the underlying cause of WD, and have high rates of discontinuation. UX701 is an investigational AAV9 gene therapy designed to deliver a modified form of the *ATP7B* gene for the treatment of WD. UX701 leverages our proprietary producer cell line platform, Pinnacle PCL™, to produce rAAV in a 2000L bioreactor (Figure 1). Process characterization (PC) of UX701 is an essential aspect of the process validation lifecycle, aimed at defining manufacturing process ranges to maintain the target product profile. In this work, we have characterized the cell culture manufacturing process and demonstrate a robust and high yielding process for the manufacture of UX701. This is the first PC study for our Pinnacle PCL™ rAAV platform.

Methods/Approach:
A risk-based approach was applied to the late-stage development activities for UX701 upstream process including process parameter risk assessment, scale-down model (SDM) qualification, and PC studies, to establish process controls for the upstream unit operations in the 2000L manufacturing process. Specifically, we assessed a total of 224 upstream process parameters and raw materials on their impacts to process performance indicators (PIs) and

critical quality attributes (CQAs) and classified them into high, medium or low risk parameters. Of these, a total of 11 parameters and 2 raw materials were classified as high or medium risk and were assessed in PC studies. Upstream PC studies were conducted in a qualified SDM using 3L bioreactors coupled with high throughput purification via Tecan™ affinity chromatography and high throughput analytics including PCR-based methods for rAAV titer, host-cell DNA impurities, and helper virus impurities. High throughput AAV packaging characterization was performed using mass photometry as a surrogate for analytical ultracentrifugation.

Results:
We identified 8 process parameters to be critical (CPP) or key (KPP). Temperature and pH in the N-1 and production stages as well as production target seeding density and helper virus concentration were all found to be CPPs, which have significant impact on at least one CQA and one PI. N-1 dissolved oxygen and production harvest time relative to infection are KPPs, which have significant impact on at least one PI, but no significant impact on CQAs. PC studies also provided insights on process improvements. Delaying the harvesting time by 6hr from target can increase rAAV titer by 2-fold; increasing production temperature by 2°C can significantly increase rAAV titer and %full capsids (Figure 2).

Conclusion:
We have successfully risk assessed the UX701 upstream process, qualified a SDM, and characterized the process design space for our first Pinnacle PCL™ program. We have generated a comprehensive set of process-product relationships for UX701 as well as our rAAV platform, which will benefit other ongoing PCL™ programs in our clinical pipeline. These studies will continue to help us understand and mitigate operational and quality risks, which are critical for successful implementation of a robust commercial manufacturing process to provide consistent product quality throughout the product's lifecycle.

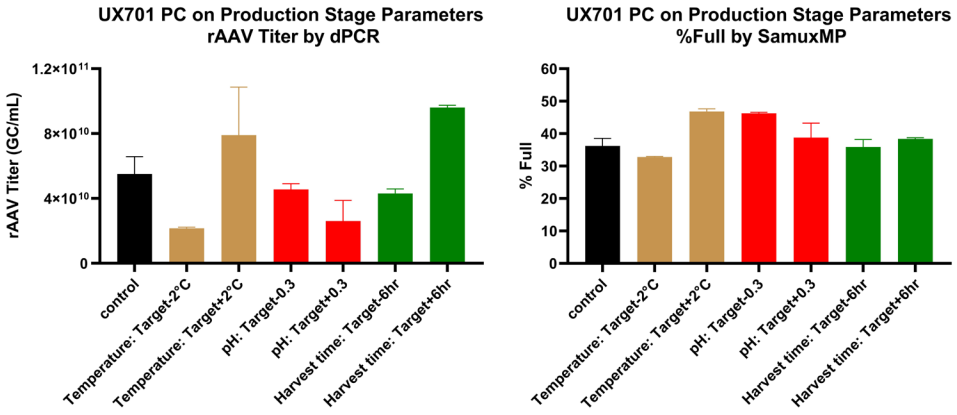

Figure 2. UX701 PC on some production stage parameters and their impacts on rAAV titer and % full capsids, bar plots by mean (SD)

378 Machine Learning-Enhanced Design of Experiments (DoE) for Optimizing AAV Plasmid Ratios in Gene Therapy Manufacturing

Von Wiltman[1], Jorge Santiago-Ortiz[1], Blake Albright[2], Max Ezekiel[3], Andrew Steinsapir[8]
[1]Apertura Gene Therapy, New York, NY, [2]Unaffiliated, New York, NY, [3]Apertura Gene Therapy, New York City, NY

Introduction:
Efficient adeno-associated virus (AAV) production is critical for the success of gene therapy programs. However, optimizing upstream processes remains challenging due to complex multivariate interactions, biological variability, and resource constraints. This study leverages a machine learning-augmented statistical approach, Self-Validating Ensemble Modeling (SVEM), to enhance traditional Design of Experiments (DoE) for plasmid ratio optimization. SVEM enables predictive modeling with limited experimental data, improving process efficiency and robustness.

Methods:
A space-filling DoE was designed to investigate the impact of varying molar fractions of pHelp, pRepCap, and pTransgene plasmids on genomic titer and empty-to-full capsid ratio in HEK293 cell-based AAV production. A total of 26 experimental conditions were tested in shake flask transfections at 30mL working volume. SVEM applied autovalidation, iterative model selection, and ensemble averaging to refine predictive accuracy and accommodate biological variability. Bayesian I-optimal design principles were incorporated to maximize model information content while minimizing experimental burden. SVEM's ability to handle supersaturated models allowed for the identification of key interactions that traditional DoE approaches might miss.

Results:
SVEM-based DoE modeling identified an optimal plasmid ratio that improved genomic titer by 42% while reducing empty capsid formation by 28% compared to baseline conditions. Traditional DoE approaches failed to capture nonlinear interactions that were resolved through SVEM's ensemble modeling, leading to more reliable predictions and faster optimization cycles. SVEM's capacity to extract insights from small datasets resulted in a 35% reduction in total experimental runs while achieving superior model robustness.

Conclusion:
SVEM enhances AAV upstream process optimization by enabling more accurate predictions from limited datasets, addressing key challenges in biomanufacturing scalability. This study demonstrates that machine learning-augmented DoE can significantly improve process development efficiency, reduce resource expenditure, and enhance reproducibility in gene therapy vector production. The findings provide a roadmap for integrating ML-driven analytics into CMC workflows, supporting accelerated clinical translation and commercial scalability of AAV gene therapies. As SVEM continues to evolve, its application in pharmaceutical and biotech industries

presents a promising approach for enhancing predictive modeling, reducing costs, and expediting development timelines.

379 Reduce ITR related Impurities in AAVone Single-plasmid System Using Secondary Structure DNAs

Jiantao Zhang[1], Yuling Dai[2], zhen shi[3], Yuyan Wang[4], Huan Hu[4], Danhui Lu[4], Rongze Yang[1], Yu Liu[3], Lemin Wang[4], Jun Xie[5], Daozhan Yu[6]*, Qizhao Wang[7]*

**Corresponding Author*

Adeno-associated virus (AAV) vectors are widely used in gene therapy, but high production costs limit accessibility. Recently, we introduced the AAVone single-plasmid AAV production system, which consolidates all necessary cis- and trans-acting components into a single compact plasmid. This system streamlines AAV production and increases yields compared to traditional triple-plasmid co-transfection methods. The oversized plasmid backbone of AAVone results in fewer plasmid-related impurities in produced AAV vectors, particularly bacterial elements. However, it increases VA RNA-related impurities outside the right inverted terminal repeat (R-ITR). To address this challenge, we tested DNAs with different secondary structures to block potential ITR read-through or reverse packaging. While neither short repeat telomere sequences nor G-quadruplex DNAs reduced ITR-related impurities when placed immediately outside the R-ITR, short hairpin structure DNAs (shDNAs) significantly reduced these impurities in the AAVone produced AAV vectors. The VA-RNA related impurities were reduced from 2.5% to less than 1%. Notably, incorporating shDNAs did not significantly affect AAV production. This effect was sequence-independent but structure-related, suggesting a universal strategy for reducing backbone-related impurities in AAV vectors. Using safer shDNAs, such as lo2 shDNA derivatives, may also reduce immune responses to AAVone-produced AAV vectors. These findings validate the potential of shDNA-mediated strategies to further optimize the AAVone system, providing a safer and more cost-effective AAV production method for both preclinical and clinical applications.

On and Off-Target Method Development

380 Scalable assessment of genome editing off-targets associated with genetic variants with ABSOLVE-seq

Danilo Pellin[1], Jiecong Lin[2], My Anh Nguyen[3], Linda Lin[4], Jing Zeng[5], Archana Verma[6], Nola Neri[6], Lucas Ferreira da Silva[6], Adele Mucci[7], Kit Shaw[8], Kendell Clement[9], Scot Wolfe[10], Christian Brendel[11], Luca Pinello[12], Daniel Bauer[3]
[1]Boston Childrens Hospital, Brookline, MA, [2]Division of Hematology/Oncology, Boston Children's Hospital, Boston, MA, [3]Boston Children's Hospital, Boston, MA, [4]Division of Hematology/Oncology, Boston Children's Hospital, Department of Pediatric Oncology, Department of Pediatrics, Harvard Medical School, Boston, MA, [5]Harvard Children's Hospital, Boston, MA, [6]Division of Hematology/Oncology, Boston Children's Hospital, Department of Pediatric Oncology, Department of Pediatrics, Harvard Medical School, Boston, [7]Boston, MA, [8]Boston Children's Hospital, Boston, MA, [9]University of Utah, Salt Lake City, UT, [10]UMass Chan Medical School, Worcester, Massachusetts, [11]Boston Children's Hospital/Dana-Farber Cancer Institute, Boston, MA, [12]Massachusetts General Hospital, Boston, MA

Genome editing with RNA-guided nucleases and nickases holds transformative potential for therapeutic applications but carries inherent risks of off-target modifications. Genetic variants may create off-target sites not found in the reference genome, but these can be difficult to identify with standard in silico, in vitro, and in cellulo nomination methods. Even after nomination, verifying these candidate variant-associated off-target sites is challenging due to the limited availability of primary cells harboring relevant genotypes. To address this challenge, we developed

ABSOLVE-seq (Assessment By Stand-in Off-target LentiViral Ensemble with sequencing), a scalable, high-throughput method for experimental verification of candidate off-target sequences that can be performed in primary cells. ABSOLVE-seq employs lentiviral delivery to integrate candidate sequences tagged with unique molecular identifiers (UMIs) into the genomes of living cells, followed by gene editing using clinically relevant protocols. This approach enables the multiplexed evaluation of dozens of candidate off-targets in a single experiment with high sensitivity and precision. Our analytical pipeline processes multiplexed sequencing data, classifies reads based on evidence of editing activity, aggregates data from multiple biological and technical replicates to estimate editing frequency by applying a penalized logistic regression model, and identifies significant editing activity using robust statistical tests based on permutation methods. We validated ABSOLVE-seq using CRISPR-Cas9 guides targeting the BCL11A erythroid enhancer employed in approved and experimental therapies for sickle cell disease and β-thalassemia. Experiments were conducted with wild-type Cas9 and high-fidelity Cas9 variants, targeting the +55 and +58 BCL11A erythroid enhancer regions. Four filtering strategies were compared, with an optimized approach reducing background indel rates to 0.002%. ABSOLVE-seq consistently identified both on-target and verified off-target sites. We observed a reduction in off-target activity with high-fidelity Cas9 compared to wild-type Cas9, as evidenced by the detection of significant off-target editing at a lower number of candidate sequences. We combined experimental data and Monte Carlo simulations to estimate statistical power at specific loci, ensuring reliable detection of rare off-target events and defining sequencing depth requirements. We demonstrated that ABSOLVE-seq maintains a high level of statistical power to detect off-target editing events as rare as 0.01% indel frequency, exceeding conventional detection thresholds. This high sensitivity enables the detection of low-frequency variant-associated off-target events. ABSOLVE-seq addresses key regulatory and scientific challenges in genome editing safety by providing a quantitative, scalable, and biologically relevant platform for preclinical off-target assessment of genetic variant-associated candidate off-target sites.

381 CHANGE-seq-BE Enables Simultaneously Sensitive and Unbiased *In vitro* Profiling of Base Editor Genome-Wide Activity

Varun Katta[1], Cicera Lazzarotto[2], Yichao Li[1], Garret Manquen[3], Rachael Wood[4], Jacqueline Chyr[5], Azusa Matsubara[1], GaHyun Lee[6], Xiaolin Wu[7], Suk See De Ravin[8], Shengdar Tsai[9]*

Corresponding Author

Base editors (BEs) enable precise editing of individual DNA bases without requiring DNA double-strand breaks in the genome and holds a great promise to correct pathogenic single nucleotide variants in many genetic disorders. However, it is crucial to directly evaluate the safety and potential risks associated with BEs in clinical translation of genome-edited medicines. In this study, we introduce CHANGE-seq-BE, a novel, sensitive and unbiased biochemical approach designed to assess the genome-wide activity of base editors. This method selectively sequences genomic DNA modified by adenine or cytosine base editors (ABE or CBE) *in vitro* to identify candidate off-target sites across the genome.

To assess CHANGE-seq-BE performance, we used it to characterize ABE8e-NRCH base editor activity targeting sickle mutation (HBB^S) in the *HBB* gene to convert into non-pathogenic Makassar variant. After systematic optimization of CHANGE-seq-BE, we consistently detected all 54 validated off-targets that were previously reported by the nuclease-based CIRCLE-seq method. Moreover, CHANGE-seq-BE identified additional 29 (53% more) *bona fide* off-targets with cellular activity ranging from 0.55-13.9%. CHANGE-seq-BE also exhibited higher (2.1-fold) enrichment ratio at *bona fide* off-targets than CIRCLE-seq for HBB^S-gRNA. These results emphasize the importance of employing sensitive and unbiased approaches like CHANGE-seq-BE to directly define the genome wide off-target activity of base editors.

To evaluate the ABE8e (ABE) and eA3A-BE3 (CBE) off-target activity, we performed CHANGE-seq-BE for five therapeutically relevant loci (*B2M*, *CBLB*, *CD7*, *CIITA*, and *PDCD1*) in human primary T-cells. We selected 10,142

and 757 sites for ABE and CBE targets nominated by CHANGE-seq, CHANGE-seq-BE, and Digenome-seq and validated cellular off-target activity for 9,251 and 709 amenable sites by hybrid capture sequencing. Overall, 99 *bona fide* off-target sites nominated across all three methods exhibited significantly higher base editing activity above background. 36 ABE and 6 CBE off-target sites are exclusively identified by CHANGE-seq-BE, compared to Digenome-seq. This suggests that CHANGE-seq-BE is highly sensitive and capable of detecting *bona fide* off-targets while requiring approximately 20-fold less sequencing reads.

To understand the biological differences in genome-wide activity between Cas9 nuclease and base editors, we delivered Cas9 nuclease and ABE8e as mRNA for five therapeutically relevant ABE targets. We are currently examining *in vitro* off-target profiling of CHANGE-seq and CHANGE-seq-BE sites and corelating the differences with cellular activity validated by hybrid capture sequencing. Lastly, we applied CHANGE-seq-BE as an IND-enabling assay to support an emergency FDA-cleared IND study to treat a patient with X-linked Hyper IgM syndrome due to *CD40L* mutation. By CHANGE-seq-BE, we identified a total of 81 potential off-targets and confirmed 95.4% frequencies of on-target editing with no evident off-targets above the detection threshold of rhAmp-seq.

Overall, we present CHANGE-seq-BE as a highly sensitive and unbiased biochemical assay for characterizing genome-wide off-target activity of base editors. We envision CHANGE-seq-BE method may be used as a key assay to assess the specificity of therapeutic genome editors in biomedical research and clinical settings

382 Population-scale Cellular GUIDE-seq-2 and Biochemical CHANGE-seq-R Profiles Reveal Human Genetic Variation Frequently Affects Cas9 Off-target Activity

Yichao Li[1], Cicera Lazzarotto[2], Ashley Flory[3], Jacqueline Chyr[4], Varun Katta[1], Elizabeth Urbina Obregon[3], GaHyun Lee[5], Rachael Wood[6], Azusa Matsubara[1], Yong Cheng[7], Shengdar Tsai[8], Muyu Yang[9], Jian Ma[9], Sara Rashkin[4]
[1]St. Jude Children's Research Hospital, Memphis, TN, [2]Be Biopharma, Cambridge, MA, [3]Memphis, TN, [4]St. Jude Children's Research Hospital, Memphis, TN, [5]St. Jude Children's Research Hospital, Western Springs, IL, [6]St. Jude Children's Research Hospital - Alsac, Memphis, TN, [7]St Jude Children's Research Hospital, [8]St. Jude Children's Research Hospital, Memphis, Tennessee, [9]Carnegie Mellon University, Pittsburgh, PA

Genome editing technology holds tremendous promise for treating genetic diseases, exemplified by the recent approval of a CRISPR-Cas9-based therapy for sickle cell disease in the US and Europe. However, their genome-wide activity can be altered by genetic variation at on- or off-target sites, potentially impacting both precision and therapeutic safety.

Here, we present the first population-scale study of how genetic variation affects the cellular genome-wide activity of CRISPR-Cas9, enabled by a novel, sensitive, and unbiased cellular assay, GUIDE-seq-2 with improved scalability and accuracy compared to the original broadly adopted method. We evaluated cellular on- and off-target sites associated with six gRNA targets from 95 donors across four genetically diverse populations. Our analyses identified 1,115 unique on- and off-target sites. Notably, cellular Cas9 activity detected by GUIDE-seq-2 frequently overlapped with human genetic variants. Within our study cohort, 16.6% of off-target sites (185 of 1,115) overlapped with one or more genetic variants, with individuals of ASW ancestry (African Ancestry in Southwest USA) having the highest frequencies of off-targets overlapping genetic variation (13%), and those of CHB ancestry (Han Chinese in Beijing) having the lowest (7.8%).

To validate the discovered off-target sites and identify a high-confidence set of variant effects on Cas9 editing activity, we conducted multiplexed targeted sequencing and integrated five variant effect measures based on GUIDE-seq-2 read counts, indel frequencies, tag integration frequencies, and allele-specific editing (indels or integrations). A high proportion of variants (12.6%) measured by both GUIDE-seq-2 and targeted sequencing significantly impacted off-target activity, of which 11 and 10 variants led to increased or decreased editing, respectively. Variant effects on indel percentage ranged from -25% to 32% and were corroborated by comparable changes in GUIDE-seq-2 read counts, tag-integration, and allele-specific editing frequencies. Notably, same variant

effects were confirmed in therapeutically relevant primary human T cells, with up to 3000-fold change in GUIDE-seq-2 read counts.

To understand common features of high-impact variants, we designed a massively parallel biochemical assay that measures Cas9 activity within highly diverse, partially randomized, off-target libraries which we call CHANGE-seq Randomized (CHANGE-seq-R). Each level of mismatch (up to 6) was covered by a million sequences. We further trained CHANGE-net, a deep learning model using CHANGE-seq-R data, achieving high accuracy (Spearman R=0.93) in predicting variant effects from our high-confidence set and outperforming other state-of-the-art methods. Finally, we applied CHANGE-net to predict variant effects from the 1000 Genomes Project, identifying 39 common variants that significantly impact Cas9 activity (predicted effects ranged from -64% to 4%). These findings underscore the potential of our massively parallel assay in modeling variant effects that are difficult to fully explore in cellular studies.

Our results illuminate the profound influence of genetic variation on genome editing outcomes, emphasizing the need for population-aware design in CRISPR-based therapies. Our integrated approach, combining GUIDE-seq-2, CHANGE-seq-R, and CHANGE-net, establishes a framework for rapidly assessing and mitigating variant-induced off-target genome editing risks.

383 Pooled GUIDE-seq-2 enables simultaneous assessment of cellular activity and specificity for thousands of Cas9 targets

Azusa Matsubara[1], Elizabeth Obregon[2], Yichao Li[1], Claire Greene[1], Cicera Lazzarotto[3], Yong Cheng[4], Shengdar Tsai[5]
[1]St. Jude Children's Research Hospital, Memphis, TN, [2]St Jude Children's Research Hospital (currently Vanderbilt University, Nashville, TN, USA), Memphis, [3]Be Biopharma, Cambridge, MA, [4]St Jude Children's Research Hospital, [5]St. Jude Children's Research Hospital, Memphis, Tennessee

GUIDE-seq is a sensitive and unbiased cellular method to define the genome-wide activity of genome editors that has been broadly adopted for research and therapeutics. Although we have recently increased the scalability of GUIDE-seq with the development of a streamlined method called GUIDE-seq-2, it remains challenging to characterize sufficiently large numbers of targets to train accurate predictors of genome editing activity and specificity. This is because GUIDE-seq (and GUIDE-seq-2) are typically performed on a single target basis, limiting not only the scalability but also the comparison of relative activity. Thus, we sought to develop a version of GUIDE-seq-2 capable of simultaneously surveying activity and specificity across thousands of Cas9 gRNA targets. First, we designed a list of 500 and 4501 gRNA sequences targeting the human genome with high enough edit distance to be easily distinguishable from each other. Next, we transduced human primary T-cells with the gRNA libraries encoded in lentivirus, delivered purified Cas9 protein together with a short double-stranded oligodeoxynucleotide (dsODN) tag, and performed GUIDE-seq-2 on the pooled edited T-cells. All gRNAs were detected to have activity from the smaller pool of 500, and 99.8% (4,491 out of 4,501) was detected from the 4501 pool. Replicate experiments showed that the pooled GUIDE-seq-2 results were highly reproducible (Pearson's r = 0.95). A key advantage of this new method is that both activity and specificity can be compared and ranked across thousands of guides simultaneously. For example, 48 out of 500 (9.6%) guides were highly specific to the intended target, where only the on-target edit was detected. To determine whether pooled GUIDE-seq-2 results were comparable to individual GUIDE-seq-2, we selected a set of 20 targets for direct comparison. We found that activity and specificity were strongly correlated between pooled and individual GUIDE-seq-2 experiments (Pearson's r = 0.91, 0.89 and Spearman's R = 0.94, 0.94, respectively). Interestingly, sequence feature analysis from 500 and 4501 pools both showed high tolerability of G to A in the 11th position of the protospacer. To allow analysis of targets that do not start with a 5'G as required by standard U6 RNA Pol III promoters for gRNA transcription, we are currently collecting data from a tRNA-encoded guide library that enables targets to start with any base. This will increase the diversity of the first nucleotide of gRNAs to train deep learning models for accurate prediction of guide activity and specificity.

In summary, we have established pooled GUIDE-seq-2, a sensitive, unbiased cellular method to simultaneously evaluate the genome-wide activity of thousands of guides. Pooled GUIDE-seq-2 will support rapid selection of the

best gRNA sequences for genome editing therapies, build databases for selective guides, and may improve predictors of highly active and specific gRNA targets.

384 Single-Cell Profiling of Genome-Editing Alterations and Functional Outcomes in CRISPR-Engineered Cells

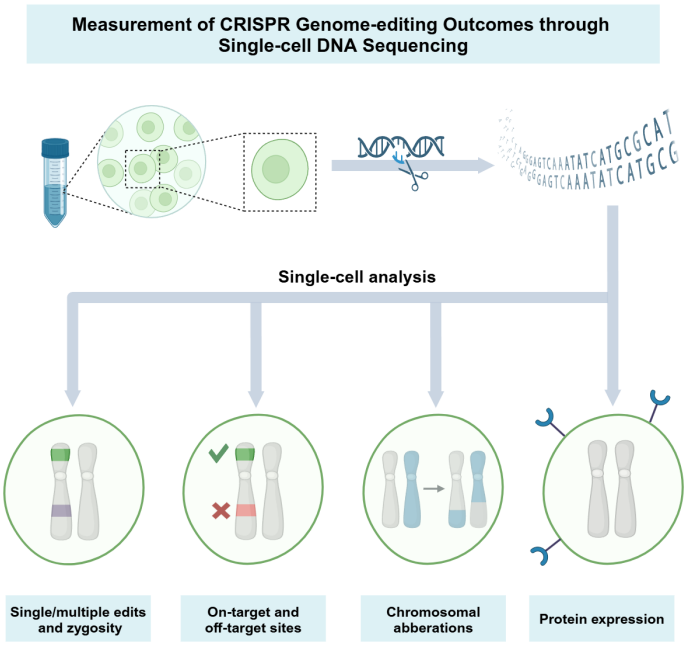
Nechama Kalter[1], Saurabh Gulati[2], Michael Rosenberg[3], SHU WANG[4], Benjamin Schroeder[5], Alex Li[6]*, **Ayal Hendel[7]***
[1]Bar-Ilan University, Ramat-Gan, Israel, Israel, [2]Mission Bio, South San Francisco, California, [3]Bar-Ilan University, Ramat-Gan, Israel, [4]Mission Bio, South San Francisco, CA, [5]Mission Bio, San Francisco, CA, [6]Genomic Insights Consulting, Rowland Heights, CA, [7]Bar Ilan University, Ramat-Gan, Tel-Aviv, Israel
**Corresponding Author*

CRISPR-Cas genome-editing technology has become a cornerstone in advancing innovative clinical therapies for treating a wide range of diseases. However, the technology encounters a bottleneck in the form of off-target activity (OTA), the unintended cleavage by the Cas nuclease at non-target genomic loci. OTA introduces insertions and deletions (inDels) and structural variations (SVs), potentially driving oncogenic mutations. While many studies have characterized OTA at a cell-population level using bulk-sequencing-based methods, these approaches are limited as they fail to examine OTA at the single-cell level. Furthermore, current approaches fail to capture the functional consequences of specific genotypes in individual cells, leaving a critical gap in our understanding of the interplay between genomic modifications and functional outcomes.

To address this gap, we leveraged the Tapestri platform, a cutting-edge single-cell DNA sequencing (scDNA-seq) technology, integrated with multi-omics profiling. This approach enables precise characterization of the distribution of genotypes and phenotypes in CRISPR-engineered cells (Fig. 1). As a proof-of-concept, we engineered human primary T-cells using a multiplex of three guide RNAs (gRNAs) adapted from the first in-human CRISPR trial, designed to knock out the *PDCD1*, *TRAC*, and *TRBC* anti-cancer targets. We then created a panel of 111 putative off-target sites, amplified and sequenced these sites using the Tapestri platform, generating high-resolution data from thousands of cells per donor. Cells from the same donors were also analyzed using the rhAmpSeq targeted bulk sequencing assay. We then evaluated the inDel profile at each allele and quantified the CRISPR editing. While population-level editing levels were similar between single-cell and bulk-sequencing, single-cell analysis enabled a more detailed understanding of zygosity and the co-occurrence of specific editing outcomes. Single-cell analysis revealed a heterogeneous spectrum of CRISPR outcomes, with each cell exhibiting a unique on-target and off-target profile, highlighting the importance of thoroughly characterizing genome-engineered cell products. We also quantified translocations between on-target and off-target loci, including novel translocations previously unreported for these gRNA combinations.

Finally, to evaluate how different types of editing outcomes influence the desired phenotype, we conducted a longitudinal study on primary cells edited with the same gRNAs, sampling them over a 12-day period. Our analysis revealed a notable increase in the fraction of inDels within the population, peaking at 3 days post-editing and stabilizing thereafter through day 12. Additionally, we observed consistent downregulation of the TCRa/b and CD3 surface proteins in cells harboring bi-allelic inDels at the TCRA and TCRB on-target sites, highlighting the power of this approach for detailed characterization of genome-engineered cells.

In summary, scDNA-seq, combined with in-depth proteomic characterization, provides a robust framework for evaluating genome-engineered cells, enabling precise measurement of editing activity, detailed profiling of outcomes, and direct links between genotypes and phenotypes. This high-resolution methodology advances our understanding of CRISPR outcomes and offers a powerful platform for quality control, with the potential to enhance therapeutic applications of CRISPR-Cas genome-editing.



385 Development of a Comprehensive Framework for Assessing the Genomic Safety Profile of RNA Gene Writer Targeting Alpha-1 Antitrypsin Deficiency

Sumanprava Giri[1], David Kuo[1], Robin Chan[1], Miles Duncan[1], Tong Wu[1], Sudeepa Syamala[1], Mugdha Bedekar[1], Lavanya Venkatesan[1], Mae Caldwell[1], Maria Muraca[1], Suravi Pramanik[1], Kimberly Harris[1], Ian Lin[1], Ayaan Hossain[1], Jainy Thomas[1], Zach Berman[1], Akhilesh Dhanani[1], Maple Gioia[1], Zsanett Jancso[1], Gang Sun[1], Jeff An[1], Bill Querbes[1], Andrea Calabria[1], Michael Holmes[1], Gregory McAllister[1], Anne Bothmer[1], Cecilia Cotta-Ramusino[1]

[1]*Tessera Therapeutics, Somerville, MA*

RNA Gene Writers are unique and engineerable constructs that leverage all-RNA components and harness the mechanism of target-primed reverse transcription, or TPRT, to introduce a broad range of edits to the genome, from inserting a transgene or exon to introducing single nucleotide changes. RNA Gene Writers are designed to provide a versatile toolkit for the treatment of a wide variety of genetic diseases. Here we focus on the genomic safety assessment of an RNA Gene Writer developed to correct one of the mutations leading to alpha-1 antitrypsin deficiency (AATD). Mutations in the SERPINA1 gene (Serine Protease Inhibitor, group A, member 1) lead to AATD, an inherited disorder linked to an increased risk of liver and lung disease. One of the most clinically relevant variants is the PiZ mutation, which results in a substitution of lysine for glutamic acid at amino acid position 366 (E366K). Individuals with two copies of the PiZ allele (PiZZ genotype) develop a liver phenotype due to the accumulation of toxic misfolded protein aggregates in the endoplasmic reticulum of liver cells, while lower levels of circulating AAT contribute to lung disease by impairing the inhibition of neutrophil elastase. To address this, we developed an RNA Gene Writer aimed at correcting the E366K mutation in the SERPINA1 gene, restoring it to its wild-type form. We developed an RNA Gene Writer that achieved an estimated average of 89% correction of the *SERPINA1* E366K mutation in hepatocytes of a mouse model of disease, using a single low dose of 0.25 mpk. The mouse model is a humanized mouse model with only two PiZ alleles to better approximate the efficacy of our product in patients with the homozygous PiZZ genotype. In addition, in non-human primates, a surrogate RNA Gene Writer achieved an estimated 79% editing of the SERPINA1 gene in hepatocytes of cynomolgous monkeys. One of the keys to supporting the advancement of any new genome editing technology through preclinical development is the building of a comprehensive data package assessing genomic safety. Here we present our assessment of the genomic safety profile of the RNA Gene Writer that includes a comprehensive and unbiased off-target discovery using in-silico, in-vitro and in-cell methods. We assessed nominated putative off-target sites using single and

multiplexed amplicon sequencing and our initial data showed that the RNA Gene Writer did not show any detectable off-target activity across any of the putative off-target sites enumerated during discovery. In addition, we evaluated the biodistribution of the RNA Gene Writer in the mouse model of disease and did not observe any unintended editing at putative off-target sites in any of the 31 tissues/ biofluids examined. By using this comprehensive array of orthogonal assessments of genotoxicity we characterized the genomic safety profile of the RNA Gene Writer that supports its potency and safety.

475 Joint Single-Cell Profiling of CRISPR-Cas9 Edits and Transcriptomes Reveals Widespread Off-Target Events and Affected Gene Expression

Mickey Lorenzini[1], Brad Balderson[2], Karthyayani Sajeev[2], Aaron Ho[2], Graham McVicker[2]
[1]Salk Institute, La Jolla, CA, [2]Salk Institute for Biological Studies, La Jolla, CA

Off-target genotoxicity is a pressing challenge in therapeutic genome engineering. A longstanding barrier has been an inability to measure the consequences of off-target events on cell function. Here we present Superb-seq, a new technology that leverages T7 in situ transcription and single-cell RNA sequencing to jointly detect genome breaks and downstream effects on gene expression. We performed Superb-seq on CRISPR-Cas9 edits in 10,000 K562 cells, targeting four chromatin remodeler genes with seven guide RNAs. Superb-seq identified 11,891 edit events in 6,230 edited cells at all seven on-target sites and an additional 36 off-target sites. Although all guides were selected for high specificity, 6/7 guides caused off-target edits, ranging in frequency from 0.03% to 18.6% of total cells. Furthermore, Superb-seq identified hundreds of differentially expressed genes associated with specific off-target events. A notable off-target within the first intron of *USP9X* disrupted the expression of this gene and over 150 downstream genes. In summary, Cas9 off-targeting is a pervasive combination of rare and common edit events, frequently damages introns of off-target genes, and can exert widespread effects on gene expression. Superb-seq uses off-the-shelf kits and standard equipment, which will enable scalable screening of preclinical candidates with reduced off-target gene perturbation

Pharmacology/Toxicology Studies and Analytics/Assay Development Session II

386 Preclinical Models for Oncolytic Adenoviruses: Evaluating Replication and Blood Cell Interactions

Margarita Romanenko[1], Kazuho Inoko[2], Sacha Robert[1], Mark Carlson[3], Michael Hollingsworth[4], Melanie Graham[5], John Carney[1]
[1]University of Minnesota, Minneapolis, MN, [2]University of Minnesota, Saint Anthony, MN, [3]University of Nebraska Medical Center, Omaha, NE, [4]University of Nebraska Medical Center, Omaha, [5]University of Minnesota

Oncolytic adenoviruses (Ads) are promising cancer therapeutics, capable of selective elimination of tumor cells while sparing healthy tissue. Beyond direct oncolysis, Ads also activate antitumor immune responses by modulating the immunosuppressive tumor microenvironment. However, systemic delivery of OAd, which is necessary for treating metastatic disease, remains a significant challenge in the field owing to the lack of animal models that support adenovirus replication (mice do not support replication of human adenoviruses). Another key challenge is understanding how adenoviral particles interact with blood components during systemic delivery, particularly red blood cells (RBCs), which can significantly impact viral half-life in circulation, biodistribution, and systemic side effects. Our recent *in vitro* and *in vivo* findings demonstrated that porcine cells and tissues effectively support the replication of both Ad5 (coxsackie and adenovirus receptor (CAR)-targeted) and Ad5/3 (retargeted to CD46 and human desmoglein 2 receptors) Ads. However, our previous work was limited by the absence of cancerous porcine tissues. To expand this, we have obtained porcine pancreatic ductal epithelial cells transformed with $KRAS^{G12D}$ and

assessed viral binding, transduction, and replication efficiency of multiple Ad types (Ad3, Ad5, Ad6, Ad11, and Ad26) as well as Ad5/3 and integrin-targeting Ad5RGD vectors, using normal and cancer human cell lines as a control. The findings suggest that porcine cells support Ad5 and Ad6 replication at levels comparable to human cells. The Ad5/3 and Ad5RGD vectors also displayed strong oncolysis and replication in porcine cells. Intriguingly, while species B Ad3 and Ad11 Ads induced cytopathic effect in porcine cells, their replication was significantly lower than in human cells, likely due to differences in viral replication machinery. Species D Ad26 showed no significant replication in either porcine or human cells. To explore systemic delivery challenges, we investigated the interaction of Ads with blood factors X (FX), a pivotal element influencing adenoviral transduction, across different mammalian species. Our results suggest that human, porcine, canine and murine FXs significantly improve the transduction of Ad5, Ad6, and Ad5/3 in CAR-, hDSG2-, and CD46-deficient CHO cells, matching human FX levels. In contrast, Ad11 transduction was enhanced only by human and porcine FXs, underscoring species-specific differences in FX-mediated transduction. Additionally, we examined hemagglutination patterns of Ad vectors with RBCs from various species (human, pig, dog, mouse, hamster, cynomolgus, rhesus macaque, and baboon). Our current results indicate that unlike human RBCs, which hemagglutinate with Ad5, Ad6, Ad26, and Ad5RGD, RBCs from pigs, dogs, mice, and hamsters did not hemagglutinate with any tested adenovirus. Interestingly, non-human primate RBCs hemagglutinated only with Ad11, highlighting species-specific viral interactions that may impact systemic vector delivery. This study enhances our understanding of preclinical models for adenoviral vector evaluation, providing valuable insights into systemic delivery mechanisms, species-specific interactions, and oncolytic efficacy, ultimately optimizing the development of more effective Ad therapies.

387 Safety and Biodistribution Assessment of Novel AAV Capsid Developed for the Treatment of Myotonic Dystrophy Type 1 (DM1)

Basel Assaf[1], Martin Goulet[1], Shuwen Cao[1], Giulio Srubek Tomassy[1], Wei Fan[1], Tracy Zhang[1], Alessandro Magli[1], Kristen Boyle[1], Jennifer Sullivan[1], Amy Frederick[1], William McCarty[1], Catherine O'Riordan[1], Christian Mueller[1]

[1]*Sanofi, Waltham, MA*

Recombinant adeno-associated virus (rAAV) vectors have emerged as a promising tool for gene therapy. However, high dose systemic administration of rAAV vectors pose a potential limitation for safe and effective gene therapy, particularly for dose levels >1×10^{14} viral genome per kilogram of body weight (vg/kg). Here, we tested a novel delivery platform comprising a new AAV capsid (AAV.SAN011) with high muscle transduction efficiency and a promoter with strong activity in skeletal muscles to deliver and express an artificial microRNA targeting DMPK for DM1 treatment. AAV.SAN011 was administered intravenously at 3 dose levels in cynomolgus macaques for 13-week observation period following vector administration. Pre-screened animals seronegative for AAV.SAN011 neutralizing antibodies were divided with 6 animals per group receiving vehicle formulation buffer or AAV.SAN011. Blood was assessed at different time-points to evaluate hematology, clinical chemistry, and coagulation. Minimal to mild acute and transient elevation in liver enzymes (ALT, AST) and coagulation parameters (PT, APTT) were observed in individual animals at all dosed groups that reversed to baseline following a 3-month observation period. Vector genome and artificial microRNA levels in target skeletal and cardiac muscles were dose dependent. Remarkably, no findings were observed on microscopic evaluation of liver, dorsal root ganglion, heart, skeletal muscles, and an extensive list of peripheral organs. No clinical observations or changes were reported in body weights, body temperatures, heart rates, blood pressures, respiratory rates, neurological clinical assessments, cardiac biomarkers, ophthalmology, quantitative or qualitative electrocardiology. AAV.SAN011 expressing an artificial microRNA against DMPK was well tolerated up to the highest dose level and demonstrated robust biodistribution and expression of a new gene therapy for the treatment of DM1.

388 Critical Parameters for AAV Vector Genome Titer Determination: a Multi-Laboratory Collaborative Study

Benjamin Clarke[1], Li Ma[2]
[1]*US Pharmacopeia, Germantown, MD,* [2]*United States Pharmacopeia, Rockville, MD*
Critical Parameters for AAV Vector Genome Titer Determination: a Multi-Laboratory Collaborative Study

Adeno-associated virus (AAV) vector genome titer is a critical quality attribute that is assessed at release to ensure consistent dosing and product safety. The primary methods used are quantitative PCR (qPCR), digital PCR (dPCR), and digital droplet PCR (ddPCR), which should target a sequence in the transgene. A risk-based approach should be used to select the method, but method comparisons are difficult due to lab-to-lab differences in implementation and the absence of well-characterized reference materials. We address this challenge with a multi-platform and multi-laboratory collaborative study using a common reference material, preparation protocol, primers, and probes. To develop a suitable protocol appropriate for a collaborative study, we reviewed technical notes from instrument providers and peer-reviewed articles from product developers to determine critical method parameters. For the broadest applicability, we screened reported and novel primers and probes for the CMV promoter, SV40 poly(A) terminator, CBA promoter, ITR2 inverted terminal repeats, and GFP target sequences. We then developed a precise, accurate, specific, and robust sample preparation protocol. The well-characterized analytical reference material is based on a vector genome with a GFP reporter and capsid of the AAV5 serotype. The reference material is formulated at 5x10 10 vector genomes/mL to reduce the need for serial dilution that could compromise accuracy. This concentration is appropriate for method development, system suitability, calibration, and assay control. To ensure that an accurate genome titer value can be assigned to the reference material, we performed a collaborative study using multiple analytical platforms and independent laboratories across the world. The diverse collaborators are aligned using the common reference material, protocol, primers, and probes. We demonstrate the criticality of conditions for DNase I treatment, capsid lysis, dilution buffer composition, and MspI-mediated ITR2 digestion. Additionally, we highlight the importance of PCR target, primer design, and probe design. When conditions are aligned, the reference material's titer values are consistent across laboratories and platforms.

389 Preclinical Development of an AAV-delivered Zinc Finger Transcriptional Repressor Targeting the Prion Gene as a Novel Epigenetic Gene Therapy for Prion Disease

Toufan Parman[1], Annemarie Ledeboer[2], Marina Falaleeva[3], Jing Hu[4], Madelena Nguyen[5], Shih-Wei Chou[6], Yonghua Pan[5], Kimberly Marlen[7], David Ojala[5], Matthew Tiffany[2], Daniel Chung[8], Mihika Jalan[9], Patrick Dunn[5], Alaric Falcon[2], Carolyn Gasper[5], Meredith Pokatayev[10], Michael Howard[10], Kendrick DeSouza-Lenz[11], Kenia Guzman[10], Nikita Kamath[11], Alissa Coffey[10], Mary Lanier[12], Thanh-Thuy Tran[12], Miranda Johnson[12], Cody Zurhelen[13], Yanmei Lu[14], Amy Pooler[9], Eric Minikel[10], Sonia Vallabh[15], Bryan Zeitler[9], Kathleen Meyer[5]
[1]Sangamo Therapeutics, Inc., Brisbane, CA, [2]Sangamo Therapeutics, Richmond, CA, [3]Sangamo Therapeutics, Brisbane, CA, [4]Sangamo Therapeutics Inc., Richmond, [5]Sangamo Therapeutics, Inc., Richmond, CA, [6]Sangamo Therapeutics Inc., Richmond, CA, [7]Sangamo Therapeutics, California, [8]Richmond, CA, [9]Sangamo Therapeutics, Inc., Richmond, California, [10]Broad Institute of MIT and Harvard, Boston, [11]Broad Institute of MIT and Harvard, Cambridge, MA, [12]SRI International, Menlo Park, CA, [13]Neuroscience Associate, Knoxville, TN, [14]Sangamo Therapeutics San Mateo, California, [15]Broad Institute, Cambridge, MA

Prion disease is a rapidly progressing and fatal neurodegenerative disorder that occurs when the normal cellular prion protein (PrP^{C}) in the brain misfolds to a protease resistant and pathogenic form referred to as Scrapie PrP (PrP^{SC}). Given the high unmet need and lack of effective treatment, there is an urgency to develop novel therapeutics for treatment of this disease. Several lines of evidence suggest that neuronal PrP^{SC} is required for neurotoxicity and disease progression and that overall reduction of brain PrP^{C} can protect against prion disease. To address this unmet need, we are developing a therapy using STAC-BBB – our novel blood-brain barrier (BBB)-crossing adeno-associated virus (AAV) – to intravenously (IV) deliver a highly specific engineered zinc finger repressor (ZFR) targeting the human prion gene (*PRNP*). This potential treatment is expected to achieve a widespread, rapid, and sustained reduction of brain PrP^{C}, thereby reducing the misfolded protein PrP^{SC}.

To evaluate the feasibility of this approach, an AAV-delivered ZFR (AAV-ZFR) specifically targeting the mouse prion gene (*Prnp*) was designed and assessed in mice inoculated with Rocky Mountain Laboratory prions (RML), a gold standard model of prion disease. In a 500-day study, a single dose of AAV-ZFR was delivered IV -21 (pre-inoculation), 63 (onset of disease molecular changes) or 119 (post-symptomatically) days post inoculation (dpi) at doses of 0 (vehicle), 1E+13, 3E+13 and 1E+14 vg/kg body weight. Treatment with AAV-ZFR resulted in significant extension of survival ranging from a median of 251 days to 494 days compared with the inoculated vehicle control (median of 170 days). Importantly, our data show significant extension of median survival for post-symptomatically treated RML-inoculated mice with several animals in mid- and high-dose groups surviving to the

end of study. Notably, brain slices fixed and stained for PrP revealed that AAV-ZFR treatment led to reduction of prion protein, and a dose-dependent reduction in cerebrospinal fluid (~50-80% reduction) in RML-inoculated mice. Other benefits of AAV-ZFR treatment included increase in, or maintenance of body weight and dose-dependent improvement in nesting behavior compared with the inoculated control group, supporting the premise that reduction in prion protein leads to improvement in survival and function. Furthermore, AAV-ZFR treatment was well tolerated in healthy uninoculated mice with no abnormal histopathological findings or abnormal changes in neuroinflammatory or neuronal cell markers at doses administered, demonstrating safety of AAV-ZFR. Importantly, delivery of a ZFR targeting the human/nonhuman primate prion gene using STAC-BBB was well tolerated in cynomolgus monkeys at a dose level that has been shown to be pharmacologically active. Taken together, these results support further development of our novel STAC-BBB-ZFR vector for potential treatment of prion disease.

390 Hydrophilic Interaction Chromatography for Direct Online Disruption of Lipid Nanoparticles, Intact mRNA Analysis, and Measures of Encapsulation Efficiency

Mateusz Imiolek[1], Jonathan Maurer[2], Matthew Lauber[3], Szabolcs Fekete[1], Camille Malburet[4], Marc Francois-Heude[5], Davy Guillarme[6]
[1]Waters Corporation, Geneva, Geneva, Switzerland, [2]University of Geneva, Geneva, Geneva, Switzerland, [3]Waters Corporation, Miford, MA, [4]Sanofi, Marcy l'Etoile, France, [5]Sanofi, Marcy l'Etoile, France, [6]University of Geneva Medical Centre, SWITZERLAND

Messenger RNA (mRNA) based vaccines and therapies utilize lipid nanoparticles (LNPs) for efficient cellular delivery. Analysis of the mRNA content within a formulated LNP is an important part of drug product testing. The payloads must be assessed for integrity, concentration, and purity to ensure effectiveness and safety of this modality.

To date, LNP mRNA samples are mostly analyzed using surfactants for LNP disruption combined with capillary gel electrophoresis or reversed phase liquid chromatography. This approach requires offline sample preparation and can sometimes exhibit problematic repeatability and reproducibility. With this work, we have developed a hydrophilic interaction chromatography (HILIC) method that allows for the direct injection and on-column disruption of LNPs. This novel approach utilizes an initial mobile phase containing 60-80% acetonitrile at an elevated column temperature with a simple binary gradient and aqueous ammonium salt eluent. This technique rapidly disrupts lipid components which are not retained under HILIC conditions, and facilitates the subsequent elution, integrity checks, and quantitation of mRNA. Use of an amide-bonded ethylene-bridged hybrid stationary phase column constructed from vapor deposited hardware has facilitated high recovery measurements and straightforward implementation of the method.

On the other hand, we explore the potential of the method for measurement of unencapsulated mRNA under milder conditions, preserving the structure of LNPs and retaining only the free nucleic acid. Upon its elution and quantitation, the combination of both approaches can yield encapsulation efficiency in a high-throughput and straightforward assay.

In sum, this HILIC method simplifies the sample preparation and analytical testing protocols needed to access critical information for mRNA/LNP drugs, which makes it an especially promising new assay to consider for process development and release testing of mRNA-based treatments and vaccines.

This work was jointly funded by Sanofi, Waters Co., and the University of Geneva. Sanofi and Waters Co. employees may hold shares and/or stock options in their respective companies.

391 Intrastriatal AAV5.SGN.LEGB (LETI-101) administration selectively targeting mutant allele of the HTT gene resulted in broad CNS distribution and transgene expression in critical NHP brain regions associated with Huntington's disease pathology

Jing Jin[1], Logan Brown[1], Helen Mao[1], Mark Rodgers[1], Kinjal Shah[1], Ritika Jaini[1], Nancy Cheng[1], Ariel Vitenzon[1], Kathryn Woodburn[1]
[1]*Life Edit Therapeutics, Durham, NC*

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder caused by an expanded cytosine-adenine-guanine trinucleotide repeat in the huntingtin (HTT) gene. The resultant polyglutamine-containing mutant HTT protein (mHTT) disrupts wild-type HTT function causing neuronal stress and malfunction. Because the wild-type protein supports critical neural and cellular functions, a selective strategy targeting only the disease associated allele and protein is fervently sought.

Life Edit Therapeutics, an ElevateBio company, is developing a gene editing therapeutic that selectively targets the mutant HTT allele while leaving wildtype allele intact. This approach utilizes an engineered all-in-one AAV5 expressing Life Edit's proprietary CRISPR nuclease (LEGB) and single guide RNA (SGN), termed AAV5.SGN.LEGB (LETI-101) to selectively target the mutant allele based on the presence of the PAM forming single nucleotide polymorphism (SNP) rs362331 in exon 50. Allele selective editing and associated reduction of the mHTT protein was previously demonstrated in HD patient-derived fibroblasts and clinically relevant BACHD murine model following intrastriatal injections with LETI-101.

NHPs were administered either Vehicle, 2.20E12, or 1.13E13 vg LETI-101 bilaterally into the striatum using MRI guided convection enhanced delivery using the neuroinfuse™ (Renishaw, UK) drug delivery system. Blood, CSF, saliva, and urine were collected for biodistribution with blood and CSF collected for immunogenicity assessment (ElISpot). At one-month, NHPs were euthanized, and fluids and tissues harvested for biodistribution, and/or transgene expression evaluation. Vector DNA, LEGB mRNA, SGN RNA and LEGB protein were assayed by quantitative polymerase chain reaction (qPCR), reverse transcription-qPCR (RT-qPCR), and electrochemiluminescence (ECL)-enzyme-linked immunosorbent assay (ELISA), respectively.

LETI-101 administration was well tolerated with no Test Article-related clinical signs, neurological, changes in body temperature, heart rate, or respiratory findings. There was no induction of total antibody or anti-LEGB antibody in serum or CSF following dose administration. Biodistribution evaluation demonstrated considerable dose-dependent vector and transgene expression observed in the striatum (putamen and caudate) and within the cortex, presumably via retrograde transport, and in brain regions that are particularly vulnerable in HD including the thalamus, hippocampus, and globus pallidus. Limited systemic distribution occurred in spleen, liver, and draining lymph node, with nothing detected in the gonads. These results support the translation of LETI-101 to clinical trials for selective lowering of mHTT as a potential treatment for Huntington's disease.

392 Evaluation of Quality Control Methods for Circular RNA Purity and Integrity: SEC-HPLC, CE, and RP-HPLC

Xiulian Sun[1], Sheng Zhao[1], Qianbo Ma[2], Xiulan Zhu[2], Yingchun Liu[2]
[1]*Richmond, BC,* [2]*uBriGene Biosciences International Co., Suzhou, China*

Background and Aims:
Circular RNA (circRNA) has gained significant attention in biomedical research and therapeutic development due to its unique covalently closed structure, which enhances stability and resistance to enzymatic degradation compared to linear RNA. These properties make circRNA a promising candidate for vaccines, gene therapies, and diagnostic biomarkers. However, the production of circRNA—commonly achieved through enzymatic or chemical circularization of linear precursors—poses challenges in ensuring product quality. Residual linear RNA, process-related impurities (e.g., ligases and chemical byproducts), and structural degradation (e.g., nicks and breaks) can compromise its functionality and safety. Rigorous quality control (QC) is therefore crucial to validate circRNA batches for clinical and industrial applications. Chromatographic and electrophoretic techniques, including size-exclusion chromatography HPLC (SEC-HPLC), capillary electrophoresis (CE), and reverse-phase HPLC (RP-HPLC), offer high precision but vary in their analytical strengths and limitations. This study systematically evaluates these three methods to establish a robust QC framework tailored for circRNA characterization.

Methodology:
Batches of synthesized circRNA with varying degrees of purity and integrity were prepared to simulate real-world samples. Each sample was analyzed using SEC-HPLC, CE, and RP-HPLC. In SEC-HPLC, samples were injected into a size-exclusion column, and elution profiles were recorded to evaluate size distribution and purity. For CE, samples were run in a capillary with a background electrolyte optimized for RNA separation, generating electropherograms that were analyzed to identify contaminants and degradation products. In RP-HPLC, samples were analyzed on a C18 column, and chromatograms were examined to detect impurities and degradation products. The results from each analytic method were compared based on their sensitivity to contaminants and degradation products, as well as their resolution for circRNA.

Results and conclusion:
SEC-HPLC effectively separated circRNA from small contaminants and NTPs based on size distribution but showed limited resolution for distinguishing between linear RNA and circRNA of similar sizes. CE demonstrated high resolution and sensitivity in detecting small contaminants and degradation products in circRNA samples. The electropherograms successfully resolved circRNA from linear precursor RNA and other impurities but struggled to distinguish nicked linear RNA, providing a more detailed purity profile. RP-HPLC offered complementary insights by detecting hydrophobic impurities and degradation products, revealing the presence of nicked linear RNA. Therefore, due to the strengths and limitations of various analytical methods and the complexity of contaminants and impurities in circRNA, a combination of SEC-HPLC, CE, and RP-HPLC is necessary to fully characterize circRNA products.

Targeted Gene and Cell Therapy for Cancer

393 Engineered Fas88 Receptor Provides Inducible Cytokine Signaling to Enhance Functional Persistence of CAR-Vδ2 T Cells in Xenograft Models of Leukemia and Solid Tumor

Mansi Narula[1], Leonard Leong[1], Maksim Mamonkin[2], Norihiro Watanabe[2]*

**Corresponding Author*

Vδ2 T cells (Vγ9Vδ2 T cells) are a promising off-the-shelf (OTS) cell platform for CAR-mediated tumor targeting. However, short in vivo persistence of Vδ2 T cells due to the lack of cytokine support limit their therapeutic application. To overcome this, we first integrated major cytokines previously shown to promote Vδ2 T cell proliferation, namely IL-12, IL-15 and IL-18, in CAR-Vδ2 T cells. To limit cytokine diffusion and the associated toxicity, we generated bicistronic vectors coding membrane-bound (mb) cytokines with a 4-1BB-costimulated CD19.CAR (19BBz). While co-expression of mbIL-15 compromised CAR expression and mbIL-12 impeded their ex vivo expansion, mbIL-18 did not negatively impact the manufacture of CAR-Vδ2 T cells. Moreover, mbIL-18/19BBz Vδ2 T cells effectively eliminated CD19+NALM6 tumor in vitro and promoted T cell expansion (Day 6 coculture- T-cell fold change: 19BBz-0.6±0.1, mbIL-18/19BBz-3.3±0.5, $p<0.0001$). In a NALM6 xenograft mice model, mbIL-18/19BBz Vδ2 T cells outperformed the other combinations, prolonging animal survival without exogenous cytokine supplementation (median survival: control – 21 days, 19BBz – 31days, mbIL-12/19BBz – 41 days, mbIL-18/19BBz - > 70 days). Superior T cell proliferation and persistence was demonstrated by a dual-luciferase imaging system to simultaneously track tumor growth and T cell expansion.

While mbIL-18 dramatically enhanced CAR-Vδ2 T cell function, cytokine trans-presentation to the host cells poses an accelerated risk of allogeneic rejection of OTS therapeutic CAR-Vδ2 T cells. Therefore, we engineered inducible cell-intrinsic IL-18 signaling by generating a chimeric Fas88 receptor comprising of a Fas ectodomain linked to a MyD88 endodomain, a key adaptor molecule downstream of IL-18R. Fas88 leverages CAR/TCR activation-dependent surface expression of FasL in CAR-Vδ2 T cells that otherwise leads to unwanted activation-induced cell death (AICD). Upon CAR signaling, upregulated FasL engages Fas88, defusing AICD as measured by Annexin

V/7-AAD staining, and instead transmits IL-18 signaling leading to phosphorylation of NF-kB, IKKα/β and MAPK in Vδ2 T cells, on par with constitutive IL-18 signaling.

We evaluated the functional effect of Fas88 engineered CAR-Vδ2 T cells in three separate xenograft models of hematologic and solid cancers: B-cell leukemia (CD19.CAR vs NALM6), T-cell leukemia (CD5.CAR vs CCRF-CEM), and pancreatic cancer (PSCA.CAR vs CFPAC-1). In the NALM6 model, Fas88 enhanced the proliferation and persistence of CD19.CAR Vδ2 T cells, boosting tumor clearance on par with mbIL18-expressing CD19.CAR Vδ2 T cells. Similarly, the anti-tumor effect of CD5.CAR-BBz Vδ2 T cells was significantly improved by co-expressing Fas88 while unarmed CD5.CAR-BBz Vδ2 T cells failed to control tumor growth in an aggressive CD5+ CCRF-CEM T-ALL model (median survival: control – 18.5 days, CD5.CAR – 18 days, CD5.CAR/Fas88 – 56 days). Finally, in a subcutaneous CFPAC-1 xenograft model, Fas88-armed PSCA.CAR-BBz Vδ2 T cells expanded at the tumor site and controlled its growth, significantly prolonging animal survival (median survival: control – 32 days, PSCA.CAR – 38 days, PSCA.CAR/Fas88– 71 days). All experiments were performed with a single infusion of freshly thawed CAR T cells in the absence of exogenous cytokines to model conditions similar to CAR-αβT cells. Overall, Fas88 improves the functional persistence and in vivo anti-tumor effect of CAR-Vδ2 T cell across diverse tumor models.

394 STX-003: A mRNA Cancer Immunotherapy Utilizing Cancer-Selective Programmable Genetic Circuits for Systemic Tumor Control

Wen Tseng[1], Gautam Shenoy[1], Emily Clinton[1], Ryan Patenaude[1], Wuhbet Abraham[1], Zhijun Su[1], Madhuri Dey[1], Justin Letendre[2], Maeve Pattie[1], John Sexton[1], Emily Tjon[1], Nandita Menon[1], Isma Zarin[1], Breanna Burgett[3], Aidan Coia[1], Akshay Mavani[4], Weiyu Zhao[1], Kevin Shi[1], Alexander Lemaire[1], Julian Quinones[1], Ryan Sowell[1], JASPREET KHURANA[1], Joseph Barberio[1], PRASHANT NAMBIAR[1], Jacob Becraft[1], Tasuku Kitada[1]
[1]Strand Therapeutics, Boston, MA, [2]Strand Therapeutics, Stoughton, MA, [3]Strand Therapeutics, Brighton, MA, [4]Strand Therapeutics, Inc., Boston, MA

Cancer is responsible for roughly one in six deaths worldwide, with solid tumors accounting for approximately 90% of adult cancers. Immunotherapies have shown substantial promise for treating solid tumors, but achieving efficacy while avoiding toxicity is a key concern. Systemic administration of the immunomodulatory cytokine interleukin-12 (IL-12) has shown impressive efficacy in preclinical solid tumor models but is poorly tolerated in humans, likely due to off-target effects. To overcome this problem, we are developing STX-003, a self-replicating mRNA-LNP therapeutic that leverages the power of programmable miRNA-sensing genetic circuits to selectively express IL-12 in tumors while suppressing its expression in healthy tissues. Here, we present preclinical data demonstrating the effects of programmable genetic circuitry on our drug following intravenous injection. In mouse models, candidate genetic circuits downregulated the self-replicating mRNA in healthy organs such as spleen and heart, which was correlated with a reduction in tissue histopathological findings. Furthermore, candidate circuits dramatically reduced circulating levels of IL-12 induced by the drug in healthy non-human primates (NHPs). Additionally, we evaluated two candidate circuits in the B16.F10 syngeneic melanoma mouse model to assess the effects of these circuits on tolerability and anti-tumor efficacy over a range of drug doses. Both candidates were tolerated at all doses evaluated and exhibited anti-tumor activity. One of these candidates robustly controlled tumors in a dose-dependent manner, achieving an overall response rate of 100% at the highest dose, and this circuit was selected for our STX-003 development candidate. These studies are the first to demonstrate fully functional programmable genetic circuits with self-replicating mRNA in NHPs, the first to show the amelioration of drug-induced tissue histopathology via genetic circuitry in an animal model, and the first to provide evidence that genetic circuitry can improve the therapeutic indices of potent but poorly tolerated drugs. Our results highlight the potential of STX-003 for treating solid tumors and the promise of programmable genetic circuits for enabling targeted expression of genetic medicines and for surmounting the problem of previously “undruggable” targets through controlled expression.

395 Allele-Specific CRISPR/AAV6 Gene Correction of Dominant *JAK2*-V617F Mutation in Polycythemia Vera

Freja Ekman[1], Sridhar Selvaraj[2], Jason Gotlib[3], Kyle Cromer[4]*, Matthew Porteus[3]*

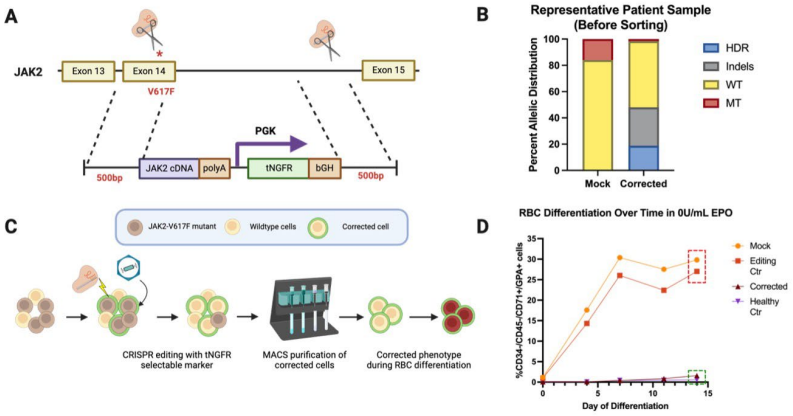
Stanford, CA, [4]University of California, San Francisco, San Francisco, CA
**Corresponding Author*

The *JAK2*-V617F gain-of-function mutation is a primary molecular driver of several myeloproliferative neoplasms, most notably occurring in ~95% of Polycythemia Vera (PV) cases. In PV, this mutation induces constitutive activation of JAK/STAT signaling, disrupting physiological erythropoietin-dependent regulation resulting in pathological erythrocytosis. There exists a need to develop more curative therapies as patients with PV are at risk of progressing to myelofibrosis or acute myeloid leukemia and current therapies only provide hematology and symptomatic benefit with variable effects on *JAK2*-V617F allele burden. As the *JAK2*-V617F mutation is autosomal dominant with high propensity for clonal expansion, curative treatment requires complete eradication of all mutant cells. To address these therapeutic limitations, we developed a dual-gRNA genome editing strategy combining CRISPR-Cas9 RNP with AAV6 to target the *JAK2*-V617F mutation in hematopoietic stem cells (HSCs). Our dual-gRNA system achieves high-efficiency mutation deactivation while maintaining allelic specificity. The first guide, targeting the V617F mutation site, achieves 51±7.9% indel formation, while a second guide directed at an intronic region ~100 base pairs downstream synergistically enhances allelic V617F deactivation to 97%. Notably, the mutation-targeting guide exhibits no activity against wild-type alleles. To enable *JAK2*-V617F correction, we engineered a homology directed repair (HDR) AAV6 vector incorporating codon-optimized downstream exons and a PGK promoter-driven tNGFR for selective enrichment (**Fig. 1A**). Electroporation of HSCs with this system yields 40.0±5.05% edited cells, with MACS enrichment achieving 97.2±1.6% edited populations. We evaluated our editing approach in HSCs isolated from PV patient bone marrow aspirates (IRB-approved) in a 14-day erythroid differentiation culture. This model replicated key PV pathophysiology, including accelerated erythroid differentiation, enhanced proliferation, and elevated mutant allele frequency. Patient-derived HSCs demonstrated spontaneous differentiation into RBCs (CD34-/CD45-/CD71+/CD235a+) at 8.0-67.8% without erythropoietin, compared to 1.3% or less in healthy controls. Under erythropoietin stimulation, patient HSCs showed accelerated differentiation (10.8-14.3% by day 4) compared to healthy controls (<0.02%). These phenotypes were validated to be *JAK2*-V617F dependent through introduction of the mutation into healthy HSCs. Application of our editing strategy without selection to these patient-derived cells achieved 81.4±12.1% elimination of mutant alleles, with 51.8±29.1% converting to wild-type sequence (**Fig. 1B**). This genetic correction significantly ameliorated the erythroid differentiation phenotypes of PV in vitro as observed by the reduction in spontaneous differentiation by 90.7±11.4% in cultures without erythropoietin (**Fig. 1C-D**), reaching levels similar to healthy controls. Similarly, erythropoietin-stimulated samples showed reduced early erythrocyte proliferation and differentiation (4.7±1.3% and 77.4±28.3% respectively) at day 4. These results provide proof-of-concept for a potential one-time gene therapy for PV, though serial transplantation studies are needed to assess impacts on clonal expansion. Moreover, our work demonstrates the potential of HDR-based gene editing for addressing autosomal dominant mutations, potentially establishing a platform for genetic correction of dominant disease alleles.

Figure 1



396 mRNA-Mediated Rescue Loss of p53 Tumor Suppressor Function as a Potent New Strategy for Cancer Therapy across Pan-p53 Alterations.

Gilles Divita[1], Audrey Grunenberger[2], Léa Cabrera[2], Julien Vollaire[3], Veronique Josserand[3], Jordi Rodon[4], Neil Desai[5]
[1]Aanastra Inc., Pacific Palissades, CA, [2]DIVINCELL, Nimes, Hérault, France, [3]Institute for Advanced Biosciences INSERM, Grenoble, France, [4]University of Texas MD Anderson Cancer Center, Houston, TX, [5]Aanastra Inc, Pacific Palisades, CA

p53 tumor suppressor mutations result in loss of function of p53 in approximately 50% of all human cancers.TP53 missense, nonsense mutations and p53 deletion are present in about 50%, 12% and 5% of all p53 driven cancers, respectively. To date there is no effective treatment for rescuing p53 function in cancers using a pan-p53 approach. We have developed ADGN-531 is a new potent strategy combining mRNA with a tumor selective peptide nanocarrier to rescue of p53 tumor suppressor function.

ADGN-531 contains proprietary p53-mRNA complexed with proprietary short amphipathic peptides in the form of nanoparticles. ADGN-531 was evaluated on 20 different cancer cell lines harboring various p53 mutations. In-vivo efficacy of IV-administered ADGN-531 nanoparticles was evaluated on colorectal cancer SW403 (p53 nonsense/$KRAS^{G12V}$), osteosarcoma SaOs2 (p53 null), and NSCLC NCI-H358 (p53 null/$KRAS^{G12C}$) mouse xenografts at a dose of 0.25-1.0 mg/kg weekly. ADGN-531/sotorasib synergy was evaluated *in vitro* on NCI-H358 (p53 null/$KRAS^{G12C}$) and Mia-PACA ($p53^{R48W}$/$KRAS^{G12C}$) cells and in vivo on NCI-H358 mouse xenograft.

ADGN-531 at low nanomolar concentration markedly inhibits the growth of a large panel of cancer cells harboring p53-missense or nonsense mutations or p53-deletion, by rescuing p53 transcriptional activity and subsequent expression of its target proteins. ADGN-531 induces cell cycle arrest in G1 due to p21 upregulation and apoptosis following BAX and PUMA activation. IV-administration of ADGN-531 resulted in dose responsive tumor growth inhibition in SaOs2, SW403 and H358 xenografts independent of KRAS status. ADGN-531 (0.5 to 3.0 mg/kg, weekly) treatment results in a tumor regression by 25 to 90%. The treatment is well tolerated as no major variation in animal weight or no major liver and kidney toxicity were detected. Tumor analysis demonstrated that ADGN-531 treatment resulted in a strong expression of p53 in the tumor, together with an activation of the apoptosis pathway in the tumor, associated to an increase of BAX expression and an up regulation of C-CAS-9 signal.

We demonstrated a strong synergy in a NSCLC H358 xenograft (tumor regression 80%) when restoring P53 function with ADGN-531 (0.5mg/kg, weekly) along with inhibition of $KRAS^{G12C}$ mutant using sotorasib (10mg/kg, daily). ADGN-531 potentiated the effect of sotorasib on sotorasib resistant cells harboring high level of $KRAS^{G12C}$ in permanent active state. ADGN-531 treatments are well tolerated, no sign of clinical toxicity was detected after single or repeated administrations.

ADGN-531 is effective in rescuing p53 function both in vitro and in vivo across a wide range of p53 alterations. Our study provides a proof-of-concept that restoration of tumor suppressor function by ADGN-531 could be used as a single agent therapy in P53 altered tumors independent of other driver mutations e.g., KRAS, or with other therapies for potent combinatorial cancer treatment.

397 CD90 Ablation on Hematopoietic Stem Cells (HSCs) Enables Targeted Leukemia Stem Cell Immunotherapy

Justin Thomas[1], Nicholas Petty[1], Kyle Swing[1], Marlena Starrs[1], Heather Mack[1], Carl Wolf[1], Alvin Tong[1], Mitchell Egan[1], Delila Evangelista[1], Malia Callier[2], Dnyanada Pande[1], Mark Enstrom[1], Clare Samuelson[1], George Laszlo[3], Roland Walter[3], Stefan Radtke[4], Hans-Peter Kiem[4]*
[1]Fred Hutchinson Cancer Center, Seattle, WA, [2]University of Washington, Seattle, [3]Fred Hutchinson Cancer Center, [4]Fred Hutchinson Cancer Center, Seattle, Washington
**Corresponding Author*

Background:
Thy1/CD90 is a known cancer stem cell marker, with high CD90 expression corresponding with increased tumor metastasis and chemoresistance. Furthermore, higher CD90 expression is found in high-risk, relapsed acute myeloid leukemias (AMLs). At the top of the hematopoietic hierarchy exists the CD34+CD90+ hematopoietic stem cell (HSC) responsible for life-long hematopoiesis. An emerging therapeutic is the ablation or epitope editing of shared cancer antigens on HSCs to protect them from anti-cancer immunotherapies. We hypothesized that modifying CD90 on healthy HSCs, combined with anti-CD90 immunotherapy, would enable a novel anti-leukemia stem cell (LSC) consolidation approach.

Approach/Results:
To study the relevance of CD90 expression on healthy HSCs, HSCs were co-transduced with either Thy1/CD90 targeted shRNA or non-targeted control shRNA and a mCherry-reporter. Transduced HSCs were then serial transplanted into primary and secondary immunocompromised mice to observe self-renewal capacity. Successful CD90-knockdown was observed with a 55% reduction of CD90+ cells in the CD34+CD38-CD133+CD45RA- subset of CD90-shRNA mice ($n=8$, $p<.05$). However, there was no significant difference in CD45 engraftment of transduced cells in either primary or secondary transplants. Furthermore, CD90-shRNA cells displayed equal myeloid and lymphoid differentiation capacity compared to control cells. We next developed an adenine base-editing strategy to remove the start codon of Thy1 (CD90-BE), allowing for complete genetic knockout of CD90. Base-edited human progenitors displayed a 22% reduction of CD90+ cells ($n=7$, $p<.05$), with no loss of human engraftment or phenotypic HSCs. Next, we applied our CD90 base-editing strategy to the nonhuman primate (NHP) autologous transplantation model. NHP HSCs were CD90-BE treated and reinfused into an autologous busulfan-conditioned recipient. Concomitant with 84% Thy1 allele editing, we observed complete platelet and neutrophil recovery at days 12 and 22 post-transplant, respectively. Furthermore, CD90-ablated NHP HSCs maintained in vitro serial re-plating capacity, confirming sustained self-renewal. These findings suggested that CD90 signaling is vestigial in adult HSC biology. We next analyzed CD90+ versus CD90- cells from bone marrow (BM) aspirates of six leukemia patients for the presence of AML driver mutations (i.e., FLT3-ITD, Runx1-ETO, NPM1). In all patients, we confirmed the presence of AML mutations in CD90+ populations. Further, Cite-Seq analysis of BM aspirates from 3 leukemia patients revealed CD90+ cells that concurrently expressed a leukemia stem cell (LSC) transcriptomic signature but did not express other known LSC markers (i.e., CD33, CD117). As such, we developed CD90-directed CAR-T (CD90-CAR-T) cells to ablate CD90-expressing malignant tumors. CD90-CAR-T cells displayed CD25 surface expression and secreted IL2 and IFN-γ only in the presence of CD90-expressing cell lines. Additionally, co-cultures of HSCs with CD90-CAR-T led to significant abrogation of serial re-plating capacity. By comparison, engrafted CD90-BE HSCs were protected against CD90-CAR-T in vivo, while CD90-expressing tumors were eliminated as measured by flow cytometry and genomic sequencing. Thus, we developed a novel LSC-targeted immunotherapy platform by ablating CD90 on non-malignant HSCs, enabling the targeting of chemoresistant AML subsets while reducing the risk of treatment-associated BM failure.

398 Single Dose AAV-Mediated Immuno-Gene Therapy With a Dual Targeted T-Cell Engager is Superior to Mono Targeted Engagers for Multiple Myeloma

Pin-Yi Wang[1], Chun-Yu Chen[2], Brian Hutzen[2], Andrea Glaspell[3], Mark Currier[4], Allen Reha[5], Samit Varma[6], Brian Kaspar[6], **Timothy Cripe**[7]

[1]The Research Institute at Nationwide Children's Hospital, Columbus, OH, [2]The Research Institute at Nationwide Children's Hospital, Columbus, OH, [3]Nationwide Children's Hospital, Columbus, OH, [4]Nationwide Children's Hospital, [5]Vironexis Biotherapeutics, Millstone Township, NJ, [6]Vironexis Biotherapeutics, Inc., San Diego, CA, [7]Nationwide Children's Hospital, Columbus, Ohio

Multiple myeloma (MM) is characterized by the abnormal clonal proliferation of plasma cells. It is the second most common hematologic malignancy, accounting for 1-2% of all cancers and 10% of hematologic malignancies worldwide. Despite many effective treatments, including chemotherapy, radiation therapy, stem cell transplants, CAR-T and T-cell engager (TCE) therapies, MM remains incurable, with a 5-year overall survival rate of around 55%. We aim to tackle MM using recombinant adeno-associated virus (rAAV)-based TCE gene therapy to improve patient outcomes due to its long-lasting, single dose, and off-the-shelf characteristics. We selected BCMA (B-cell maturation antigen) and GPRC5D (G protein-coupled receptor class C group 5 member D) as tumor immunotargets. BCMA is expressed on mature B cells and is a key target for MM immune therapies. GPRC5D, an orphan receptor typically expressed only in the hair follicle, is also highly expressed on myeloma cells. We designed several rAAV plasmids encoding CD3-targeted TCEs that bind BCMA, GPRC5D, or both targets simultaneously. In vitro, all BCMA-targeting TCE constructs effectively mediated T-cell killing of BCMA-expressing MM cell lines (MM1S & RPMI8226), but not cells lacking BCMA. The GPRC5D-targeted TCE only mediated effective killing of GPRC5D-expressing cells, but not RPMI8226, which has no detectable GPRC5D expression. Both dual-targeted TCEs (BCMA/GPRC5D) effectively mediated T-cell killing of cells expressing either target. We then selected one BCMA-targeted, one GPRC5D-targeted, and one dual-targeted TCE rAAV for in vivo assessment. We injected NSG-SGM3 mice with $1x10^6$ MM1S-LucGFP cells via tail vein and subsequently treated them with a single dose of rAAV encoding BCMA-, GPRC5D- or BCMA/GPRC5D-targeted TCEs followed by intermittent doses of human peripheral blood mononuclear cells (huPBMCs). Separate groups of mice were injected with saline or an rAAV encoding eGFP to serve as controls. Tumor burden in mice treated with rAAVs encoding BCMA- or GPRC5D-targeted TCEs was significantly reduced relative to the control mice early on, but relapse became evident in these animals as early as 4 weeks into the experiment, and all of them eventually succumbed to disease. Flow cytometry analysis of recurrent tumor cells from these TCE groups showed evidence of surface expression of both targets, suggesting that relapses were not due to antigen escape. In contrast, mice treated with the BCMA/GPRC5D dual-

targeted TCE-expressing rAAV showed a rapid decrease in tumor burden in the first 2 weeks and remained tumor-free from days 20-30 to the end of the study (days 70-77). Serum levels averaged 38.6 µg/mL in the BCMA-targeting TCE group and 22.7 µg/mL in the BCMA/GPRC5D dual-targeting group. In conclusion, our data demonstrate that tumor-targeted TCEs for multiple myeloma can be expressed via rAAV as a therapeutic strategy in vivo. Furthermore, our results suggest that dual-targeted TCEs against BCMA and GPRC5D are more effective than targeting either one alone in controlling myeloma disease burden. These data provide support for moving this construct into clinical trials.

399 Covalent Antibody Conjugation to AAV9 for Targeted Gene Therapy of Metastatic Cancer

Mirko Luoni[1], Stefano Parracino[2], Serena Giannelli[3], Tamara Canu[2], Tommaso Russo[2], Vania Broccoli[3], Antonio Esposito[4]
[1]San Raffaele Scientific Institute, Busto Arsizio, Varese, Italy, [2]San Raffaele Scientific Institute, Milan, Milano, Italy, [3]Ospedale San Raffaele, Milan, Milano, Italy, [4]Università Vita-Salute San Raffaele, Milan, Milano, Italy

Adeno-associated viral (AAV) vectors are currently the preferred technology for many gene therapy applications. AAVs can target various organs, and the engineering of novel variants broadens their potential to treat many human diseases. However, their inherent tropism, typically not specific for a single cell type, makes them poorly suited for targeting metastatic tumor cells. In response, several groups are optimizing methods to restrict the broad tropism of AAVs through rational design engineering. Between the most common methods is the chemical coupling of a specific antibody to the AAV capsid, enhancing viral infection to cells expressing the corresponding antigen.

Here, we exploited a novel strategy based on the SpyTag and SpyCatcher technology for covalently binding an antibody to the capsid of the galactose-binding deficient AAV9, redirecting its tropism towards GD2 antigen highly expressed by neuroblastoma-derived metastatic cells. We named this tool AAV-STITCH to highlight its precision in "stitching" antibodies to the viral capsid.

In vitro analyses demonstrated that AAV-STITCH specifically and efficiently transduced tumor-derived cell lines but not control cells like fibroblasts or cancer cells lacking the selected antigen. We subsequently developed two models to recapitulate neuroblastoma metastasis in mice: by injecting tumor cells subcutaneously (xenograft model) or into the bloodstream (pseudometastatic model). In both models, we confirmed the specificity of our technology in targeting only tumor cells while avoiding any transduction in other organs. Then, we demonstrated that AAV-STITCH can be leveraged to deliver suicide genes to metastatic cells dampening their growth and significantly improving the survival of treated neuroblastoma animal model. Currently, this technology is under evaluation in a model closer to clinical settings using a patient-derived xenograft mouse model.

In summary, we have optimized a groundbreaking strategy to generate AAVs that precisely target cancer cells. This innovative approach has the potential to ameliorate cancer treatment by offering a highly specific and efficient method for delivering therapeutic agents directly to neuroblastoma tumor cells, paving the way for a new generation of targeted cancer therapies.

Chemistry, Manufacturing, and Controls

400 Comparative Potency Analysis of iPSC-derived and PBMC-derived NK cells for Immunotherapeutic Application

Tejashree Redij[1], RANRAN ZHANG[2], Ping Wei[3], Pankaj Mishra[1], Xuan Guo[4], Junxia Wang[5]
[1]Catalent Pharma Solutions, Princeton, NJ, [2]Catalent Cell & Gene Therapy, Princeton, NJ, [3]Catalent Pharma Solution, Princeton, NJ, [4]Catalent Cell and Gene Therapy, Princeton, USA, Princeton, NJ, [5]Premier Biosciences, Princeton, NJ

Background & Aim
The generation of natural killer (NK) cells from induced pluripotent stem cells (iPSCs) has created new opportunities for scalable, homogeneous, and "off-the-shelf" cancer immunotherapies. iPSC-derived NK (iNK) cells offer several advantages, including uniformity, enhanced genetic engineering capabilities (e.g., CAR-NK cells), and the potential for large-scale production. However, challenges such as complex production processes and achieving functional maturity comparable to peripheral blood mononuclear cell (PBMC)-derived NK cells must be addressed. PBMC-derived NK cells, despite their high functional maturity and extensive clinical study, face limitations on donor variability, restricted expansion potential, and challenges in genetic engineering. This study aims to compare the functional potency of NK cells produced from iPSC and PBMC to determine their efficacy and acceptability for therapeutic applications.

Methods
PBMC-derived NK cells were isolated from PBMC. iPSC-derived NK cells were differentiated from cord-blood-derived iPSC using previously established differentiation methods. We conducted a comparative analysis of iNK cells, focusing on their potency through a matrix of bioassays. This included phenotypic analysis, degranulation, cytokine profiling, and cytotoxicity assessment.

Results
iPSC-derived NK cells exhibit comparable cytotoxic abilities to PBMC-derived NK cells, despite differences in surface marker expression. Both cell types demonstrate an accumulation of cytotoxic components critical for precision killing, including increased levels of interferon gamma (IFN-γ), tumor necrosis factor alpha (TNF-α), perforin, and granzyme, in the presence of target cells. This functional activity is further supported by the analysis of cytokine secretion profiles, which confirm their potent cytotoxic response. Interestingly, iPSC-derived NK cells display a distinct pattern of surface marker expression compared to their PBMC-derived counterparts, indicating potential differences in maturation or activation states.

Conclusions
Our study provided critical insights into the relative capabilities and therapeutic potential of NK cells from PBMCs and iPSCs. These findings highlight the feasibility of iPSC-derived NK cells as a scalable, uniform, and genetically modifiable alternative to donor-derived NK cells, supporting their acceptability for clinical applications and advancing the development of NK cell-based immunotherapies.

401 Novel Nanoneedle Technology for Integrating Critical Quality Attributes: Enabling Accurate and Cost-Effective Manufacturing

Qimin Quan[1]*, **Tal Raz[2]**, Angad Garg[3], Eli Litton[2]
[1]NanoMosaic LLC, Waltham, MA, [2]NanoMosaic, Waltham, MA, [3]NanoMosaic LLC, Newton Highlands, MA
**Corresponding Author*

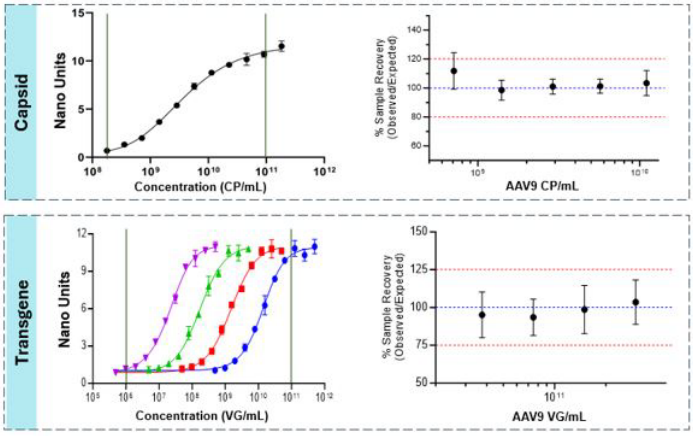
Introduction:
With the rapid growth of AAV-based therapies, various technologies are being employed throughout the manufacturing process to ensure product quality and improve process efficiency. However, there is a pressing need for the standardization of robust analytical methods alongside a deeper understanding of product heterogeneity. Standardization will foster more efficient manufacturing, reduce costs, improve scalability, increase productivity and yield, and ultimately enabling the delivery of safer, more cost-effective gene therapies.

Methods:
We have developed the multi-omic Tessie platform, based on nanoneedle technology, to quantitatively characterize the capsid titer, transgene titer, empty/full ratio, genome integrity, and contaminants (e.g. host cell DNA and proteins) in a single platform. Notably, current analytical methods either target only a short region (such as PCR) or rely on mass-based approaches (such as AUC or mass photometry) as surrogates for detecting full-length transgenes. In contrast, the Tessie platform enables precise, reproducible quantification of full-length transgenes, distinguishing them from partial genomes and bridging the gap between current analytical methods and potency assays.

Results:
We have densely integrated nanoneedles on a silicon chip using a complementary metal-oxide-semiconductor (CMOS)-compatible process developed in-house. For viral genome assays, two oligonucleotide probes are mixed with the sample and amplified into a double-stranded DNA product using the viral genome as a template. The positions of the probes define the specific transgene sub-population to be quantified. Full-length transgenes are detected using probes at opposite ends, while truncated transgenes are quantified with probes spanning the region of interest. The resulting double-stranded product is quantified on the Tessie nanoneedle sensors. For capsid assays, antibodies replace the probes, and the final sandwich complexes are quantified on the same platform. The "Empty/Full ratio," combining full-length transgene and capsid titers, can be calculated by integrating both capsid and transgene quantifications.

We have characterized the performance of the assay using standard reference well-characterized samples. Intra- and inter-assay coefficient of variation (CV), and spike-in recovery data are summarized in **Fig. 1**. The assay workflow is compatible with crude lysate samples and provides accurate quantification, which aligns with ddPCR for short-region transgene quantification and ELISA for capsid titer measurements in orthogonal comparisons. While there is currently no comparable technology for full-length transgene quantification, the data obtained show strong alignment with AUC and electrophoresis results. Additionally, we have developed an electronic signature tracking function within both the instrument and analysis software, ensuring that the system is 21 CFR Part 11 compliant.

Conclusions:
The Tessie platform offers a new methodology for integrating the gene therapy analytics into a single system, ensuring 21CFR part 11 compliance. Its ability to provide molecularly specific quantification of viral genomes and serotype-specific capsids is an advance over existing methodologies. The Tessie platform has the potential to advance AAV-based gene therapy development by providing accurate, integrated measurements, ultimately driving a more cost-effective and standardized manufacturing process.



✓ Multi-omic in one system
✓ Compatible with crude
✓ Genome Integrity
✓ Single data report 21CFR part 11compliant

Viral capsid assay spec	
Dynamic range	2E+08 – 1E+11 cp/mL
Intra- CV (duplicates)	3.3%
Inter- CV (13 plates, 3 uers, 3 instruments)	7%
Recovery-spike in rate	< 80-120%
Viral genome assay spec	
Dynamic range	9.8E+5 – 1E+11vg/ml (tunable)
Intra- CV (duplicates)	2.5%
Inter- CV (17 plates, 3 users, 3 instruments)	14%
Recovery-spike in rate	< 80-120%

Fig. 1: Top row: The capsid assay demonstrates a dynamic range of 2E8 to 1E11 cp/ml, with an intra-assay coefficient of variation (CV) of 3.3%. The inter-assay CV, tested across 13 plates, 2 users, and 3 instruments, is 7%. Bottom row: The viral genome assay offers a tunable dynamic range, depending on the number of primer extension cycles after probes are mixed with the sample. The dynamic range spans from 9.8E5 to 1E11 vg/ml, with an intra-assay CV of 2.5%. The inter-assay CV, tested across 17 plates, 3 users, and 3 instruments, is 14%. Recovery in spike-in experiments returned expected quantification within 80-120%.

402 Mastering hcDNA: A Harmonized Approach for AAV Gene Therapies

Steven Henry[1], Simon Walker[2]*
[1]Eurofins BioPharma Product Testing, Lancaster, PA, [2]BioPhorum, HARROGATE, North Yorkshire, United Kingdom
**Corresponding Author*

BioPhorum's mission is to create environments where the global biopharmaceutical and device industry can collaborate and accelerate its rate of progress, for the benefit of all. To support organizations developing viral-based therapeutics, BioPhorum initiated the Impurities in Viral-Based Therapies workstream which comprised of 34 members from 20 organizations. The workstream members elected to focus on host cell DNA (hcDNA) impurities in AAV gene therapy products.

This poster will present the results of industry benchmarking surveys that provide insights as to actual hcDNA levels dosed, methods of quantitation, and strategies to control the impurity level during production. A key focus of the presentation will be the proposal of a harmonized approach to hcDNA reporting. Normalizing hcDNA levels by the number of vector genomes (vg) dosed, as well as reporting total hcDNA/dose, facilitates easier comparison within and across AAV gene therapy products.

Current FDA guidance recommends limiting hcDNA to less than 10 ng/dose and smaller than 200 base pairs. By surveying the actual number of vector genomes dosed and correlating them to the percent of development programs achieving the current hcDNA limit, we found that beyond 10^{13} vg/dose the number of programs meeting the guidance falls to less than 20 %. The wide range in vg dosed (10^{11}-10^{16} vg/dose) suggested adding vg as a normalizing factor to allow for easier comparison of hcDNA levels achieved based on the current state of technology (process and analytics). On a per 10^{13} vg basis, the 95 % confidence interval for hcDNA in drug product was found to be 39 – 235 ng hcDNA/10^{13} vg. Interestingly, in recent guidance for neurodegenerative disease gene therapies, the FDA has omitted an explicit hcDNA limit and encourages manufacturers to assess the characteristics of their production cell lines.

In conclusion, the BioPhorum workstream aims to standardize the industry approach to hcDNA reporting and serve as a barometer of the current hcDNA state of the art.

403 Breaking Boundaries in AAV Production: Exploiting High Salt Concentrations for increased AAV yields and infectivity.

Dmitry Zabezhinsky, Merck Life Science KGaA, Darmstadt, Hessen, Germany

Enhancing adeno-associated virus (AAV) production while maintain highest safety standards is of utmost importance in the field of gene therapy. In this study, we have confirmed previous approaches to boost AAV production utilizing higher salt concentrations during the lysis process. Our research yielded impressive results, demonstrating that elevated salt levels, such as 500 and 1000mM, effectively enhance AAV process intensification by eliminating adhesive DNA from the AAV capsids and reducing aggregation. However, it is worth noting that high salt concentrations exceeding 200mM hamper the activity of standard endonucleases, which are virtually inactive at high salt environment. To overcome this challenge, we have engineered a cutting-edge enzyme called the Benzonase® Salt Tolerant Endonuclease, specifically designed to function optimally in high salt conditions ranging from 500-1000mM. This remarkable enzyme efficiently digests DNA fragments shorter than 10 base pairs and remains fully compatible with commonly used detergents. By incorporating >500mM salt in the lysis buffer, we have achieved remarkable outcomes. Our experimental results indicate a substantial improvement in AAV titers by 20-30% (evaluated using ELISA) and a remarkable 10-fold enhancement in viral transduction capability. These findings provide valuable insights to intensify AAV production, solving one of the key bottlenecks of the gene therapy industry: AAV production yield.

404 Scalable Hematopoietic Stem Cell Expansion in Stirred-Tank Bioreactors for Advancing Cell Immunotherapies

Grace Eppolito[1], Rukmini Ladi[2], Kevin Shek[1], Eric Burden[3], Sean Devine[4], Bauer Lesavage[1], Michael Roberto[5], Ece Canan Sayitoglu[1], Everardo Hegewisch-Solloa[1], Noushin Dianat[6], Nina Horowitz[1], Rui Tostoes
[1]ImmuneBridge, San Francisco, CA, [2]Sartorius, Ann Arbor, MI, [3]Sartorius Stedim North America, Bohemia, New York, [4]Sartorius, Bohemia, New York, [5]Sartorius, Bohemia, NY, [6]Sartorius, Paris, Paris, France

Hematopoietic stem cells (HSCs) are pivotal for off-the-shelf allogeneic immune cell therapies, including natural killer (NK) cells. While HSC expansion molecules (like our proprietary IBR403) enable CD34+ cell growth, conventional 2D cell culture methods are inefficient, costly, labor-intensive, and lack scalability, limiting large-scale clinical and commercial production. To overcome these challenges, we developed a robust, scalable, and high-throughput platform using automated stirred-tank bioreactors to expand cord blood derived HSCs (CBUs) and differentiate them into NK cells.

Using a Design of Experiments (DoE) approach with MODDE® software and multivariate analysis,we optimized culture conditions by comparing CellGenix® GMP grade SCGM with RUO media, supplemented with IBR403 and key cytokines (SCF, Flt-3 ligand, TPO, IL-6). Over 70 bioreactor conditions were tested, evaluating parameters such as perfusion rates (0.5-2 VVD) and cytokine concentrations (0-100 ng/mL) across multiple donors over 28 days. CD34+ cell expansion and differentiation were performed in the Ambr® 15 bioreactor system, with functionality and purity assessed for clinical relevance.

HSCs cultured at a perfusion rate of 2 VVD produced an average of 5×10^7 CD34+ cells per mL of input cord blood in GMP-grade media, compared to 1.4×10^6 in RUO media. The DoE identified an optimal cytokine formulation that reduced costs by 50% while achieving $>6 \times 10^7$ CD34+ cells per mL of input cord blood. Media formulation and a high perfusion rate were critical for maximizing CD34+ yields per mL of input CBU. Variations in CO2 (5% vs. 10%) and dissolved oxygen setpoints (15% vs. 30%) showed no significant impact on CD34+ expansion. NK cells differentiated in bioreactors under optimal conditions showed >95% CD56+ expression (55-98% on Day 28) and >75% cytotoxicity against A549 cells at a 1:1 effector-to-target ratio, with donor variability impacting HSC expansion and NK differentiation.

This study successfully optimized CBU-derived HSC expansion and NK cell differentiation in GMP-grade media using the Ambr® 15 bioreactor system. By refining key process parameters, we achieved high-yield, cost-effective CD34+ cell expansion and scalable NK cell production. These findings establish a robust platform, transforming cord blood into a valuable resource for advancing allogeneic immune cell therapies in oncology and immune-related diseases.

405 Negative Impact of Leukapheresis Collection on Blood-derived B-cell Gene Expression — An Artificial Intelligence and Machine Learning Enhanced Study

Ethan Deitcher[1], Kirk Trisler[1], Steven Deitcher[1]*
[1]*Bespoke Biotherapeutics, San Mateo, CA*
**Corresponding Author*

INTRODUCTION:
Leukapheresis (LA)-derived peripheral blood mononuclear cell (PBMC) products are the starting material for the manufacture of many T-cell, NK-cell, and B-cell adoptive cell immunotherapies. Experts have implicitly assumed that immune cells isolated from LA products are the same as those in venous whole blood (WB). This study used bioinformatics, artificial intelligence (AI), and machine learning (ML) to compare gene expression profiles of B-cells isolated from matched LA-derived PBMC and subject matched WB.

METHODS (see Figure 1):
WB was collected via venipuncture prior to LA in 3 healthy adult donors. All starting materials were transported at 4°C. B-cells were positively isolated using anti-CD19 immunomagnetic MACS® MicroBeads, without prior density gradient centrifugation or RBC lysis, within 3 hours of collection. After RNA extraction from the B-cell isolates, individual samples underwent bulk RNA sequencing. Relative proportions of immune cell subtypes were quantified using CIBERSORT *iSort™ Fractions v1.4* blood mode, AI/ML-based digital cytometry deconvolution algorithm applied to the bulk RNAseq gene expression data. CIBERSORT *iSort HiRes v1.1* was run and sequencing reads were mapped and quantified by Salmon v1.9 with Gencode v31 annotation. Significant inferred, differentially expressed genes were defined as having log2foldchange >0.5 or <−0.5 (>1.42 fold-change) and false discovery rate adjusted *p-value* <0.05. Significance vs. magnitude of expression changes were visualized via volcano plot.

RESULTS:
iSort Fractions inferred 69.7%±16.9% vs. 94.5%±1.6% B-cells, 5.9%±0.1% vs. 5.3%±1.4% T/NK cells, and 24.4%±16.9% vs. 0.2%±0.2% monocytes in the B-cell isolates from LA-derived PBMC vs. WB. Flow cytometry corroborated these findings. The 27 genes significantly upregulated after LA included ones associated with V(D)J recombination (*HMGB2*), autophagosome assembly (*ATG2A*), NF-Kappa-ℝ?-mediated transcription down-regulation (*ZCCHC9*), 4-1BB signaling regulation (*LRR1*), Wnt signaling (*SLC9A3R1*), p53-associated apoptosis (*ING1*), B-cell negative regulation (*HMGB3*), folate depletion (*MTHFS*), and several mitochondrial stress proteins. The 119 genes significantly downregulated after LA included ones associated with prevention of reactive oxygen species accumulation (*SESN1*), cell survival (*DYRK1B*), RAS signal transduction (*RAPGEF5*), B-cell reactivity and splenic localization (*KLF2*), B-cell mediated extracellular matrix remodeling (*LOXL2*), T-cell co-stimulation (*CD200*), cell cycle control (*BCAR3*), and B-cell migration (*SHCBP1*). (see Figure 2)

DISCUSSION:
We set out to determine if the gene expression profiles of human B-cells isolated from LA products are comparable to those isolated from matched venous WB. This required elimination of misleading gene expression noise from non-B-cells, mostly monocytes, found in the B-cell isolates. We used *iSort Fractions* and *HiRes* to conduct AI/ML-based digital cytometry and inferred B-cell specific gene expression. The differential gene expression profile suggests that LA-derived B-cells are significantly more mitochondrially stressed and likely less functionally active than WB-derived B-cells. This may reflect the markedly greater PBMC density and cell-to-cell contact specifically in LA products. Method of collection of B-cells, and probably other immune cells, for the manufacture of adoptive cell therapies should be carefully reassessed in order to optimize infused product performance.

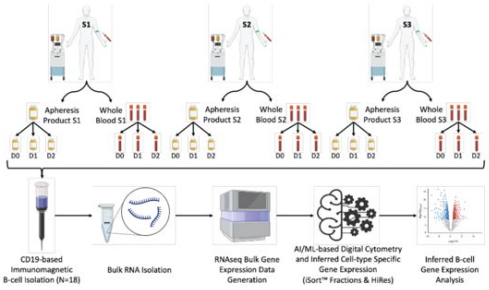


Figure 1. Study infographic illustrating the collection of source material by leukapheresis and venipuncture, isolation of B-cells, isolation of bulk RNA, gene expression data generation, AI- and ML-based digital cytometry and inferred B-cell gene expression, to generation of volcano plots for analysis.

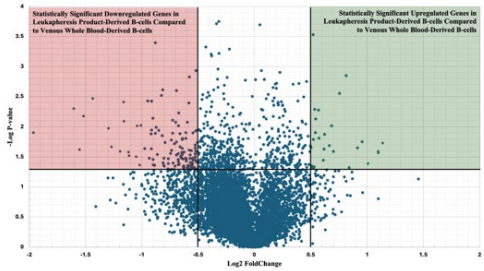

Figure 2. Volcano plot of the inferred gene expression for B-cells isolated from leukapheresis-derived PBMC products compared to the inferred gene expression for B-cells isolated from subject matched venous whole blood. The reddish and greenish shaded areas represent statistically significant and relatively downregulated and relatively upregulated genes, respectively.

406 Quantification of residual host-cell DNA fragments of the E1A gene from HEK293 via qPCR assay

Li Yi[1], Lei Ye[2], **Lijun Wang[3]**
[1]CoJourney, Hangzhou, Zhejiang, China, [2]Hangzhou CoJourney Bio Ltd., Hangzhou, Zhejiang, China, [3]CoJourney, Lower Gwynedd, PA

Background:
Viral vector gene therapy has made significant strides over the past decade, with numerous products, including those based on adeno-associated virus (AAV) and other viral vectors, achieving global commercialization. The HEK293 transfection platform, which employs the HEK293 cell line as the production host, is widely used for high-titer recombinant AAV (rAAV) production. These cells are genetically engineered to express the E1A adenoviral gene, enabling efficient rAAV production. However, the process inevitably generates impurities, including the E1A gene, which can transcriptionally activate other adenovirus early genes and pose potential tumorigenicity risks to patients. Accurate quantification of residual E1A DNA in viral vector drug products is therefore critical to guide process optimization and minimize E1A residuals. While process optimization can reduce E1A impurity levels, controlling the size distribution of residual E1A DNA fragments remains challenging. Robust analytical methods are essential to monitor these fragments. In this study, we developed a TaqMan real-time PCR assay to quantify E1A DNA. Although commercial E1A DNA quantification kits are available, they are often limited to measuring a single fragment length and are cost-prohibitive. To overcome these limitations, we established a cost-effective and versatile assay capable of quantifying E1A DNA fragments of varying sizes. Three primer-probe sets were designed based on the E1A gene sequence, enabling the development and validation of a tailored TaqMan real-time PCR method.

Results:
The E1A gene was synthesized and cloned into the pUC57-GW-Kan vector backbone to serve as the assay standard. The TaqMan qPCR standard curve exhibited a slope ranging from -3.60 to -3.10, with a linear correlation coefficient (R^2) of ≥ 0.98 and amplification efficiency between 90% and 110%. The assay demonstrated high specificity, with no cross-amplification signals detected. The limit of detection (LOD) was 50 copies/µL, and reproducibility testing showed intra- and inter-assay variability within 10%, indicating excellent precision. Spike recovery ranged from 91% to 113%, confirming the method's accuracy. The assay displayed a broad dynamic range, quantifying E1A DNA concentrations from 5.0×10^1 copies/µL to 5.0×10^6 copies/µL.

Conclusion:
The TaqMan real-time PCR method was successfully developed to detect residual host-cell E1A DNA by amplifying signals from three fragment lengths (100 bp, 300 bp, and 500 bp) of the E1A gene. The method demonstrates exceptional specificity, linearity, accuracy, and precision, enabling reliable quantification of residual E1A DNA fragments from HEK293 cells. Applicable to a wide range of sample types, including in-process intermediates and final drug products, this assay serves as a valuable tool for process development and quality control in gene therapy manufacturing. It provides a robust, cost-effective solution for monitoring and optimizing the production of gene therapy products, ensuring both operational efficiency and compliance with regulatory standards.

AAV Gene Transfer (C): Antibody Evasion, Cardiac & Neuromuscular Targets

407 Engineering non-mammalian chimeric AAVs for evasion of pre-existing antibodies and vector-induced immunity

Ezra Loeb[1], Sophia Fergione[1], Vivian Yudistyra[1], Marco Fanous[2], Abigail Benkert[3], MA ALEJANDRA VARGAS RETANA[4], Delaney Fisher[1], Aravind Asokan[5]
[1]Duke University, Durham, NC, [2]Duke University, Chapel Hill, NC, [3]Duke University Medical Center, Durham, NC, [4]Duke University, Raleigh, NC, [5]Duke University, Durham, North Carolina

Adeno-associated virus (AAV) immunity remains a significant barrier in the gene therapy field, with 30-80% of adults harboring pre-existing antibodies against endemic AAV isolates. Further, AAV redosing is significantly limited since patients develop robust antibodies following an initial dose. One approach to overcoming AAV immunity is vectorizing non-mammalian AAV isolates. Currently, all AAV serotypes used in the clinic were derived

from human or NHP samples, leading to high similarity with endemic isolates. Non-mammalian AAVs, on the other hand, display significant capsid variability from these isolates. Typically, non-mammalian AAVs cannot transduce human cells; however, we recently overcame this barrier using a rational engineering approach that unlocks robust transduction in human cells and mouse tissue.

Here, we apply this discovery to engineer immuno-evasive AAV capsids for gene therapy applications. First, we performed a barcoded screen of diverse rationally engineered chimeric capsids from across the genus Dependoparvovirus. The top-performing capsid across cell types and tissues was derived from a Muscovy duck isolate. This novel chimeric capsid, termed AAV-div3A, demonstrates high transduction in murine liver, heart, and muscle tissue following intravenous dosing. To determine whether humans have pre-existing immunity against div3A, we screened serum from 20 donors for neutralizing antibodies (NAbs). While 6 donors had NAbs against AAV9, a clinically validated human AAV isolate, all donors were negative for NAbs against div3A. Mice were then passively immunized with serum from AAV9 NAb+ donors and dosed with div3A 72 hours later and showed robust transduction with no decrease in transgene expression compared to non-immunized controls. To validate that these results extend beyond AAV9 NAbs, we also interrogated the cross-reactivity of div3A with NAbs against ten commonly used AAV serotypes. Promisingly, div3A showed no neutralizing effects or cross-reactivity with any sera.

Next, we examined the immune evasion of div3A in the context of vector-induced immunity. Mice were initially dosed with AAV9 and then successfully dosed again with div3A six weeks later, yielding robust and unabated transduction across multiple tissue types. In order to extend our findings into a therapeutic context, we demonstrate the successful re-administration and cumulatively improved expression of a therapeutic transgene (acid alpha-glucosidase) in Pompe mice. Additional rational engineering of div3A through peptide surface display yielded a new variant, div3A-M1 with 14-fold higher transduction in murine heart tissue, 11-fold higher transduction in diaphragm tissue, and 90% reduction in liver targeting. Additional results from continued evaluation of AAV.div3A and div.3A-M1 in mouse models of disease and non-human primate models will be presented. Overall, the vectorization of chimeric AAVs promises to improve patient access to gene therapies by expanding inclusion criteria and enabling repeat dosing by evading pre-existing immunity from natural exposure and acquired immunity from previous sub-therapeutic treatment exposure.

408 It's a Zoo Out There: Analyzing the Cross-Reactivity of Human Antibodies Towards Animal AAVs to Expand the AAV Vector Toolkit for Gene Therapy Applications

A major obstacle to AAV vectors is the presence of pre-existing neutralizing antibodies (NAbs) that circulate among the general human population, leading to vector inactivation and to a loss of treatment efficacy. One alternative to the primate-based vectors are AAVs are those found in species that may be naïve to human infections, thus exhibiting low to no pre-existing antigenicity. Such animal dependoparvoviruses include quail AAV (QAAV), bovine AAV (BAAV), serpentine AAV (SAAV), goose parvovirus (GPV), porcine AAV isolates (AAVpo.1 and AAVpo.6), rat AAV (AAVra.1), mouse AAV (AAVmo.1), bat AAV (BtAAV), and bearded dragon AAV (BDPV). Native-immuno and/or neutralization assays were used to assess the reactivity of the non-primate AAVs against human sera samples obtained from 50 healthy patients. However, with ~25-30% detection or neutralization rates, the animal AAVs were not as non-reactive to the NAbs as anticipated. To investigate the antibody-capsid interactions, anti-AAV9 and AAV2 monoclonal antibodies (mAbs) were obtained from patients treated with Zolgensma® and individuals naturally exposed to AAV2, respectively. Their binding sites to the AAV capsids were previously determined by cryo-electron microscopy (cryo-EM). While the antibodies bound to different regions, such as the 2-fold, 2/5-fold wall, 3-fold, and 5-fold symmetry axes of the capsids, only the 5-fold antibodies showed cross-reactive properties, with several non-primate AAVs. The capsid structures of the animal AAVs listed above were

determined by cryo-EM, ranging from 1.77 to 3.30 Å resolution. These structures allowed the analysis and comparison of the highly conserved 5-fold regions of the primate and the non-primate AAVs. Amino acid sequence alignments and structural superpositions of the 5-fold channel pores revealed highly conserved epitopes, most likely responsible in the observed cross-reactivity. This conservation is likely due to the AAV Rep proteins also interacting with the 5-fold region during genome packaging. Understanding the interactions of the 5-fold antibodies to the AAV capsids will aid in engineering variants capable of escaping this class of Nabs and will expand the current toolkit of AAV vectors towards human gene therapy applications.

409 AAV-CM1, a Human Receptor-Targeted Capsid with an Enhanced Tropism for the CNS, Skeletal Muscle, and Heart

Many monogenic disorders, including neuromuscular diseases, lysosomal storage disorders, and dystroglycanopathies, affect multiple organs. To effectively treat disease manifestations across multiple organs, it is crucial to develop delivery vehicles that efficiently reach multiple cell types and tissues. We have derived several families of AAV9-based capsids that target the CNS, skeletal muscle, and heart *in vivo* by binding to human CD59 (hCD59). CD59 is a GPI-anchored surface protein widely expressed in many cell types, including vascular and parenchymal cells of most organs in mice, non-human primates (NHPs), and humans.

When administered intravenously at $5e^{12}$ vg/kg to transgenic mice ubiquitously expressing hCD59, our top capsid, AAV-CM1, achieved significantly enhanced transduction compared to AAV9 in the CNS (21x), skeletal muscle (19x), and heart (3x). Notably, AAV-CM1 exhibited reduced liver transduction (0.01x that of AAV9), a challenge with many AAV serotypes. AAV-CM1 transduces cells and crosses the blood-brain barrier by binding human or macaque CD59 *in vitro* and *in vivo* (Fig. 1), allowing evaluation in NHP models. Remarkably, after systemic delivery of an epigenetic editor by AAV-CM1 at $1.5e^{13}$ vg/kg in humanized CD59 mice, we achieved 81%, 87%, 73%, and 47% mean reductions in target gene expression in the forebrain, skeletal muscle, heart, and liver, respectively (Fig. 2). In contrast, delivery of the same epigenetic editor with AAV9 mediated reductions only in the heart (37%) and liver (78%) but not brain or muscle. Importantly, AAV-CM1 can be produced at yields comparable to AAV9 and purified using commonly used affinity resins. Studies are underway to evaluate transduction and safety profiles in NHPs.

To our knowledge, the expanded tropism of AAV-CM1 is unique among natural and engineered capsids. AAV-CM1 is a promising delivery vehicle for targeting gene therapies to the CNS, skeletal muscle, and cardiac tissue, with a human-relevant mechanism of action and the advantage of enabling evaluation in humanized mice and NHPs without the reliance on surrogate capsids.

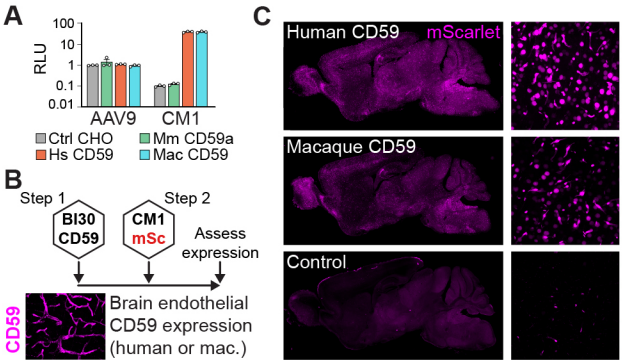

Figure 1. (A) AAV-CM1 transduces human or macaque CD59- expressing cells more efficiently than AAV9, but not control or mouse CD59-expressing cells. **(B,C)** Our "two-step" assay first mediates exogenous CD59 expression in the mouse brain vasculature using AAV-BI30, then AAV-CM1:mScarlet is administered. Brain images show transduction by AAV-CM1 in mice expressing human, macaque, or no exogenous CD59.

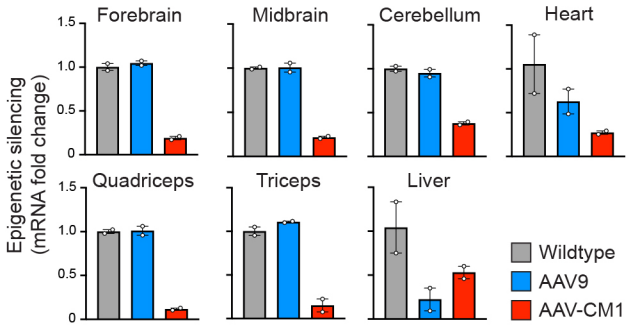

Figure 2. AAV-CM1 mediated efficient epigenetic silencing in the brain, skeletal muscle, and heart. Mice were systemically injected with 1.5e13 vg/kg of an epigenetic editor packaged into AAV9 or AAV-CM1. C57BL6/J and iCMV-hCD59 mice (C57BL6/J background) were used for AAV9 and AAV-CM1, respectively. Target mRNA fold changes in the indicated tissues at three weeks post dosing are shown.

410 Position-Specific Impact of RGD Motif in AAV Capsid Variants on Muscle Tissue Targeting and Integrin Binding Affinity

Rosemary Meggersee[1], Payal Grover[2], Swapnil Shewale[2], **R. Jason Lamontagne[1]**, Juliette Hordeaux, Jenny Greig[3], James Wilson[2]

Monogenic diseases that affect heart and skeletal muscle function are usually associated with substantial morbidity and early mortality. Several gene therapy products based on clade E and clade F capsids for these types of diseases are in the clinic with one recently approved. Most applications require high doses of intravenous adeno-associated virus (AAV) vector that are expensive to produce and associated with severe innate and adaptive immune responses. We and others have attempted to improve the performance of AAV vectors for cardiac and skeletal muscle applications by redirecting binding to integrins through the incorporation of RGD-containing peptides into exposed capsid loops. Our family of cardiac and skeletal muscle vectors, referred to as the GCap family, has been evaluated in various mouse and NHP models expressing a variety of therapeutic transgenes. These studies have produced engineered capsids with 10-to-1000-fold improvements in cardiac and skeletal muscle transduction during evaluation in NHPs. A number of themes emerged with the new capsids: 1) The position of the RGD within the engineered loop had a substantial impact on the transduction profiles, with RGD located at the N terminus of the peptide (proximal variants) showing primarily skeletal muscle transduction while RGD peptides embedded within

the loop were much more efficient in transducing heart and diaphragm with lower transduction in skeletal muscle. 2) Proximal variants showed a qualitatively different integrin binding profile than embedded variants. 3) Studies in NHPs demonstrated levels of therapeutic transduction at doses 10- to 30-fold lower than that achieved with first-generation vectors with no toxicity and up to 160-fold reductions in liver targeting. 4) Only a small fraction of the RGD library produced functional vector. Our studies demonstrate a clear but unexpected relationship between the structure of the inserted RGD peptide, its integrin binding profile, and its performance in NHPs in terms of efficiency and distribution of transduction. The repertoire of biological properties exhibited by the GCap family of vectors allows one to better address the needs of diseases affecting heart and skeletal muscle. We are advancing into the clinic a proximal RGD capsid for a muscular dystrophy and an embedded RGD capsid for a common inherited cardiomyopathy.

411 Antibody-evading AAV capsids compatible with CNS and muscle-targeting modifications

Adeno-associated virus (AAV) capsids have been successfully engineered via surface loop modifications to target different organs such as the central nervous system (CNS), muscle, retina, and liver following systemic delivery. However, to enable the use of lower AAV doses and bring gene therapies to a larger fraction of affected patients, it will be necessary to prevent their neutralization by antibodies. The challenge is to develop AAVs that evade neutralizing antibodies (NAbs) while also maintaining their enhanced tropisms and manufacturability. To address this challenge, we generated AAV9-based libraries through the diversification of broadly distributed capsid regions, using multiple tropism-enhanced capsids as seeds. We then selected variants exhibiting resistance to intravenous immunoglobulin, while maintaining the enhanced tropism, production fitness, and compatibility with capture affinity resins of their parental capsids. When applied to BI-TFR1v2, one of our group's second generation human transferrin receptor-targeting capsids, this strategy resulted in a novel variant (BI-hTFR1v2-NAbE) that evades detectable neutralization by more than 40% of the polyclonal human serum samples that neutralized AAV9 or AAV5, while maintaining the BBB-crossing phenotype and manufacturability of its parental capsid. We tested the compatibility of our antibody-evading capsids with several cross-species RGD motif-containing capsids, and successfully obtained muscle-specific variants with improved antibody evasion. This work holds promise for expanding the pool of patients eligible for CNS and muscle-targeted gene therapies.

412 Insight into the mechanism of action of AAV-SLB101, a novel muscle-tropic capsid for neuromuscular and cardiac indications

Jessica Boehler[1], Prushti Bhavsar[1], Jennifer Gifford[1], Widler Casy[2], Tiffany Willacy[3], Irene Larena[1], Glen Banks[4], Sharon McGonigle[1]
[1]Solid Biosciences, Charlestown, MA, [2]Solid Biosciences, Cambridge, MA, [3]Solid Biosciences, [4]Solid Biosciences, Yardley, PA

Adeno-associated virus (AAV) mediated gene therapy continues to be a promising therapeutic for various diseases; however, high systemic doses currently required to achieve widespread therapeutic benefit for indications like Duchenne muscular dystrophy (DMD) can pose potential safety risks. To develop a more targeted and efficacious vector, AAV-SLB101 was rationally designed to increase muscle tropism. Presently, it is utilized in Solid Bioscience's next generation gene therapy SGT-003, which is currently in a clinical study for the treatment of DMD (NCT06138639).

In multiple non-clinical studies, the novel vector AAV-SLB101 has demonstrated increased muscle tropism and decreased liver uptake in both healthy animals and disease models (wild type and mdx mice, non-human primates

and human iPSC-cardiac myocytes). Currently, the hypothesized mechanism for increased muscle uptake is through interaction of the inserted RGD peptide with integrin receptors.

To further explore AAV-SLB101's mechanism of action, a panel of studies comparing AAV-SLB101 to AAV9 in cells and in vivo demonstrated increased binding, transduction and expression of AAV-SLB101 over AAV9 in all cases. Additionally, in AAV-SLB101 binding assays the signal was reduced by the addition of anti-integrin antibody and by increasing concentration of a tight binding integrin ligand partner in both mouse and human dystrophin-deficient muscle cells. These studies provide further insight and characterization of the mechanism for AAV-SLB101.

413 A Novel Neuromuscular AAV Capsid Combines Efficient Systemic Muscle and CNS Delivery with Liver Detargeting in NHP

Megan Cramer[1], Barbara Diaz-Rohrer[1], Aiswarya Krishnamohan[1], Samuel Wolock[1], David Brookes[1], Daniel Bloodgood[1], Lindsey Campion[1], Michael Stiffler[1], Amanda Miles[1], Sarah Hilton[2], Carrie Maryak[1], Adithya Ramesh[1], Arpan Ghosh[1], Hanna Levitin[1], Jamie Kwasnieski[1], Mugdha Deshpande[1], Sam Sinai[1], Daniela Pignatta[1], Adrian Veres[1], Eric Kelsic[1]
[1]Dyno Therapeutics, Watertown, MA, [2]Dyno Therapeutics, Seattle, WA

Neuromuscular diseases are complex conditions that require a long-term, multisystemic approach to treat all affected tissues. Current therapeutic strategies to target both nervous and muscle tissues utilize multiple injection sites at high doses. Here we present the first demonstration of a novel AAV capsid that efficiently and specifically transduces the heart, skeletal muscle, and central nervous system (CNS) in non-human primates (NHPs). Using a single intravenous dose of 4e12 vg/kg, this first-in-class capsid can lead to wide biodistribution of skeletal muscle and enables crossing of the blood-brain barrier while maintaining a favorable safety profile by detargeting the liver. The high specificity and efficiency of this capsid in on-target tissues permits the use of lower doses, increasing the safety profile for patients and lowering manufacturing costs.

Using our AI-driven design platform, we engineered a liver detargeted neuromuscular capsid, validating its novel tropism through a single capsid study in adult NHPs. This capsid is highly compatible with large scale AAV manufacturing methods, producing 1.2-fold higher harvest yields than AAV9 with comparable purification by affinity chromatography. While the manufacturability profile of this capsid enables high doses of AAV in NHPs, even a low dose of 4e12 vg/kg systemically delivered was sufficient to effectively target skeletal muscle, heart, and CNS tissues. Across all tested skeletal muscles, including biceps, gastrocnemius, and diaphragm, we measured 57-90% of myofibers transduced and 32-66% of cardiomyocytes transduced in the heart. This capsid demonstrated blood-brain barrier crossing across cortical and deeper brain regions, transducing up to 5% of neurons. We further confirmed the specificity of this capsid to neuromuscular tissues and high safety profile by measuring low viral biodistribution in off-target tissues, such as liver (<10 vg/dg) and spleen (<0.5 vg/dg). We have identified a putative receptor for our capsid that is expressed in both brain and muscle tissue, suggesting the receptor can mediate both blood-brain barrier crossing as well as muscle transduction. This receptor is highly conserved between NHP and human, supporting potential human translatability of our capsid.

The unique characteristics of this novel neuromuscular AAV capsid enable therapeutic access to a wide range of tissues affected by neuromuscular disorders that might otherwise go untreated with the use of neuro- or myotropic capsids.

Hematopoietic Stem and Progenitor Cell Gene Therapy (HSPC-GT) uses retroviral vectors such as self-inactivating (SIN) lentiviral vectors (LVs) to insert therapeutic genes into target genomes. Once reinfused, these modified HSPCs fully reconstitute hematopoiesis, maintain lifelong blood cell homeostasis, and provide therapeutic benefits. However, vector integration may inadvertently activate oncogenes, potentially causing malignancies, as seen in an LV-based trial for adrenoleukodystrophy. Moreover, ectopic oncogene activation in HSPCs induces oncogene-induced senescence (OIS), leading to proliferation arrest and the secretion of pro-inflammatory cytokines, a process known as the senescence-associated secretory phenotype (SASP). Transplantation of oncogene-expressing HSPCs in a xenogeneic model resulted in senescent cell accumulation and chronic inflammation, which triggered myeloid-restricted hematopoiesis and eventually led to bone marrow failure. These findings raise concerns that insertional mutagenesis in HSPC-GT could produce similar adverse effects. To address this issue, we monitored the hematopoiesis of wild-type (WT) mice transplanted with WT HSPCs transduced with either a genotoxic LV carrying the Spleen Focus Forming Virus promoter in its long terminal repeats (LV.SF) or a safer SIN LV with the PGK promoter in an internal position (SINLV.PGK). We applied the same approach to HSPCs from Cdkn2a-/- mice, which lack the key senescence cell cycle inhibitors p16INK4A and p19ARF. Blood composition was monitored every four weeks (up to 2.5 years), and vector integration sites (IS) were retrieved from purified B, T, and myeloid cells for clonal tracking. The genotoxic LV.SF accelerated myeloid tumor onset in mice transplanted with Cdkn2a-/- cells ($p < 0.0001$) but not in WT mice. However, WT/LV.SF mice exhibited marked myeloid skewing and a dramatic reduction in clonality across all hematopoietic lineages over time, suggesting accelerated aging compared to WT SINLV.PGK mice. Insertions activating the Braf oncogene were prevalent in tumor-infiltrated tissues of the Cdkn2a-/- group and, to a lesser extent, in WT mice. Given the link between OIS, chronic inflammation, and somatic mutations, we analyzed genomic sequences flanking each IS to assess mutation accumulation using a novel Mutation Index (MI), normalized by clone number and coverage. Analysis of over 200,000 IS covering more than 9 Gb of genomic data revealed significantly higher MI in both LV.SF groups than in LV.PGK groups ($p < 0.001$), with myeloid clones accumulating more mutations than B and T cells. This effect was exacerbated in Cdkn2a/LV.SF mice, indicating that the absence of proto-oncogene activation barriers leads to increased somatic mutations. Whole-genome sequencing confirmed a higher mutation rate in LV.SF groups compared to LV.PGK, validating that no biases were present in the flanking region analysis. Finally, a Bayesian model developed to trace the dynamics of clonal and subclonal evolution based on IS and mutations, confirmed greater mutational diversity and complexity, increased mutation burden and accelerated clonal expansion in LV.SF groups. Overall, our data show that random insertional activation of oncogenes in vivo induces accelerated stem cell aging, clonal hematopoiesis, and heightened somatic mutation burden due to persistent senescent cell accumulation in tissues and justifies further exploration of this underappreciated aspect of vector genotoxicity.

415 Decoding the Molecular Signature of Expanded Gamma Delta T Cell Products; TCR and Immune Gene Expession from Allogeneic derived Products

Mariska Ter Haak[1], Caitlyn Lucas[2], Becca Weekley[3], Guoling Chen, Wenjing Pan[4], Daniel Weber[4], Miranda Byrne-Steele[4], Lawrence Lamb[5], Kate Rochlin[6]
[1]IN8bio, New York, NY, [2]IN8bio, Inc, Birmingham, AL, [3]IN8bio, Inc., New York, NY, [4]iRepertoire, Huntsville, AL, [5]In8Bio, Birmingham, AL, [6]IN8bio

Gamma-delta (γδ) T cells are a powerful cellular therapy approach due to their unique ability to differentiate between stressed/sick and healthy cells, and subsequently eliminate the sick cells, including cancer cells. γδ T cells typically comprise a small percentage of peripheral T cells (~1-5%) and can require manufacturing processes of up to 10 days to reach clinical doses. Understanding the molecular changes that occur throughout this process can provide insight into the potency, effector and trafficking capabilities of the manufactured cells as well as the reproducibility, and robustness of the process. Previous work demonstrated that our genetically engineered DeltEx drug resistant immunotherapy (DRI) γδ T cells, manufactured from diverse starting materials, exhibited similar TCR and gene expression profiles. To strengthen these findings, we analyzed our DeltEx Allogeneic (Allo) products. Here, we assessed TCR repertoire and gene expression from both (a) the apheresis starting material and (b) final manufactured γδ T cell products derived from different allogeneic donors. γδ T cell clinical products were generated from using proprietary manufacturing protocols. TCR libraries were prepared with VDJ-specific primers for α, β, δ and γ chains by dimer-avoided multiplex PCR (dam-PCR) using iRepertoire's RepSeq+. Concurrently, RNAseq libraries were prepared with iRepertoire's Immunosight, a targeted sequencing panel encoding +150 immune profiling genes. TCR repertoire and gene expression profiles were compared for the starting material and final manufactured products. Additionally, gene expression profiles of DeltEx Allo and DeltEx DRI were compared. Multigroup comparisons were performed by nonparametric statistical test while controlling for false discovery rate. While the TCR repertoire at initiation primarily consisted of αβTCR clones, the final product exhibited a shift towards γδ TCR expression, with a notable expansion of Vγ9 clones in the DeltEx Allo. Interestingly, gene expression analysis revealed a significant increase in markers of cellular activation and cytotoxicity in the final product, as previously observed in DeltEx DRI. Upregulated gene expression of cytotoxicity, proliferation and effector markers were observed related to type 1 cytokines, the TNF super family, IL7 -, IL15 -, and IL-12-family signaling pathway, as well as runt-related transcription factors, which suggest that the DeltEx cells are active and primed to kill. Similarly, the expression of immune trafficking and stimulation markers was elevated in the final product, including TBOX transcription factors, type 2 cytokines and immune cell trafficking genes, suggesting that the cells are capable of both tissue trafficking and immune cell recruitment with no observed upregulation of γδT17 and/or terminally exhausted γδ cells. Gene expression levels for both DeltEx products were similar, suggesting our manufacturing platform is robust and reproducible. Our research demonstrates that similar activated, cytotoxic γδ T cell products were successfully manufactured from different allogeneic healthy donors. Both DeltEx DRI and Allo products exhibit similar gene expression profiles at high levels and showed an upregulation of genes unique to γδ T cells. These insights help elucidate the overall gene signatures that may play a key role in the unique biology and mechanism of γδ T cell therapies.

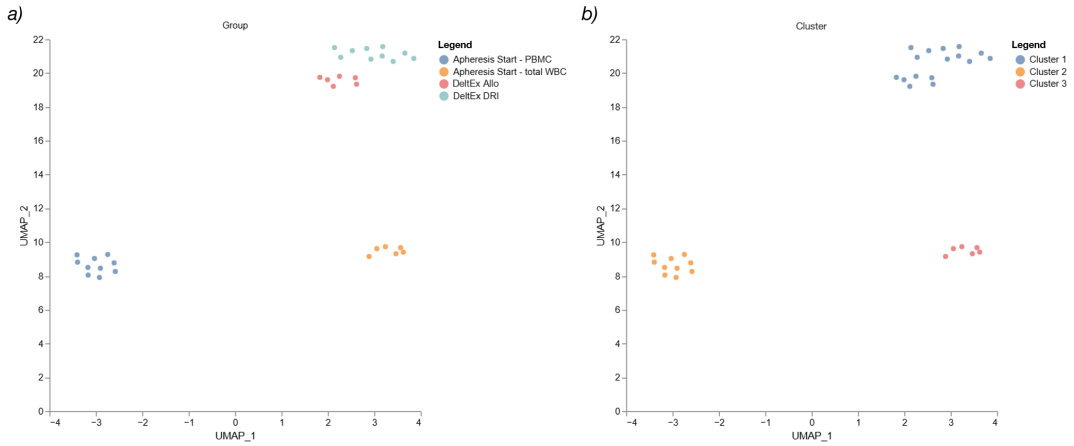

Figure 1: ***UMAP Immune Profiling Gene Expression*** *a) UMAP depicting the different groups including the manufacturing starting material: apheresis gradient separated (PBMCs) in blue, apheresis unmodified (total WBC) in yellow, and final γδ T cell products: DeltEX Allo in red and DeltEx DRI in teal. b) UMAP separated by cluster, where DeltEx Allo and DeltEx DRI form one cluster.*

416 Methods for characterizing AAV integration and genomic rearrangements *in vivo.*

Aoife Doto[1], John Everett[1], Aradhana Kasimsetty[1], Maria Seleme[2], Angelina Petrichenko[3], Denise Sabatino[4], Frederic Bushman[5]
[1]University of Pennsylvania, Philadelphia, PA, [2]Children's Hospital Philadelphia, Philadelphia, PA, [3]University of Pennsylvania, Philadelphia, [4]The Children's Hospital of Philadelphia, Philadelphia, PA, [5]University of Pennsylvania School of Medicine, Philadelphia, PA

Gene therapy is an exciting and rapidly evolving field of medicine. Many viral vectors have been explored for gene delivery, including lentiviral and adeno-associated viral (AAV) vectors. Lentiviral vectors allow larger cargo to be introduced into dividing cells and mediate their effect by preferentially integrating within transcription units in the host genome. Recently, there has been some concern about potential insertional mutagenesis in lentiviral based CAR T cell therapy. However, several global reviews of large datasets show that the risk of insertional mutagenesis is very low, but warrants continued monitoring.

In contrast, typically non-integrating AAV vectors have become the vector of choice for much of gene therapy research. Despite limitations in cargo size, they have become a popular delivery vehicle for *in vivo* therapy due to their strong safety and efficacy profile. However, AAV integration does occur in many settings, and AAV vectors commonly show extensive rearrangement. This rearrangement likely reduces the efficacy of the therapeutic vector. Thus, it is crucial to characterize and understand AAV integration patterns to better inform safety and efficacy.

We developed and optimized methods for characterizing AAV vectors *in vivo*. Using ligation mediated PCR, we prime on the vector ITR to sequence either outwards (to determine host integration site) or inwards (to measure genomic rearrangements). The data is analyzed using a custom software pipeline, AAVengeR. This modular R pipeline allows analysis of integration of various vector types to determine the host-ITR/LTR junctions. Additional modules allow estimation of the percentage of sequencing reads associated with rearranged vector forms when sequencing reads face inward.

In one application, these methods were used to characterize samples from a non-human primate model of factor VIII (FVIII) gene therapy. African green monkeys were infused IV with varying doses of AAV8 containing the FVIII transgene under the liver-specific TTRm promoter. We collected liver biopsy samples at D14 and D90 post-infusion and selected 6 animals that had the highest vector copy numbers for characterization of both the integration site pattern (outward sequencing) and level of genomic rearrangement (inward sequencing). We detected high-levels (>1000 sites) of integration sites in 2/6 animals and mid-levels (>500 sites) in remaining 4/6 animals at these time points. Estimates of the frequency of genomic rearrangements ranged from 2-6%. These lower frequencies are in contrast to previously studied dogs after 10-years of treatment, where levels of rearrangement reached over 10% following the longer incubation period.

Thus, these methods are a powerful tool to characterize AAV integration patterns *in vivo* and to understand the status of the vector genome after AAV gene therapy. These methods, along with lentiviral integration site analysis and CRISPR off-target analysis, are available from the Viral Molecular High Density Sequencing Core at the University of Pennsylvania.

417 Unraveling the Dynamics of Senescent Cell and Immune System Interplay in HSPC Gene Therapy

Hematopoietic stem and progenitor cells (HSPCs) are key targets in gene therapy (GT) due to their ability to reconstitute the hematopoietic system after gene correction and reinfusion. This approach allows the correction of genetic defects for various inherited and acquired diseases. However, vector integration near oncogenes and the acquisition of somatic mutations during hematopoietic reconstitution increase the risk of malignancies, as observed in clinical trials. Moreover, we previously showed that oncogene (BRAFV600E) expression in human HSPCs induces Oncogene-Induced Senescence (OIS), leading to irreversible cell cycle arrest and a pro-inflammatory senescence-associated secretory phenotype. This usually activates immune cells to clear senescent cells, but in immunodeficient (NSG) mice inefficient clearance leads to myeloid-skewed hematopoiesis, multi-organ histiocytosis, and bone marrow failure. Thus, understanding factors influencing senescent cell persistence or clearance is critical for improving GT safety and efficacy. Here, we investigated if a functional immune system in wild-type (C57) mice could counteract the toxic effects observed in NSG mice. Also, we explored immunological clearance as a protective mechanism to potentially identify genotoxicity biomarkers for future GT applications. We transduced mouse BM-derived HSPCs with lentiviral vectors expressing BrafV600E or GFP and transplanted them into lethally irradiated C57 mice or sub-lethally irradiated NSG mice. We monitored mice for long-term survival and performed peripheral blood (PB) analysis to assess hematopoietic reconstitution over time. NSG mice transplanted with oncogene-expressing (OE) HSPCs (NSG-V600E) exhibited rapid lethality and paracrine senescence, impairing donor and recipient PB cells. In contrast, 40% of OE-transplanted C57 mice (C57-V600E) survived long-term, showing only transient B and T cell impairment and clearing OE cells within three months. To identify biomarkers of genotoxicity, we performed RNA sequencing on donor myeloid (My) and B cells and cytokine profiling. Both models showed upregulation of multiple immune checkpoint genes in donor cells, implying immune suppression induced by OE cells. However, NSG-V600E mice had more differentially expressed genes (DEGs) in My cells, elevated IL-10, and downregulated Sirpa and Cd47, impairing donor My cell phagocytosis. This indicates an immune-suppressive environment enabling senescence cells persistence in NSG-V600E mice. C57-V600E mice displayed more DEGs in B cells, upregulated MHC Class II signaling in My and B cells, and a T-cell-related cytokine profile (IL-17A, IL12p70, IL-5), indicating recognition of OE cells by the adaptive immune system. To verify the role of adaptive immunity in the clearance of OE cells and exclude conditioning differences, we transplanted OE HSPCs into Rag1KO mice, which lack B and T cells and tolerate lethal irradiation. Rag1KO mice failed to clear OE cells and died within 40 days, proving adaptive immunity is essential for senescent cell clearance, inflammation resolution, and survival. These findings emphasize the importance of the interactions between senescent cells and the immunological status of the recipient, implying the active regulation of oncogene-induced genotoxicity by immune cells. Our results highlight the need to understand immune mechanisms governing senescent cell clearance to assess genotoxicity risks in GT and identify safety biomarkers.

418 Multiplex ddPCR Platform for Precision Monitoring of Multi-Antigen CAR T Cells in Pediatric CNS Cancer Therapy

Background:
Pediatric central nervous system (CNS) tumors are the leading cause of cancer-related deaths in children. Targeting these tumors via surface antigens is challenging due to the antigen heterogeneity and temporal changes in tumor antigen expression. While our BrainChild-03 (BC-03, NCT04185038) demonstrated tolerability of intracerebroventricular (ICV) delivery of B7-H3 CAR T cells for diffuse intrinsic pontine glioma (DIPG), efficacy was inconsistent. To address this, we initiated BrainChild-04 (BC-04, NCT05768880), a first-in-human phase 1 clinical trial delivering ICV multi-antigen (B7-H3, EGFR, HER2, and IL-13Ra2) CAR T cells in children with recurrent/refractory CNS tumors and DIPG. Here, we present analytical methods to accurately quantify and characterize CAR T cells in patient infusion products and in post-infusion biospecimens to optimize patient outcomes.

Methods:
A fluorescence amplitude multiplex droplet digital PCR (ddPCR) assay was developed to quantify vector copy number (VCN) in infusion products and patient samples (Figure 1a). Using a probe ratio-based strategy, the two-channel ddPCR system simultaneously detected individual CARs (B7-H3, IL13zetakine, EGFR806, HER2) within a single well alongside FLAP-EF1a (total CAR) and albumin (reference gene) in a parallel well. The assay was used to analyze infusion products (n=31), as well as cerebrospinal fluid (CSF) and peripheral blood (PB) samples (n=45) post-dosing from BC-03 and -04 trials. The samples included post-flow cytometry PFA-fixed samples (CSF n=13) and fresh samples (PB n=28, CSF n=4) unsuitable for flow cytometry due to time or quality constraints.

Results:
The assay demonstrated high sensitivity, specificity, and a dynamic range of 1-100,000 copies/reaction (Figure 1b). Validation against a qPCR-based FLAP-EF1 assay showed strong concordance (R^2 =0.999), confirming assay reliability for clinical sample analysis. The assay characterized CAR representation and transduction patterns in BrainChild-04 infusion products (n=31), (Figure 1c), detecting FLAP-EF1 at 2.00 ± 0.26 copies/ng, with individual CARs detected as follows: B7H3 (0.577 ± 0.11), EGFR806 (0.366 ± 0.07), HER2 (0.536 ± 0.09), and IL13zetakine (0.440 ± 0.07). Preliminary patient sample analysis (n=45) revealed CAR T cell persistence in CSF. In BC-04 CSF samples (n=13), FLAP-EF1 was detected in 92% of samples, with CAR-specific frequencies of B7H3 (6/12), EGFR806 (9/12), HER2 (8/12), and IL13zetakine (10/12 samples). Matched BC-04 CSF and PB samples (n=13) showed higher CAR detection in CSF (12/13) versus PB (0/13), indicating localized expansion. Flow cytometry data using EGFRt (a CAR transduction tag) cross-validated ddPCR findings. In BC-04 CSF samples, all EGFRt-positive (5/5) and EGFRt-negative (5/5) samples by flow cytometry were detected by FLAP-EF1 ddPCR, demonstrating the assay's higher sensitivity. Similarly, all EGFRt-positive BC-03 CSF samples (4/4) by flow cytometry were FLAP-EF1 positive by ddPCR.

Conclusion:
Amplitude multiplex ddPCR is a robust platform for multi-antigen CAR quantification, offering critical insights into CAR T cell persistence in pediatric CNS tumors after ICV delivery. Ongoing correlative analysis from the BC-04 trial will further validate its utility. Combining VCN-based ddPCR with multiparameter flow cytometry enhances understanding of CAR T cell dynamics, guiding future therapy design, dosing strategies, and mechanistic studies for CNS tumors.

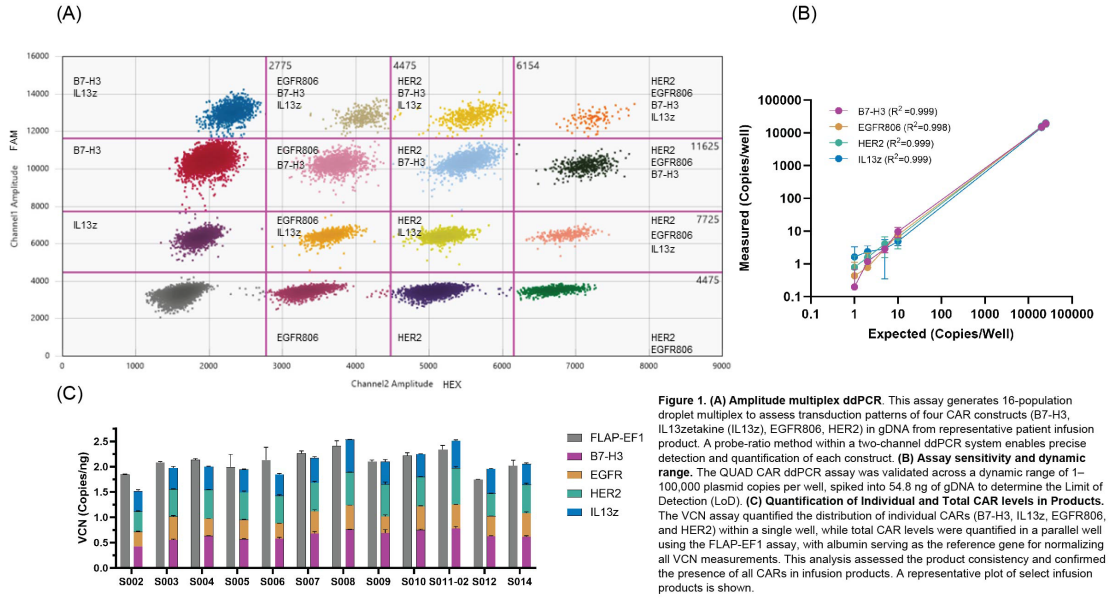

Figure 1. (A) Amplitude multiplex ddPCR. This assay generates 16-population droplet multiplex to assess transduction patterns of four CAR constructs (B7-H3, IL13zetakine (IL13z), EGFR806, HER2) in gDNA from representative patient infusion product. A probe-ratio method within a two-channel ddPCR system enables precise detection and quantification of each construct. **(B) Assay sensitivity and dynamic range.** The QUAD CAR ddPCR assay was validated across a dynamic range of 1–100,000 plasmid copies per well, spiked into 54.8 ng of gDNA to determine the Limit of Detection (LoD). **(C) Quantification of Individual and Total CAR levels in Products.** The VCN assay quantified the distribution of individual CARs (B7-H3, IL13z, EGFR806, and HER2) within a single well, while total CAR levels were quantified in a parallel well using the FLAP-EF1 assay, with albumin serving as the reference gene for normalizing all VCN measurements. This analysis assessed the product consistency and confirmed the presence of all CARs in infusion products. A representative plot of select infusion products is shown.

419 Non-*Rian* Integrations in AAV-Associated HCCs From a Murine Model of Krabbe Disease

Stephanie Smith[1], Tyra Wolfsberg[2], **Mark Sands[3]**, Charles Venditti[2]
[1]NIH - National Human Genome Research Institute, Bethesda, Maryland, [2]NIH, Bethesda, MD, [3]Washington University School of Medicine, Saint Louis, MO

Background
Prior studies established that genotoxic vector integrations into the mouse *Rian* locus are associated with hepatocellular carcinoma (HCC) following systemic administration of AAV vectors. The Twitcher (Twi) mouse, a model of Krabbe disease, is deficient in galactosylceramidase (GALC) activity. While CNS-directed AAV2/9-GALC-mediated gene therapy combined with bone marrow transplantation and a substrate reduction drug results in an impressive increase in the median lifespan from ~45 days to ~400 days, >90% of the Twi mice, as well as 100% of the wild type controls, succumb to HCC (PMC7854295). HCC has never been reported in untreated Twi mice. A targeted sequence capture analysis using a tiling array with probes specific for the AAV vector was used to map ITR-containing integrations in or near *Rian*, or other cancer- and cell-growth/death-associated genes, in the HCCs. However, the integrations were not further characterized.

Methods
We developed a bioinformatics method designated as AVITA (Assembly of Viral Integrations from Tiling Arrays) to mine tiling array sequence data to reconstruct full length integrations and have applied it to both *Rian* and non-*Rian* integrations. We then used targeted PCR amplification followed by Sanger sequencing to validate the *in silico* predictions.

Results
Two non-*Rian* integrations were fully reconstructed *in silico:* one in intron 8 of the *Akap13* gene, and one in intron 5 of *Foxp1*. Both have a single truncated 3' ITR and an intact β-globin polyA signal. The integration in *Akap13* is a single 612nt fragment of the AAV vector transgene, while the event in *Foxp1* appears to be the product of a rearrangement that resulted in a ~1500nt insertion composed of two vector fragments. Using primers outside of the integration and primers designed from the assembly, we PCR amplified the left and right sides of the integrations. The PCR products were cloned into the pCR.4-Topo vector and sequenced, confirming the *in silico* integration site predictions.

Discussion
A-kinase anchor proteins like AKAP13 confine protein kinase A to specific locations within the cell; FOXP1 is a forkhead box transcription factor active in development and maturity. Both may have tumor suppressor activity. In the mouse, the integrations in *Akap13* and *Foxp1* fall near predicted enhancer-like elements. In the orthologous regions of the human genome, both integrations fall in DNAse hypersensitive regions that also contain histones with methylation patterns consistent with regulatory elements. Thus, the mouse and human genomic contexts of the two integrations suggest that they could disrupt regulation of *Akap13* and *Foxp1*. Furthermore, the integrated AAV sequence in the two non-*Rian* integrations contains the vector 3' ITR and polyA signal. This contrasts with the six *Rian* integrations that we identified by AVITA, which all contain a single truncated 5' ITR and parts of the vector enhancer. Thus, while genotoxic integrations into the *Rian* locus appear to act by transactivation of proximal microRNAs and the *Rtl1* gene (PMC4319425), the polyA signal in the non-*Rian* integrations could serve as a gene trap, disrupting the tumor suppressor activity of *Akap13* or *Foxp1*. Mechanistically, these integration events resemble some of the human genotoxic events described by Nault et al (PMID 26301494). Determining whether non-*Rian* AAV integrations can act synergistically in the formation of HCC will require further functional studies.

420 A PCR-Free Approach Combining CRISPR-Cas9 and Long-Read Sequencing Reveals Unpredictable AAV Integration in the Host Genome

Jiahe Tian[1], Xuong Yu[2,3], Thao Chi Dang[2], Jie Huang[2,3], Fang Fang[2,3], Hongyu Gao[2,3], Yue Wang[2,3], Roland W. Herzog[4], Yulong Liu[2,3], Kenneth G. Cornetta[2], Weidong Xiao[4], Junping Zhang[4]

Indianapolis, IN,[4] Department of Pediatrics, Herman B Wells Center for Pediatric Research, Indiana University School of Medicine, Indianapolis, IN

The integration of AAV vector genomes has been documented for many years. While no direct evidence has established that vector genome integration causes tumorigenicity, experts remain concerned about this theoretical risk to patients. Our understanding of vector genome integration remains limited, primarily due to sequencing technology constraints. Currently, efforts to enrich integrated AAV genomes often rely on PCR-based amplification strategies. Typically, sequencing templates are generated using a combination of AAV-ITR-specific and adaptor-specific primer amplification. However, these PCR-based methods face challenges, particularly due to the highly complex structure of the AAV ITRs, which are rich in GC content. This complexity often results in the generation of non-native sequence reads, further complicating accurate characterization of integrated AAV genomes. To address these challenges, we have introduced an amplification-free approach using a CRISPR-Cas9-based method for upstream library preparation, coupled with long-read sequencing on a nanopore platform. This strategy aims to provide a more accurate analysis of AAV vector genome integration.

The method was assessed using the HeLa cell line, which was transduced with the AAV2-CAG-GFP vector for six weeks. HeLa cells expressing GFP were harvested via flow cytometry, followed by DNA extraction and library preparation as described in Figure 1A. A total of 44181 valid, integrated vector genome reads containing both AAV and human genomic sequences were obtained. Of these, 25255 reads contain both ITR and CAG promoter. The 14588 unique sub-reads originating from CRISPR-Cas9 cleavage were aligned to the AAV genome reference sequence (Figure 1B). The plot in Figure 1C illustrates the ratio of CRISPR-Cas9 cleavage reads to total integration reads at each cleavage position, covering almost all integration sites. The integrated vector genomes primarily included (1) backbone DNA without ITR (8.10%), (2) 5′ ITR plus truncated AAV DNA (16.5%), (3) 3′ ITR plus truncated AAV DNA (22.8%), and (4) partial AAV DNA without ITR (52.2%). Typical structures of the integrated vector genomes include both the basic structures and the complicated re-arranged structures with multiple full or partial ITR elements in various directions (Figure 2B). The junction sites along the ITR element mainly locate in the “trs” and “the outside border of D’”. The reads were widely distributed across all 24 chromosomes (reference Human hg38). The lengths of integrated vector genome sequences ranged from a maximum of 6987 bases to a minimum of 29 bases. These results reveal that AAV integration events in the host genome are complicated and unpredictable.

The PCR-based amplification methods often exclude partial vector genomes lacking ITRs due to the reliance on ITR-specific primers. In contrast, this study revealed that approximately 52% of reads integrated into host genomes were from partial AAV DNA sequences lacking any ITRs and around 8% of reads were from the vector backbone sequence, even containing full-length Ampicillin gene, which will further raise concern on AAV safety. These findings suggest that this amplification-free method is a valuable tool for analyzing AAV genome integration. Additionally, it may be broadly applicable to virus integration research, facilitating and accelerating studies on vector biology.

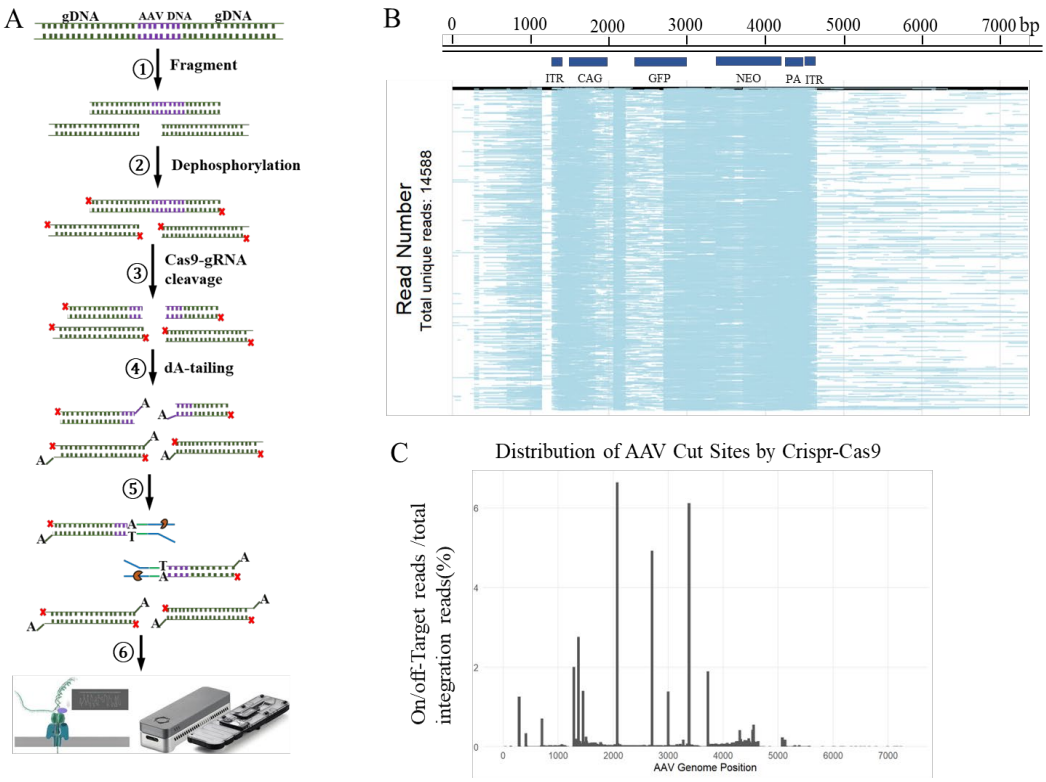

Figure 1. AAV integration analysis through PCR-free amplification based on Crispr-Cas9 cleavage combining Nanopore long-read sequencing.
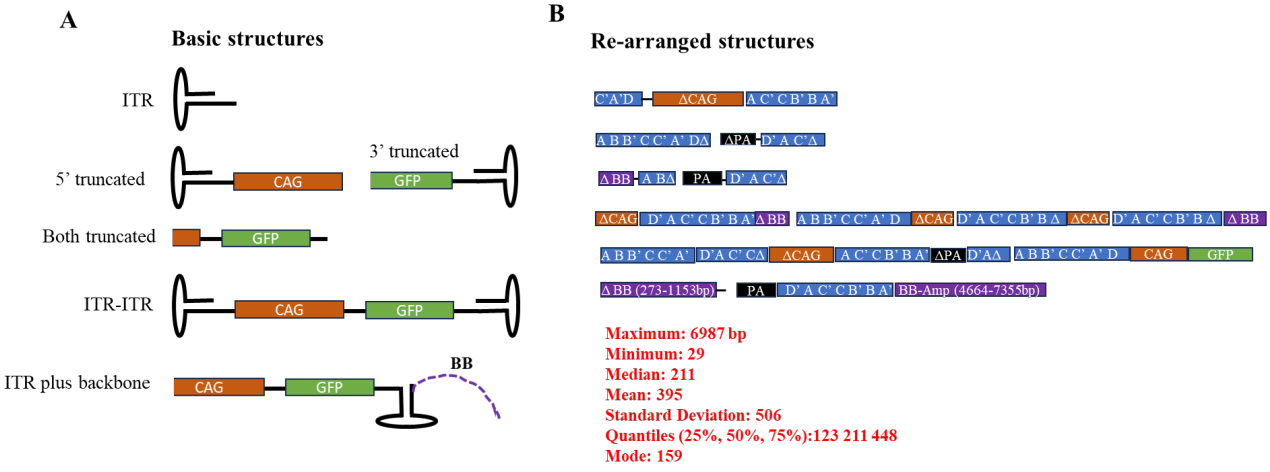
A: Workflow for Nanopore long-read sequencing AAV integration DNA. The procedure starts from a randomly fragmented DNA sample (1). All ends of the fragmented DNA molecules are dephosphorylated to block adapter ligation (2). The integrated AAV DNA fragments containing gRNA binding sites are cleaved by Cas9 (3) and all 3′ ends are dA-tailed (4). Sequencing adapters are then ligated to Cas9 cleaved and dA-tailed ends (5) and these molecules are sequenced on the Nanopore PromethION P24 system (6). **B:** All Cas9-cut reads (14588, after removing barcodes and following A/Ts) were aligned to the AAV2-CAG-GFP vector genome reference sequence. The details of integration and Crispr-cas9 cleavage determination can be found in **C**. **C:** From all sequencing reads that contain both AAV and human genomic sequences (the total integration reads of 45255), we identified the subset of reads that show evidence of being cleaved by Cas9. These "Cas9 cleavage" reads are then mapped back to the AAV vector genome, and the plot displays the ratio of Cas9 cleavage reads to the total integration reads. Integration reads are determined as follows: BWA is used in Linux to align sequencing reads to both AAV and human (hg38) AAV reference genomes (pssAAV-CB-EGFP_ARM), followed by sorting and indexing using Samtools. If both human and AAV genome pieces are present in a read, then that read is an integration read. Cas9-cleavage reads are determined as follows: R is used to analyze each read for the presence of any barcode sequence (from a known list of barcode sequences). Once a barcode is found, we skip all consecutive A or T nucleotides immediately following it and then check the next portion of the read for a gRNA-related sequence. Two criteria are used to identify a crispr-cas9 cut read, allowing up to 2 nucleotide mismatches:3′-end + PAM check: The next 6 bases in the read should match the last 3 bases of any of the 10 known gRNAs, plus the associated PAM sequence. 5′-end check: Alternatively, the following 17 bases in the read should match the first 17 bases of any of the 10 known gRNAs. If either of these conditions is met (with up to 2 mismatches allowed), the read is classified as having been cut by crispr-cas9.



Supplementary Figure 3 The integrated AAV DNA molecular structure.
A: Basic structures of integrated AAV DNA. ITR: only containing full or partial ITR sequence; 5' truncated: 5'ITR plus partial vector genome; 3' truncated: 3'ITR plus partial vector genome; Both truncated: partial vector genome without any ITR sequence; ITR-ITR: full length vector genome from 5'ITR to 3'ITR; ITR plus backbone: ITR plus partial vector DNA backbone sequence. B: Typical rearranged structures of integrated AAV DNA. BB-Amp (right, bottom): the whole Ampicillin expression cassette is included. Δ means truncated.

421 Overcoming Barriers To Accessibility: Scalable, Cost-Efficient Biomanufacturing For Gene Therapies.

Thomas Robert[1]*, Alex Chatel[2], Matt Kremer[3]
[1]Univercells Technologies, Nivelles, Brabant Wallon, Belgium, [2]Donaldson, Lyon, France, [3]Univercells Technologies, Philadelphia

The transformative potential of cell and gene therapies is evidenced by the increasing number of regulatory approvals, with over 20 products now on the market. However, pricing and reimbursement have affected **patient access**, highlighting significant commercial hurdles. These challenges, exacerbated by **high manufacturing costs** and the **constrained funding landscape**, threaten the ability of developers to address unmet medical needs effectively. In this context, achieving **cost-efficient, large-scale production** is paramount to ensuring the commercial viability of gene therapies. While the biologics industry has made remarkable strides in volumetric productivity through **upstream intensification** and **continuous processing** in stirred-tank bioreactors (STRs), gene therapy developers lag behind. This gap is largely attributed to the unique complexities of viral vector manufacturing. STR systems also face inherent scalability limitations—shear stress, mixing, and gas exchange cannot be simultaneously and linearly scaled—restricting process design flexibility. These constraints delay time-to-market, inflate costs, and limit accessibility, thus increasing risks for developers. Structured fixed-bed bioreactors (FBRs) present a compelling solution to these challenges by enabling significant upstream process intensification and facilitating continuous processing without the scalability constraints of STRs. FBRs support **low-volume, low-footprint biomanufacturing**, allowing for substantial **reductions in cost of goods (COGS)** while **expediting development timelines**. This presentation will highlight real-world case studies demonstrating the advantages of FBR technology, including

- Enhanced productivity: Achieving **2- to 10-fold higher specific productivities** for a wide range of viral products.
- Improved product quality: Delivering a **3-fold increase in AAV full-to-empty capsid ratio** and up to **5- and 10-fold reductions in host cell protein and DNA**, respectively.
- Cost efficiency: **Reducing drug substance COGS by up to 50%**.
- Accelerated scalability: **Successful transfer and scale-up** of a viral manufacturing process by a CDMO, from bench to commercial scale **in under nine months**.

These insights underscore the transformative potential of structured FBRs to **redefine scalability, cost efficiency, and accessibility** in gene therapy manufacturing.

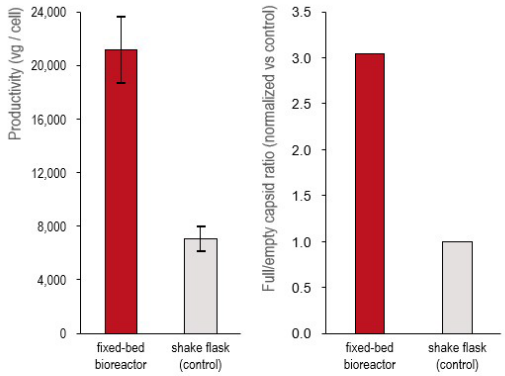

Fig 1. Fixed-bed bioreactor displays 3-fold increase in productivity and in full/empty capsid ratio for AAV2 production

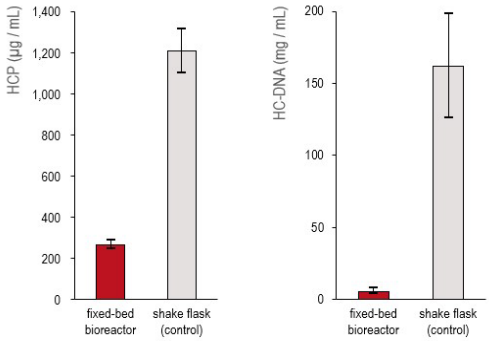

Fig 2. Fixed-bed bioreactor displays 5- and 10-fold reduction in host cell protein (HCP) and host-cell DNA (HC-DNA), respectively, for AAV2 production

422 "Improved AAV Vector Production Yields From An Optimised Manufacturing Process in Fixed-Bed Bioreactors"

Ruchita Selot[1], Ashish Khaparde[2], Sharath Babu[3], Arkasubhra Ghosh[2]*
[1]GROW LAB NNF, Bangalore, Karnataka, India, [2]Narayana Netralaya Foundation, Bangalore, Karnataka, India, [3]Grow Research Lab

Introduction:
Developing reliable and efficient AAV vector manufacturing processes is a top priority in the field of gene therapy to ensure broader accessibility. AAV vector production in fixed-bed bioreactor has shown high potential due to benefits like a single-use, fully integrated system with large surface area in a small footprint as compared to suspension culture systems. The main challenges in bioreactor-based vector production are low yield and prolonged production time, which lead to higher costs for the final product. Optimising the bioreactor culture, transfection, harvest, and recovery processes can be optimised to improve the per cell vector production potential. Therefore, we tested, using a DOE approach, the effect of a set of parameters such as seeding density, plasmid DNA/cell transfected and combined harvest of both supernatant and lysate on final AAV yields.

Methods:
All bioreactor runs were performed in Cytiva® iCellis Nano bioreactor (1.06m^2). The Hek293T cells were seeded at 30,000-37,000 cells/cm^2 following aseptic conditions and expanded to reach 1.7-2x10^^6 cells/carrier strip before transfection with packaging plasmids [pRep2-Cap9, pHelper, and pAAV-ITR.EGFP] and PEIPro® (Polyplus) transfection reagent in a 1:1 to 1:2 ratio. The cell numbers, and culture conditions (pH, Dissolved Oxygen, and Media Glucose concentration) were closely monitored throughout the run. Post transfection (72 hrs and 120 hrs), culture media was harvested followed by cell lysis from carrier strips. Post-harvest, AAV vectors were captured using an Affinity chromatography-based system. Vector titration and quality checks were carried out following standard methodologies.

Results:
Our results indicate that process variables like cell seeding, DNA amount/per cell, and harvesting methods contribute most significantly towards increasing vector yields. The high cell seeding density (30,000 cells/carrier strip) resulted in a reduced cell expansion phase (3-5 days) and further compressed run time to 10 days compared to earlier reports. We have used lower amounts of total DNA (1ug/million cells) for transfection and achieved 2.5 × 10^5 vg/cell at this ratio, improving on previously published reports. Intensification of vector harvesting steps during these runs resulted in an 8-fold increase (crude yield 4.92x10^14vg) compared to the first run (crude yield 5.66x10^13vgs). This enhancement was also evident during the vector purification process, with a recovery rate of 90.26%-98.65%.

Conclusion:
To address challenges in the AAV vector production process, we have systematically optimized critical production parameters. The duration of cell expansion phase had a significant impact on vector production along with biological parameters such as pH, plasmid concentration, and metabolite concentration. We report an AAV vector production process with a significantly shorter timeline (10 days) in fixed-bed bioreactor. Our data shows that this process can serve as a scalable and cost-effective strategy for vector production. We anticipate that our optimized bioreactor-based vector production protocol can be adapted effectively for pilot-scale production processes.

423 Simplifying Large-Scale Upstream AAV Production Via a Transfection Complex Stabilizing Reagent

James Ludtke[1], Nick Rossi[2], Becky Reese[2], Jenni Swanson[3], Austin Storck[2], Yuyuan Wang[4], Oksana Hart[2], Neha Andhole[2], **Laura Juckem**[5]
[1]Mirus Bio LLC, Madison, Wisconsin, [2]Mirus Bio LLC, Madison, WI, [3]Waunakee, WI, [4]Madison, WI, [5]Mirus Bio, Madison, WI

Adeno-associated virus (AAV) has become the leading vector for gene therapy due to minimal pathogenicity and the ability to facilitate long-term gene expression. The success of AAV as a gene therapy has resulted in the transition from treatment of rare diseases to broad disease indications where the treatable population is sizeable; likewise, there is an increase in the development of high dose therapies. To meet the supply needs from both a therapeutic and cost prospective, the industry is moving to increasingly larger scale bioreactors for the manufacture of recombinant AAV. The production of AAV in bioreactors via transient transfection requires large volumes of liquids to be mixed, incubated, and then transferred to the bioreactor. Transfection complexes often demonstrate optimal performance after a short complex formation time (CFT), which typically range from 10-45 minutes. This small window of time can present challenges and risk in properly forming complexes and delivering them to the bioreactors quickly enough. For example, a 1000 L bioreactor would require transferring 50 L of a 5% complex, which at a pumping rate of 1 L/min would take almost an hour to deliver.

To navigate this hurdle, Mirus Bio has developed a transfection stabilization reagent which can extend the CFT for a transfection complex made with *Trans*IT-VirusGEN® from minutes to several hours, without a loss in performance. This reagent stabilizes transfection complexes across several GOIs, serotypes, DNA doses, and reagent:DNA ratios. As demonstrated through dynamic light scattering (DLS), this stabilization effect is the result of slowing the growth of transfection particles, resulting in similar sized particles at both short and long CFTs. Transfection complexes can also be stabilized by this reagent when the complex volume is reduced from 5% to 2%, which will also decrease the volume and therefore the time needed to transfer a transfection complex to a large-scale bioreactor. The complex stabilization reagent can be used successfully in a wide range of complex formation media and maintains performance after filtering, allowing it to be easily integrated into an existing workflow with the *Trans*IT-VirusGEN Transfection Reagent and the *Rev*IT™ AAV Enhancer. The transfection complex stabilizer is scalable, as stabilized transfection complexes were successfully delivered to 2 L bioreactors after 3 hours of complex formation with equivalent performance to transfection complexes formed for 30 minutes. These data demonstrate the efficacy of the transfection complex stabilizer during AAV manufacture and will substantially improve workflows and success rates in large-scale bioreactors.

424 From Bench to Bioprocess: Bridging AAV Capsid Engineering and Scalable Manufacturing for Clinical and Commercial Translation

Lewis Hall[1], Giulia Massaro[2], Ahad Rahim[2], Qasim Rafiq
[1]University College London, LONDON, London, United Kingdom, [2]University College London, London, United Kingdom

Introduction
The development of novel recombinant AAV vectors aims to improve tropism, transduction efficiency, and immune evasion for targeted gene delivery in clinical and commercial applications. However, capsid engineering and bioprocess optimization have traditionally been pursued separately—with capsid innovation focusing on biological function and bioprocess development optimizing production efficiency. This disconnect results in promising capsids encountering the same scalability challenges as existing serotypes, including packaging efficiency, high-titer production, and downstream purification. To address this, we present an integrated strategy aligning capsid engineering with scalable manufacturing, evaluating the production of AAV-LH9, a rationally engineered vector, and an AAV capsid library using commercially available bioprocess technologies, including the iCELLis Nano™ fixed-bed bioreactor and AAVX affinity purification. This approach ensures that vector design and optimization incorporate scalability considerations from the outset.

Methods
A systematic DoE was conducted in HEK293T adherent cultures to optimize transfection conditions, DNA:PEI ratios, and media composition for AAV-LH9 and AAV9. Optimized parameters were transferred to the iCELLis Nano, a scalable fixed-bed bioreactor designed for high-density AAV production, and an AAV capsid library was produced to assess high-throughput vector screening potential. Following harvest, AAV-LH9, AAV9, and the library were purified using AAVX affinity chromatography, a platform optimized for large-scale AAV recovery. qPCR quantified vector genome (vg) titers, and ELISA determined the full:empty capsid ratio. Transduction

efficiency was assessed in vitro and in vivo by delivering equivalent vg doses of AAV9, AAV-LH9, and selected library variants, with transgene expression analyzed to evaluate infectivity and tropism.

Results
Comparable titers were achieved for AAV9 and AAV-LH9 in small-scale adherent cultures and the iCELLis Nano, demonstrating process scalability. The AAV capsid library was successfully produced in the iCELLis Nano, confirming its suitability for large-scale capsid screening. AAVX affinity purification enabled efficient downstream processing, ensuring a robust workflow. Transduction studies in vitro and in vivo demonstrated that AAV-LH9 exhibited comparable transduction efficiency to AAV9, supporting its therapeutic potential. Library screening identified variants with similar or improved transduction profiles, reinforcing the feasibility of high-throughput capsid discovery using scalable platforms.

Conclusions
This study demonstrates the successful integration of capsid engineering with scalable AAV bioprocess development, ensuring high-yield production using commercially available technologies. The optimized process was successfully scaled from small-scale cultures to the iCELLis Nano, confirming robustness and reproducibility. The efficient production of an AAV capsid library in iCELLis Nano highlights its potential for large-scale high-throughput screening, accelerating the discovery of novel vectors. AAVX purification enabled scalable downstream processing, while AAV-LH9 showed comparable transduction to AAV9 in vitro and in vivo, supporting its therapeutic viability. By aligning capsid innovation with scalable bioprocesses, this approach facilitates the efficient translation of engineered AAV vectors for clinical and commercial applicatio

425 Enhancing AAV Production Efficiency: A Dual Approach to Design of Experiments Optimization and Economic Feasibility Analysis

Igor Alves Mancilla[1]*, Irene Ferreira[2], Janina Haar[3], Michelle Fraser[4]
[1]Revvity Gene Delivery, Graefelfing, Bavaria, Germany, [2]Revvity, Germany, [3]Revvity Gene Delivery, Heidelberg, Baden-Wuerttemberg, Germany, [4]Revvity, Waltham, MA

Adeno-Associated Virus (AAV)-based gene therapies show great promise, but their development is hindered by high production costs, particularly due to expensive plasmids and transfection reagents used in transient transfection. This study applies Design of Experiments (DoE) to select plasmid ratios and quantities in AAV vector production, focusing on two critical aspects: enhancing manufacturing productivity and assessing the economic viability of DoE implementation in preclinical studies. We applied DoE to improve transfection-related parameters for cost-effective AAV production scaled up for non-human primate studies. Using an R-based open-source DoE pipeline, we reduced the 3-plasmid ratio combinations to be tested from 14,553 to 28. Transfections were performed in a HEK293F-derived clonal suspension cell line, with vector titers measured by ITR2-qPCR. We identified plasmid ratios that increased productivity up to 4-fold compared to other conditions in the same experiment, achieving titers of up to $7.0x10^{14}$ VG/L. A Response Surface Model (RSM) was created and verified, demonstrating significant improvements over our previous best-performing conditions. We then tested the optimized conditions across multiple AAV serotypes (2, 3, 5, 8) and two transfer plasmids. While most serotypes showed improved productivity, with AAV2 achieving nearly 300% increase, AAV5 experienced a slight titer decrease. These results underscore the importance of serotype and construct-specific optimization in AAV production processes. To address the economic viability of DoE implementation in preclinical studies, we conducted batch size and cumulative production analyses using cost modeling. We evaluated DoE applicability across various scales ($1.0x10^{13}$ to $1.0x10^{16}$) and in scenarios of multiple independent productions. This analysis provides insights into the production scale and frequency at which DoE implementation becomes cost-effective. Our comprehensive approach not only demonstrates the benefits of DoE in AAV vector production but also offers valuable guidance for strategic decision-making in vector manufacturing. These findings have the potential to accelerate the development of more affordable gene therapies by optimizing production processes and resource allocation in preclinical studies. Moreover, this study provides a framework for balancing productivity gains against implementation costs, potentially streamlining the path from preclinical development to clinical trials in the gene therapy field.

426 Transfection Reagent Selection and Post-Transfection Feeding of HEK293 AAV Production Platforms Based on GOI and Serotype

Kim Schrag[1], Jessica Haywood[1], Charlotte Javalet[2], Katelyn McLaughlin[1], Nathan Stegemann[1]
[1]MilliporeSigma, Lenexa, KS, [2]MilliporeSigma, Meylan, France

Adeno-associated virus (AAV) has become a prominent vector to treat life-threatening genetic diseases. As the demand for AAV therapeutics increases, so does the need for large quantities of high titer AAV. For HEK293 production platforms, transfection reagent selection, experimental optimization, and post-transfection feeding are vital to achieving the high AAV titers essential to support this rapidly growing industry. PEI (polyethyleneimine) has been the most commonly used transfection reagent for AAV viral gene therapies, and we have optimized PEI transfections with multiple HEK293 cell lines, AAV serotypes and GOIs (gene of interest) to maximize AAV titers. In addition to PEI transfection optimization, we have found a commercially available feed (Cellvento® ModiFeed Prime) that can significantly increase titers across multiple cell lines and serotypes but varies based on GOI and transfection reagent. Recently, we have begun working with non-PEI based transfection reagents from Mirus Bio, *Trans*IT-VirusGEN®+ RevIT® AAV Enhancer and the TransIT®-AAViator System. The titers achieved with the Mirus reagents are 2 logs higher than PEI-based reagents prior to transfection optimization and the ideal reagent varies with the GOI (3 evaluated) and serotype (AAV5, AAV8, and AAV9).

427 The use of novel PAT and soft sensor as process monitoring tool during AAV manufacturing

Due to the high manufacturing costs of viral vector-based gene therapies, ensuring product quality, safety, and consistency is pivotal. In adeno-associated virus (AAV) manufacturing, in-line monitoring technologies provide real-time insights into critical process parameters (CPPs) and quality attributes (CQAs). In this work, a miniaturized process analytical technology (PAT) platform from Jobst Technologies, specifically designed for cell and gene therapy manufacturing, was applied. The novel sensor system is being developed to monitor key metabolites (glucose, lactate, glutamine, glutamate), pH, and dissolved oxygen with minimal sampling volume and without human intervention. The prototype demonstrated robustness and accuracy with calibration solutions and under process conditions. For AAV production, this type of sensor is essential for understanding cell culture dynamics, particularly during transfection and virus production. Data sets were generated using the exoReady manufacturing platform in a Bioblu 1c stirred tank bioreactor and compared with offline and historical data (Cedex Bio HT, Roche). Novel PAT tools are enablers for the development of process soft sensors. Lactate, ammonium (metabolic byproducts), and LDH (cell health marker) have been identified as key indicators of shifts in the cell culture phases and AAV yield. Correlations between metabolic rates and AAV accumulation were calculated. The validity of the correlations is being further evaluated in a perfusion process. Prediction of AAV titers with a model allowed us to use them as soft sensor of process performance. When soft sensors alone were insufficient to explain low or instable titers, we evaluated the potential of novel transcriptomics PAT platform (Gensensor) to analyze gene expression, uncovering cellular stress pathways and production bottlenecks.

Real-time metabolite tracking, combined with transcriptomic when deeper insights is needed, allows early detection of process deviation. Looking towards the future, the application of soft sensors is expected to evolve further to include the monitoring of CQAs, such as product-related impurities (e.g., empty capsids, host cell proteins, and nucleic acids). The development of soft sensors can revolutionize AAV manufacturing with proactive quality control strategies.

B-cell and Solid Organ Therapies

428 CD19 CAR EngTreg Effectively Modulate Activated Human B Cells and Antibody-Secreting Plasma Cells

Annaiz Grimm[1], Brock McKinney[1], Aesha Vakil[1], Travis Drow[1], Jennifer Mellen[2], Victoria DeVault-Nelson[3], Christopher Moore, Alberto Del Rio-Espinola[3], Peter Cook[4], David Rawlings[5]

Preliminary results from Phase I clinical trials of adoptive CD19 CAR T cell therapy in treatment-refractory systemic lupus erythematosus (SLE) demonstrated rapid and sustained therapeutic benefit despite limited CAR T cell persistence. However, CAR T therapies face potential challenges, including cytokine release syndrome (CRS) and limited ability to modulate the pathogenic memory T cell subsets that drive autoreactive B cell proliferation and differentiation and additional disease manifestations. To address these potential limitations, we developed CD19 CAR-engineered regulatory T cells (EngTreg), which leverage the CD19-targeting specificity of traditional CAR T cells but are anticipated to operate through multiple mechanisms including modulation of both pathogenic B and T cells, and therefore hypothesized to provide broad and sustained bystander immune tolerance with an improved safety profile. We generated and tested EngTreg expressing both CD19 CAR and a chemically inducible IL-2 receptor (CISC) using homology directed repair (HDR)-based gene editing. As previously described by our group, this approach overcomes the scarcity of antigen-specific natural Treg by converting bulk CD4+ T-cells to a Treg phenotype via enforced expression of FOXP3. To produce CD19 CAR EngTreg, human $CD4^+$ T cells were isolated and transduced with lentivirus encoding the CD19 CAR. The *FOXP3* locus was HDR-edited using an AAV repair template to enforce FOXP3 expression along with expression of the CISC cassette for enrichment. We also employed an alternate method where CD4+ T cells were dual-HDR edited at *FOXP3* and *TRAC,* using AAV donor cassettes targeting both loci. Successful engineering with either strategy resulted in constitutive expression of CD19 CAR, endogenous FOXP3, and the synthetic CISC receptor, thereby permitting enrichment of therapeutic cell products to high purity in the presence of rapamycin. Cytotoxicity assays indicate that CD19 CAR EngTreg are less cytotoxic than CD19 CAR T cells and bear the hallmarks of a Treg phenotype with high FOXP3, CD25, and CTLA-4 expression. CD19 CAR EngTreg also feature reduced production of key pro-inflammatory cytokines in response to CAR stimulation when compared to CD19 CAR T cells. Next, using a robust *in vitro* human plasma cell (PC) differentiation model capable of generating engraftable, long-lived human PCs, we found that CD19 CAR EngTreg effectively block the differentiation of B cells into $CD38^{hi}$ $CD138^+$ plasma cells and inhibit IgM and IgG antibody production. PC differentiation blockade could be induced both during B cell expansion, when CD19 levels are high, and during PC/plasmablast differentiation, as CD19 is progressively downregulated. These findings underscore the versatility and broad applicability of this approach. Finally, in a humanized mouse model, adoptive transfer of autologous CD19 CAR EngTreg ablated splenic human B cells with efficacy comparable to CD19 CAR T cells. This outcome was achieved despite markedly reduced levels of pro-inflammatory cytokines including IFN-γ and CXCL10 at 7 days post T-cell transfer. Comparable numbers of CD19 CAR+, CD4+ T cells were present in the spleen at endpoint for both CAR T and EngTreg groups, indicating sustained engraftment for both products. Taken together, these findings suggest that CD19 CAR EngTreg may offer a promising therapeutic avenue for SLE and other B cell-mediated autoimmune disorders, where precise immune modulation is paramount.

429 Synthetic Signaling to Repurpose Inflammation-Associated with Arthropathy Toward Disease Resolution

Zachary Eidman[1], Jhanvi Sharma[1], Joanne Lee[1], Nicholas Schulze[2], Jonathan Brunger[1]
[1]Vanderbilt University, Nashville, TN, [2]Washington University in St. Louis, St. Louis, MO

INTRODUCTION:
Pro-inflammatory cytokines IL-1β and IL-6 are pro-inflammatory cytokines that play major roles in the pathology of arthropathies.1 Several IL-1β and IL-6 blockers have been clinically approved for use in treating arthropathies, though systemic administration of these drugs can have severe side effects. This motivates the need to develop

avenues to antagonize cytokine signaling selectively and specifically. Our prior work has demonstrated that cells engineered with synthetic Notch (synNotch)2 receptors display spatially regulated responses to soluble inputs captured by a programmable biomaterial surfaces.3 Here, we build off that work and developed methods that use IL-1β and IL-6 as inputs to activate engineered cells to respond via synthetic gene circuits to spatially constrain expression of pro-resolution transgenes. We hypothesize that combining a regenerative medicine approach with synthetic biology principles will allow for programmable responses to inflammatory cytokines.

METHODS:
We used a synthetic receptor platform synNotch, which is based on the native Notch receptor, to recognize IL-1β and IL-6 and activate downstream gene circuits. By leveraging synNotch in conjunction with ligand-capturing biomaterials targeted to cytokines of interest, we can localize soluble IL-1β and IL-6 to desired regions and rredirect cytokine signaling into transgene expression via synNotch signaling. We developed IL-1β and IL-6 responsive mouse mesenchymal stem cell (mMSC) lines that express both a cytokine-specific synNotch receptor and a reporter mCherry and luciferase transgene payload.[BJ1] Both synNotch cell lines were tested using a functionalized cell culture plate coated with a monoclonal antibody that binds to an epitope of IL-1β or IL-6 that does not overlap with the epitope recognized by the cognate synNotch receptor (Fig. A). This allows for the immobilization of either IL-1β or IL-6 and subsequent activation of synNotch cells, which is measured via plate reader-based luminescence assays. For macrophage polarization experiments, mMSCs were engineered to express mouse IL-10 and IL-4 in response to synNotch activation. Macrophage polarization was measured via flow cytometry of surface marker expression of CD163, CD206 and CD86. Cytokine levels were measured using ELISA.

RESULTS:
Here, we demonstrate that mMSCs engineered with IL-1β and IL-6 responsive synNotch receptors can significantly activate reporter luciferase transgenes with cytokine concentrations as low as 1 ng/ml (Fig. B-C). Since inflammatory macrophages are commonly found at the site of joint injury, we hypothesize that polarizing macrophages toward an anti-inflammatory phenotype will reduce local inflammation that contributes to arthritis. After co-culturing engineered mMSCs with RAW 264.7 macrophages[BJ2] , we saw significant upregulation in both CD163 and CD206 in response IL-1β supplementation, indicating a more anti-inflammatory phenotype (Fig. D) compared to control reporter cells. Quantification of mIL-10 and mIL-4 showed up to 10 ng/mL of therapeutic cytokine produced in response to synNotch activation (Fig. E). We also demonstrated a significant increase in CD206+ CD163+ primary macrophages using this system (Fig. F).

CONCLUSION:
These data suggest the potential for our engineered cells to contribute toward inflammation resolution via re-routed cytokine signaling. Cytokine-responsive cells can be programmed with anti-inflammatory transgenes to

Hypophosphatasia (HPP) is a rare inherited metabolic disease caused by deficient tissue-nonspecific alkaline phosphatase (TNSALP) which leads to defective bone mineralization and other systemic complications. HPP results from loss-of-function mutations in the *ALPL* gene that encodes the TNSALP enzyme. Deficient TNSALP activity leads to the accumulation of the enzyme's substrates, namely inorganic pyrophosphate (PPi), an inhibitor of bone mineralization, resulting in disease manifestation.

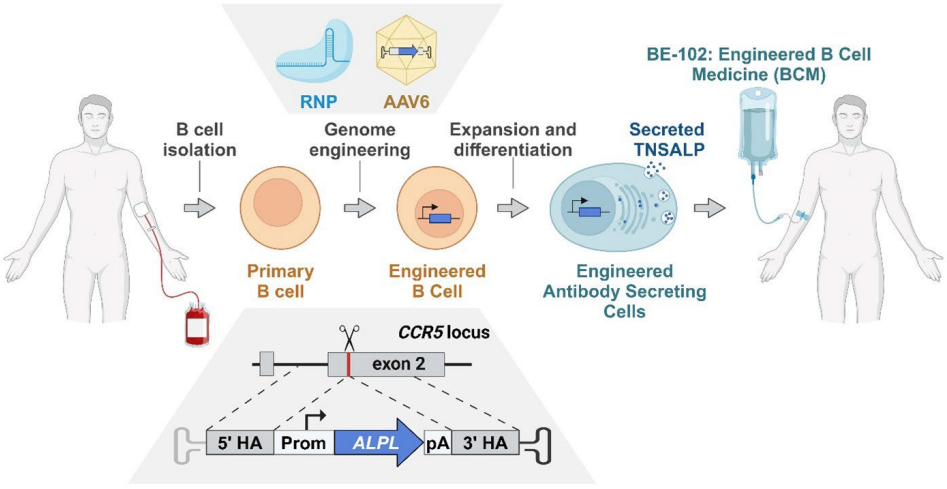
Enzyme replacement therapy is the only approved treatment for HPP which requires frequent lifelong administration accompanied by injection site reactions that can significantly affect a patient's quality of life. To address these limitations, we have developed BE-102, a B cell-based cell therapy. BE-102 is manufactured from primary human B cells by isolating, activating, and precision engineering with CRISPR/Cas9 followed by AAV-mediated homology directed repair mediated insertion of human *ALPL* gene into CCR5 locus (a safe harbor locus). The *ALPL* transgene expression cassette was designed as a soluble glycoprotein composed of two polypeptide chains. Each chain contains three segments: (1) the catalytic domain of human TNSALP, (2) a human IgG4 fragment crystallizable (Fc) domain, and (3) a deca-aspartate peptide (D10). Engineered cells were then further expanded and differentiated towards the plasma cell lineage, resulting in TNSALP-producing cells, with the properties of long-lived plasma cells. BE-102 is expected to continuously secrete active TNSALP to enable reduction of elevated levels of the enzyme's substrates that accumulate in patients with HPP.

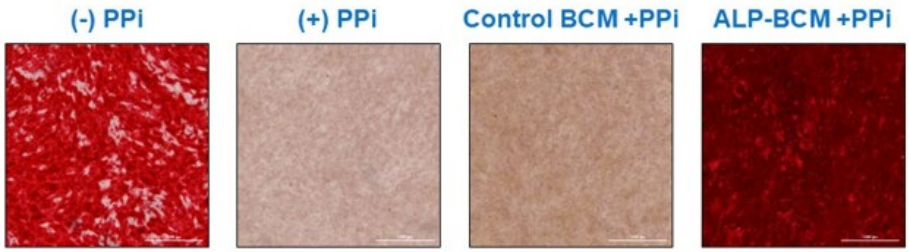
BE-102 cells were manufactured from six healthy donors and were characterized for viability (84.9 ± 3.5%), CD38+ expression (93.3 ± 4.3%), *ALPL* transgene integration (45.1 ± 7.2%) and TNSALP secretion rate (9.5 ± 10.2 ng/mL/hour). *In vitro* pharmacology results demonstrate that BE-102 secretes active TNSALP (409.7 ± 10.2 μUnits/mL using 4-MUP as the fluorometric substrate), which is capable of rescuing calcium deposit inhibited by PPi in a cell-based *in vitro* test system.

Having demonstrated the *in vitro* function of BE-102, *in vivo* studies were conducted in immune-deficient NOG-hIL6 mice. The animals received a single intravenous (IV) injection of 2 x10^7 viable cells. Human TNSALP was detected in serum at every time point starting at Day 1 and up to 6 months following a single dose of BE-102 using a human specific immunocapture assay. Consistent with BE-102 pharmacology, serum ALP activity from clinical chemistry assessment of terminal blood collection (month 5 or 6) showed statistically significant increase of ALP in BE-102 treated animals as compared to vehicle-treated animals. The *in vivo* data confirm long-term engraftment and continuous production of active TNSALP *in vivo* following a single IV injection of BE-102.

Finally, general clinical chemistry and hematology results at the end of study were all within acceptable ranges. These data together with the absence of adverse clinical observations and unscheduled animal deaths over the entire course of study support that BE-102 was well-tolerated *in vivo*.

In summary, pharmacology and safety data establish non-clinical proof of concept that BE-102 has the potential to be a disease-modifying therapy by providing sustained level of active TNSALP following a single IV infusion for patients with HPP.





The murine osteoblast cell line, MC3T3, was cultured under osteogenic conditions (ascorbic acid + β-glycerophosphate) with or without inorganic pyrophosphate (PPi) for 21 days. Supernatant from BCM control and BCMs engineered with the optimized ALP-Fc protein construct were added to cells treated with PPi. Cells were stained with Alizarin Red S to visualize calcium deposition. ALP secreted by ALP-BCMs rescued PPi-induced mineralization inhibition. Bar = 1000 μm. Control BCM: electroporated control cells.

431 Compact Transcription Factor Cassettes Generate Functional, Engraftable Motor Neurons by Direct Conversion

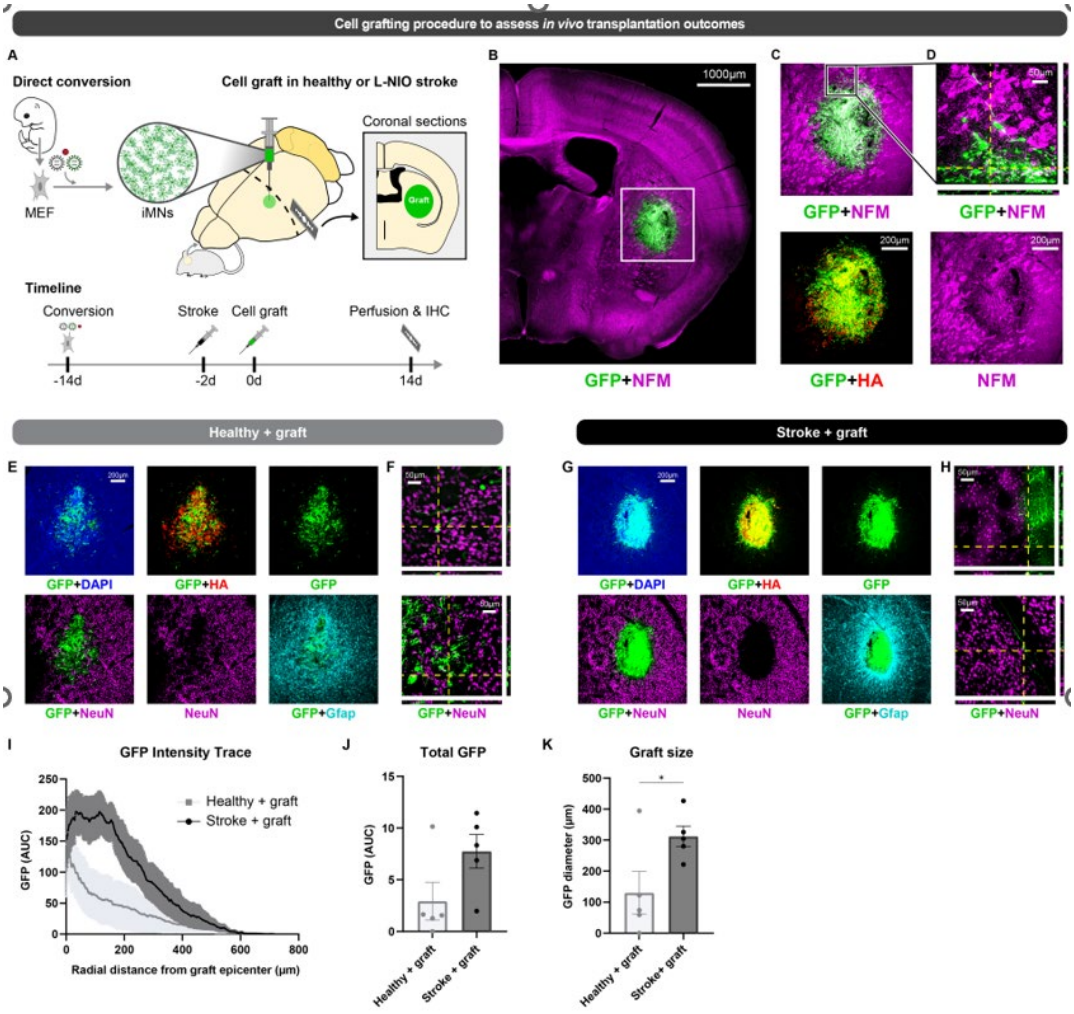
Introduction:
Cell transplantation to promote neural regeneration holds great promise to restore neurological functions. However, rapidly sourcing, and deriving, and purifying sufficient numbers primary- or iPSC-derived neurons for neuronal grafts remain a substantial challenge. By bypassing the intermediate pluripotent reprogramming step, direct conversion more quickly generates therapeutically-relevant, autologous cells from readily accessible patient cells such as those from a skin biopsy. Rapid sourcing of therapeutic cells for delivery within the short therapeutic window is critical to support optimal recovery. Yet, low rates of direct conversion and complex protocols limit scalability and thus the potential of direct cell-fate conversion for biomedical applications. In this work, we set out to develop a robust, scalable, direct conversion process to generate functional motor neurons for neural cell therapies.

Results:
We optimize the direct conversion protocol across molecular and cellular scales by examining process parameters including transcript design, delivery via AAV, retrovirus and lentivirus, cell seeding density, and the impact of media conditions. Using systems and synthetic biology approaches, we report a compact, portable conversion process that boosts proliferation and increases direct conversion of mouse fibroblasts to induced motor neurons (iMNs) to achieve high conversion rates of above 1,000%, corresponding to more than 10 motor neurons yielded per cell seeded which we achieve through expansion. We confirm electrical activity of the induced motor neurons by high-density multi-electrode assay (MEA) and genetically encoded calcium indicators (GECI). Finally, we demonstrate proof-of-principle for iMN grafting for spinal cord injuries by injecting iMNs generated by direct conversion of primary mouse embryonic fibroblasts into the central nervous system of mice.

Conclusion:
Our optimized, direct conversion process generates functional motor neurons from primary mouse embryonic fibroblasts at scales relevant for cell therapies (>10^7 cells) that graft with the mouse central nervous system. High-efficiency, compact, direct conversion systems will support scaling to patient-specific, neural cell therapies. Though there remain questions on the long-term stability, safety and efficacy of directly converted neurons when transplanted *in vivo*, we demonstrate that differentiated motor neurons generated by direct conversion can serve as a well-defined neural cell source for neural regenerative applications.



432 Broadly-neutralizing Anti-HIV Antibody Production in Rhesus Macaques Transplanted with B Cells Engineered at the IgH Locus.

Chan-Hua Chang[1], Geoffrey Rogers[1], Atishay Mathur[2], Xiaoli Huang[3], Joseph Nkolola[4], Krishna Shah[4], Wei Li[5], John Mellors[5], Dan Barouch[6], Paula Cannon[7]
[1]University of Southern California, Los Angeles, CA, [2]USC, Los Angeles, CA, [3]Los Angeles, CA, [4]Beth Israel Deaconess Medical Center, Boston, MA, [5]University of Pittsburgh, [6]Beth Israel Deaconsess Medical Center, Harvard Medical School, Boston, MA, [7]University of Southern California, Los Angeles, CA

Antibodies induced by either natural infection or current vaccines are unable to provide long-term control of HIV. In contrast, a small number of broadly neutralizing antibodies (bnAbs) have been identified that suppress virus replication when delivered as recombinant proteins or expressed from AAV vectors. As an alternative approach for long-term production of bnAbs *in vivo*, we are using genome engineering at the constant region of the immunoglobulin heavy chain (IgH) locus to reprogram human B cells to express custom heavy-chain only antibodies (HCAbs). The HCAbs mimic a natural antibody type found in camelids and can be engineered with a variety of anti-HIV recognition domains such as VHHs, scFvs, or other protein domains. Human B cells expressing HCAbs retain critical B cell functions *in vitro*, including clonal expansion in response to antigen stimulation. We hypothesize that transplantation of HCAb-engineered autologous B cells could provide long-term HIV control, including by providing B cell memory that could be boosted over time. To test HCAb-engineered B cells as a prevention or therapy against HIV, we adapted the editing approach for the IgH locus in rhesus macaques. B cells were engineered to express anti-HIV HCAbs based on either a humanized J3 VHH domain or an optimized scFv derived from the well-characterized bnAb, PGT121. Six animals received autologous infusions of 4.5–20 × 10^4 edited cells/kg, and were immunized with HIV gp140 at weeks 0, 4, and 8 post-infusion. HCAbs in serum and edited cells were detected up to 14 weeks in 4 out of 6 animals, with one animal showing a transient increase after the week 4 booster immunization. In an attempt to improve HCAb levels, we re-transplanted the four responding animals 9 months later with B cells expressing the alternate HCAb, using 3-5.8-fold higher numbers of edited cells, and including cells with reduced time *in ex vivo* culture. In this second study, we detected higher overall levels of HCAb secretion that persisted for a longer time, but were still unable to achieve stable, long-term HCAb secretion that responded to vaccination. Interestingly, the patterns of expression in individual animals were remarkably similar from one study to the next, despite the expression of two different HCAbs. Together these data show that HCAb engineered B cells can survive and secrete HCAbs in vivo over several weeks. However, the lack of response to antigen suggests the need to further optimize *ex vivo* selection and culture conditions to better support B cell subtypes that can give rise to long-lived antibody-secreting cells and memory phenotypes *in vivo*.

433 Expandable, Functional Hepatocytes Derived from Primary Cells Enable Liver Therapeutics

Introduction
Liver disease impacts millions annually in the US, with orthotopic transplantation as the only curative option for many patients. The scarcity of donor organs underscores an urgent need for alternative therapies. Hepatocyte-based approaches hold promise due to the cells' synthetic, metabolic, and detoxifying functions, but critical barriers remain, including the lack of a scalable source of functional hepatocytes and poor engraftment. We developed a scalable PHH expansion process that preserves hepatic identity and function. By leveraging heterocellular aggregation with stromal cells, we generated cryopreserved seed constructs that maintained viability and function post-thaw. Seeds demonstrated enhanced metabolic and detoxification functions and robust engraftment across multiple sites outside the liver. Our approach addresses key limitations of hepatocyte-based therapies, offering a clinically viable platform for liver cell therapy.

Methods

We utilized PHHs from multiple donors and subjected them to our expansion protocol to yield expanded human hepatocytes (EHHs). We confirmed hepatic identity during expansion through immunofluorescent co-staining of HNF4α and albumin and bulk RNA sequencing. For in vivo studies, we injected EHHs, PHHs, and iPSC-derived hepatocytes (iHeps) into Fah$^{-/-}$Rag2$^{-/-}$Il2rg$^{-/-}$ (FRG) mice and evaluated engraftment using plasma biomarkers like human albumin. NTBC was withdrawn to assess survival and liver injury biomarkers. To generate seeds, we combined EHHs with NHDFs in suspension bioreactors and assessed function across synthesis, metabolism, and detoxification axes. Cryopreserved seeds were evaluated for viability and function post-thaw. Finally, we tested engraftment at ectopic sites, including the spleen, fat pad, and kidney capsule.

Results

Our expansion protocol enabled PHH expansion across multiple donors, with 46% achieving >20-fold expansion at passage 0 and a mean fold expansion of 4,373 by passage 1. The highest-expanding donors maintained cuboidal morphology and exceeded 2,000-fold expansion per donor. EHHs retained hepatic identity, with >99% co-expressing HNF4α and albumin, and showed no significant differences in key liver-specific genes compared to PHHs ($p > 0.05$). In the FRG model, EHHs successfully engrafted and repopulated the liver, producing 1.4 - 2.2 mg/mL human albumin and improving survival ($p = 0.02$). In contrast, iPSC derived hepatocytes did not engraft (0 mg/mL albumin) (Fig 1). To further enhance engraftment, EHHs were aggregated with NHDFs into seeds. We compared EHH seeds to PHH seeds and found comparable or superior albumin and A1AT secretion in vitro, and CYP3A4 activity showed a 5.5-fold induction upon rifampin treatment. Our cryopreservation process maintained seed stability with 90% post-thaw recovery, preserved size distribution, and comparable viability (85.0% vs. 86.3%, $p = 0.43$). To assess engraftment, we tested NHDF-seeded, fibroblast-free, and MSC-seeded constructs in NSG mice, with NHDF seeds demonstrating superior engraftment (AUC: 258 µg·day/mL vs. 48 µg·day/mL for MSC, $p <$ 1E-4). NHDF-seeded constructs successfully engrafted across extrahepatic sites, confirmed by stable albumin levels and OTC staining (Fig 2).

Conclusions

PHH expansion and aggregation into seeds address key limitations of hepatocyte-based therapies, providing a scalable and clinically viable solution to advance liver cell therapy and broaden treatment options for liver disease.

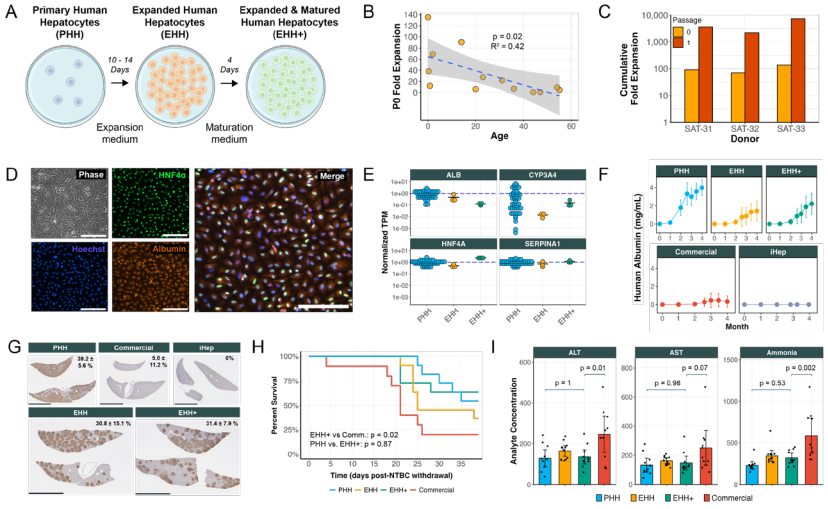

Figure 1: Primary hepatocyte expansion and maturation yield functional cell populations for therapeutic applications. (A) Illustration of hepatocyte culture, expansion, and maturation phases. (B) Correlation analysis showing a negative correlation between donor age and passage 0 (P0) fold expansion ($p = 0.02$, $R^2 = 0.42$). (C) Cell count analysis demonstrating >2,000x cumulative fold expansion with a two-passage scheme across three donor lots. (D) Imaging analysis demonstrating the characteristic cuboidal morphology of expanded hepatocytes (Phase) and robust co-expression of HNF4α (green), albumin (orange), and Hoechst (nuclei). Over 99% of the expanded hepatocytes exhibited triple positivity, confirming their hepatic identity (scale bars = 200 µm). (E) Gene expression analysis showing comparable levels of liver-specific genes (ALB, CYP3A4, HNF4A, SERPINA1) across PHH, EHH, and EHH+ samples. Each dot represents a unique donor (n = 46 for PHH, n = 3 for EHH, n = 3 for EHH+). Transcripts per million (TPM) values are normalized to the mean of the PHH group. (F) Human albumin levels in mouse plasma (mean ± 95% CI) demonstrate successful engraftment and repopulation in PHH, EHH, and EHH+ groups, with no engraftment observed in iPSC-derived hepatocytes and 'commercial' cells. (G) Liver explant staining with human fumarylacetoacetate hydrolase (FAH) confirms engraftment patterns consistent with human albumin levels (scale bar = 5 mm). Percentages within each micrograph indicate repopulation rates, quantified from FAH-stained sections (mean ± 95% CI). (H) Kaplan-Meier survival curves showing enhanced survival rates in animals receiving PHH and EHH+ cells compared to 'commercial' cells. The p-values are calculated using the log-rank test. (I) Endpoint liver function tests (ALT, AST) and plasma ammonia levels indicate reduced liver injury in PHH, EHH, and EHH+ groups compared to 'commercial' group (mean ± 95% CI). The p-values are calculated using a one-way ANOVA followed by Tukey's HSD post hoc test for pairwise comparisons. Units for ALT and AST are U/L, while the units for ammonia are µM.

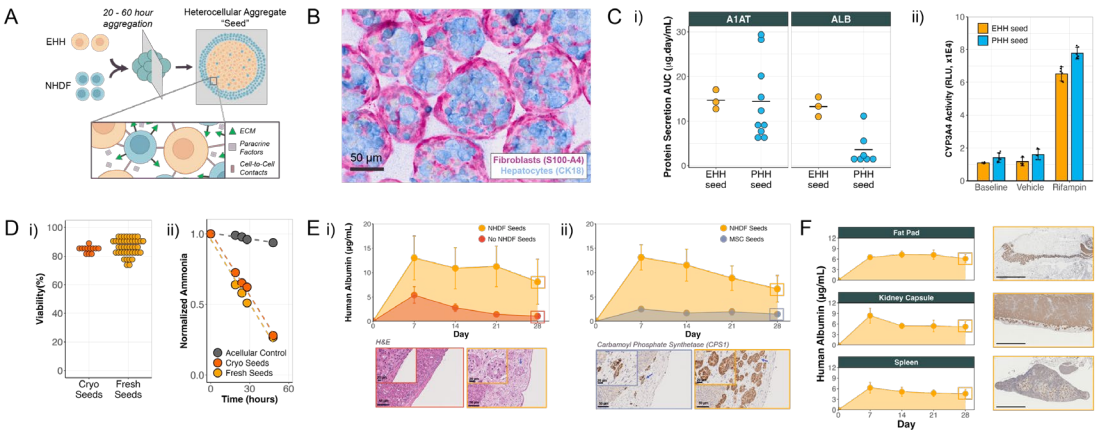

Figure 2: Expanded hepatocyte aggregation into heterocellular constructs leads to a cryopreserved drug product with enhanced functional maturation. (A) Schematic depicting the assembly of hepatocyte-fibroblast seed constructs, supported by extracellular matrix (ECM), paracrine, and cell-cell interactions. (B) Histological staining (S100-A4 for fibroblasts, CK18 for hepatocytes) highlights the integration of the two cell types within a core-shell seed structure. (C) (i) A1AT, albumin production levels (n = 3 donors for EHH seeds and n = 7-10 donors for PHH seeds, and (ii) CYP3A4 induction in EHH seeds versus PHH seed control groups, indicating comparable function to primary cells (n = 1 donor, n = 6 technical replicates). (D) Demonstrating successful cryopreservation of seeds, evidenced by comparable (i) cell viabilities (n = 12 batches for cryopreserved seeds and n = 44 batches for fresh seeds) and (ii) ammonia clearance capacity between fresh and cryopreserved seeds (ammonia values are normalized to t = 0 hours for each group). (E) Heterocellular aggregation of EHHs with dermal fibroblasts significantly enhances engraftment within the kidney capsule, as evidenced by increased plasma albumin levels (mean ± 95% CI) and histological comparisons showing reduced engraftment in (i) the absence of dermal fibroblasts or (ii) when using bone marrow-derived mesenchymal stromal cells (BM-MSCs). (F) Time-course of human albumin levels (mean ± 95% CI) and immunohistochemical analysis of ornithine transcarbamylase (OTC) across implantation sites (fat pad, kidney capsule, spleen) shows that seed constructs support stable engraftment and sustained hepatocyte activity across various extrahepatic locations (scale bar = 1 mm).

434 Curative Allogeneic Hepatocyte Transplantation without Immune Suppression

Anne Vonada[1], Leslie Wakefield[2], Craig Dorrell[3], Markus Grompe[4], Amita Tiyaboonchai[1]
[1]Oregon Health and Science University, Portland, OR, [2]OHSU, [3]Oregon Health & Science University, Portland, OR, [4]Oregon Health & Science University, Tualatin, OR

Hepatocyte transplantation is a cell therapy method with distinct advantages relative to gene therapy. One main advantage is that hepatocytes from a healthy donor can be used as a universal therapy for a multitude of genetic conditions without customization to each disease indication. However, the use of hepatocytes from an allogeneic donor requires immunosuppression. An ideal protocol for liver cell therapy would allow sustained engraftment of allogeneic cells without the need for immunosuppression. Others have reported methods to render hematopoietic and iPSC cell therapies immune stealthy by a combination of three or more genetic edits: β_2 microglobulin (*B2m*) knockout to prevent MHC class 1 presentation, Ciita knockout to prevent MHC class 2 expression, and transgenic expression of immune-inhibitory ligands to prevent NK cell responses. We have previously reported that knockout of *B2m* alone is sufficient to allow allogeneic engraftment of murine hepatocytes. This result suggests that creation of an off-the-shelf allogeneic liver-directed cell therapy product may be feasible with minimal genetic modification. Here, we report correction of two murine models of human metabolic disease: hereditary tyrosinemia type 1 (HT1) and phenylketonuria (PKU). Hepatocytes singly modified to be immune stealthy by *B2m* knockout were used and no immune suppression was needed. HT1 is a disorder resulting from a deficiency in fumarylacetoacetate hydrogenase, leading to the hepatotoxic accumulation of protein metabolites in affected hepatocytes. Congenic wild-type hepatocytes transplanted into the HT1 liver will expand in vivo as they are not susceptible to toxicity and thus have a selective advantage. We created *B2m*-deficient primary mouse hepatocytes from a wild-type donor of the C57BL/6 strain by CRISPR gene editing in vitro. When transplanted into allogeneic HT1 mice on the 129S4 strain background, *B2m*-deficient hepatocytes engrafted and expanded to repopulate the liver to >95% replacement. This corresponded with weight stabilization for over 100 days and correction of liver injury markers and amino acid levels in blood. The same result was seen when the experiment was repeated in the opposite direction, with *B2m*-knockout 129S4 hepatocytes transplanted into HT1 C57BL/6 recipients. PKU is a disorder resulting from a deficiency in phenylalanine hydroxylase, which causes increased blood phenylalanine (Phe) and neurotoxicity. Unlike HT1, PKU does not result in a selective advantage for transplanted hepatocytes. To overcome this limitation, creation of a genetic deficiency in a drug metabolism gene (*Cypor*) in hepatocytes results in a selective advantage for gene-edited transplanted cells when treated with acetaminophen (APAP). We have previously published that, in a congenic setting, transplantation and APAP selection of Cypor-deficient hepatocytes results in complete correction

of Phe levels with ~10% liver repopulation. To apply this in the allogeneic setting, we created knockouts of *Cypor* and *B2m* in wild-type cells from a 129S4 mouse using CRISPR gene editing in vitro. Following transplantation into PKU mice of the C57BL/6 background and APAP selection, this led to 15% liver repopulation with transplanted hepatocytes and a correction of blood Phe to wild-type levels. Taken together, these results indicate that *B2m*-knockout hepatocytes represent a potential off-the-shelf allogeneic cell therapy with applicability to a variety of disease indications.

Gene Therapy for Muscle Diseases

435 Recurrent Rhabdomyolysis and Fatality Following Administration of AAV Microdystrophin Gene Therapy

Michelle Lorentzos[1], Kristi Jones[2], Gina O'Grady[3], Sandra Cooper[4], Frances Evesson[5], Melanie Wong[2], Julie Crudele[6], Wui-Kwan Wong[2], Nicole Graf[7], Rhett Marchant[4], Joe Yasa[4], James Vitnell[2], Francesco Muntoni[8]
[1]Sydney Children's Hospitals Network, WESTMEAD, NSW, Australia, [2]The Sydney Children's Hospitals Network, Sydney, New South Wales, Australia, [3]Starship Child Health, Auckland, New Zealand, [4]Kids Neuroscience Centre, Kids Research, The Sydney Children's Hospitals Network, Sydney, Australia, [5]University of Sydney, Sydney, New South Wales, Australia, [6]University of Washington, Seattle, WA, [7]The Sydney Children's Hospitals Network, Sydney, Australia, [8]University College London, LONDON, United Kingdom

A 4-year-old boy with dystrophinopathy died 14 months following systemic administration of fordadistrogene movaparvovec, an AAV microdystrophin gene therapy. The discussion of his exceptional clinical course is imperative to understanding potential complications associated with gene replacement therapies.

At 3 years of age, the patient was assessed in a tertiary neuromuscular clinic. His phenotype was consistent with Duchenne muscular dystrophy with a predicted in-frame deletion of *DMD* exons 45-48.

The patient was enrolled in an early phase, open-label clinical trial and received $2x10^{14}$ vector genomes per kg of fordadistrogene movaparvovec with high-dose steroid coverage.

He presented seven weeks post gene therapy administration with his first episode of rhabdomyolysis (severe muscle pain, myoglobinuria and acute critical hyperCKaemia). Varying immune modulation regimens were trialled with minimal efficacy and the patient experienced 16 episodes of rhabdomyolysis over the following 12 months.

Despite the initial hypothesis of immune mediated myositis and consistent responses to corticosteroids acutely, there was no clear clinical, serological or tissue evidence of immune dysfunction or inflammation. Anti-dystrophin antibodies remained unremarkable. Muscle biopsy taken during a rhabdomyolysis crisis did not support an immune cause and showed significant levels of endogenous dystrophin, in keeping with the genotype. The only additional finding on genome sequencing was a heterozygous variant of uncertain significance in *DAG1*.

During the 17th episode of rhabdomyolysis, the patient experienced acute extreme hyperkalaemia and a fatal cardiac arrest, having never had elevated potassium in previous episodes. Postmortem muscle analysis demonstrated multiple areas of necrotising myopathy that appeared to have occurred at various timepoints.

The timing of the onset of clinical symptoms, consistent with the expression of the microdystrophin transgene and his subsequent clinical course presents several learnings and key questions regarding AAV gene therapy, including the implications of in frame deletion on patient selection, approaches to investigation and management of potential immune mediated adverse events and considerations of the risk versus benefit ratio for AAV gene therapy in individual patients.

436 Treatment of Myotonic Dystrophy Type 1 (DM1) by GNDM-mediated Suppression of the DMPK Gene

Keith Connolly[1], Dhruv Prasad[2], Talha Akbulut[3], Claudia Foster[3], Chanikarn Power[3], Yuanbo Qin[3], Rajakumar Mandraju[3], Seth Levy[3], Yosuke Nakashima[4], Tetsuya Yamagata[3]
[1]Modalis Therapeutics Inc., Cambridge, MA, [2]Modalis Therapeutics, Watertown, MA, [3]Modalis Therapeutics, Waltham, MA, [4]Modalis Therapeutics, Cambridge, MA

Myotonic Dystrophy Type 1 (DM1) is a neuromuscular disorder that affects over 100,000 people in the United States and Europe. The primary cause of DM1 pathology is a genetic expansion of CTG repeats in the 3' untranslated region of the DMPK gene. These expansions are believed to cause formation of DMPK mRNA aggregates that sequester and inhibit splicing factor proteins required for normal muscle function. Therapeutic treatments for DM1 have focused on the prevention or elimination of these pathogenic aggregates, though an effective treatment has not been approved for the clinic.

Modalis Therapeutics has pioneered CRISPR-based epigenetic editing, and our therapeutic platform, termed CRISPR-GNDM®, enables activation and suppression of compensatory and toxic gene expression, respectively. This platform is composed of genetic elements encoding an engineered Cas9 protein fused with a transcription modulator (GNDM) and a gRNA expression cassette, which can be packaged in a single AAV vector. Herein, we describe how CRISPR-GNDM® technology can be used to suppress the expression of DMPK mRNA for the treatment of DM1 (Figure 1). We first screened gRNAs in the regulatory region of the human DMPK gene (Figure 1a). Candidate gRNAs were varied in size to optimize potency and specificity, and, to facilitate preclinical development, they were designed to be compatible for both human and non-human primate genomes. Co-expression of GNDM and the candidate gRNAs that can suppress DMPK gene expression more than 80% in human cells were further evaluated for local specificity by measuring expression perturbation in neighboring genes. Candidate gRNAs were then tested for global gene expression alterations, allowing identification of potent and specific gRNAs as candidates for further studies (Figure 1b). Next, we tested the effect of three gRNAs for rescue of molecular phenotypes in DM1 patient-derived cells. Indeed, we found that GNDM and gRNA expression led to an almost complete removal of nuclear DMPK mRNA aggregates and reversal of aberrant splicing phenotypes (Figure 1c), which are likely the root cause of DM1 pathologies. We next optimized packaging of CRISPR-GNDM® components into an AAV vector for in vivo delivery (Figure 1d). To facilitate robust delivery to the target muscle tissue, genomes were packaged using muscle-tropic capsids. Packaged AAV genomes were also isolated and long-read sequencing approaches were used to ensure complete packaging of the CRISPR-GNDM® and gRNA components. These muscle-tropic AAVs were used to treat DMSXL mice, a mouse model for DM1, to test for in vivo potency. Treated mice showed reduced transgenic DMPK levels by >80% in the heart, and 40% to 60% DMPK suppression was achieved in all skeletal muscles tested (Figure 1e). Taken together, these results showed a promising avenue for CRISPR-GNDM® technology for treatment of DM1. Epigenetic editing holds great promise for suppressing disease-causing genes. However, its current application is limited to liver-related conditions due to the feasible access provided by non-viral particles. The CRISPR-GNDM® technology, in combination with the recently developed muscle-tropic AAV capsids, offer a promising avenue for treating various genetic muscle diseases, such as DM1.

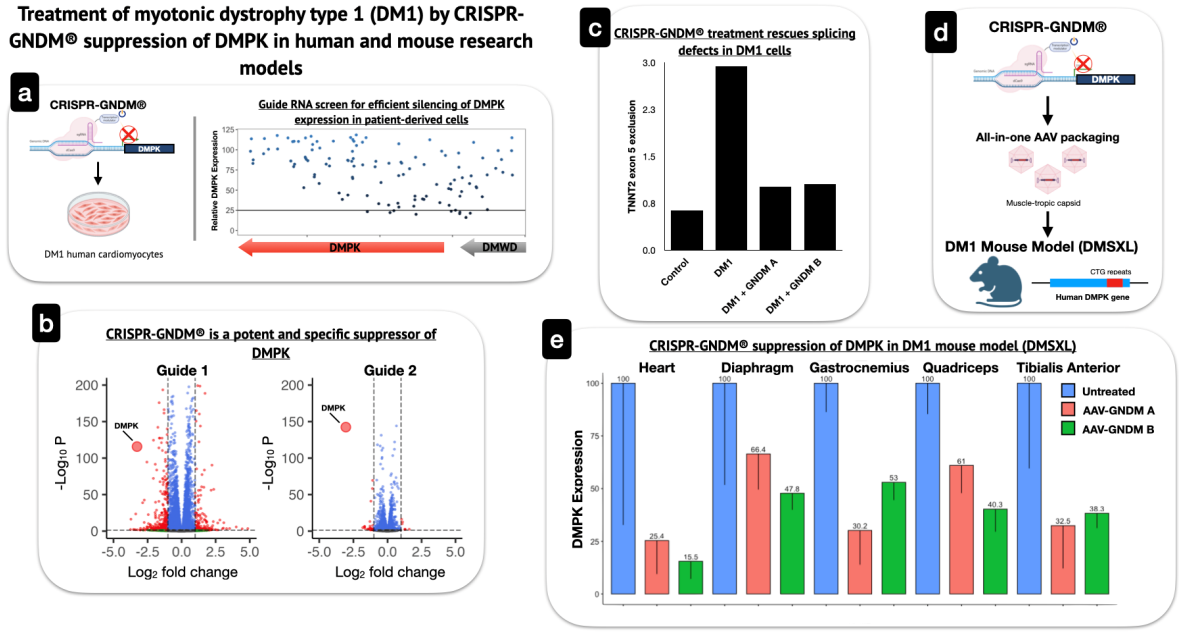

Figure 1: CRISPR-GNDM® suppression of DMPK mRNA. CRISPR-GNDM® compatible gRNAs were designed near the DMPK promoter and tested for potency **(a)** and specificity **(b)**. Candidate constructs were able to reduce splicing defects in DM1 patient-derived cells **(c)**. Muscle-tropic AAV packaging of CRISPR-GNDM® components allowed delivery **(d)** and suppression of DMPK **(e)** in target tissues of DMSXL mice.

437 A clinical DMD cytosine base editing drug

Chunyan He, Suzhou GenAssist Therapeutics Co., Ltd, Suzhou, Jiangsu, China

Duchenne muscular dystrophy (DMD) is the most severe form of muscular dystrophy affecting 1 in 3500 to 5000 boys at birth globally. Patients experience a progressive wasting of both skeletal and cardiac muscles attributable to the loss of dystrophin protein encoded by the DMD gene on chromosome Xp21. The milder symptoms in Becker muscular dystrophin (BMD) patients, who have an in-framed truncated but still functional dystrophin protein, provide a hereditary basis for exon skipping therapy against DMD.

GEN6050X is a clinical investigational drug which utilized Targeted AID-mediated Mutagenesis (TAM) cytosine base editor (CBE) to induce DMD exon 50 skipping via editing the 5'SS of human DMD IVS50. GEN6050X is an intravenous dual AAV product containing two AAV9 drug products. One encodes muscle-specific promoter-driven TAM CBE protein while the other encodes 3 copies of hE50 sgRNA targeting human DMD IVS50 5'SS. Additionally, the sgRNA vector carries a human gamma-actin gene, which can bind de novo dystrophin to rapidly facilitate costamere and dystroglycan-associated complex remodeling and provide a synergistic therapeutic effect. Single dose of GEN6050X i.v to 21-day-old humanized Dmd mouse model *Dmd*^{hE50delE51} greatly restored dystrophin protein expression in heart and skeletal muscles. Correspondingly, GEN6050X treatment significantly improved the muscle function and histopathology in both heart and skeletal muscles of *Dmd*^{hE50delE51} mice. No high-risk sgRNA-dependent or independent DNA off targets, chromosome structure variation and transcriptome off targets were found *in vitro*. In 26 weeks of cynomolgus monkey toxicology study, minimal liver toxicity was observed at Week 13 while liver toxicity was resolved at Week 26 in both 5E13vg/kg and 2E14vg/kg GEN6050X group. The Highest Non-Severely Toxic Dose (HNSTD) was identified as 2E14vg/kg in NHP. An IIT study was initiated in Aug 2024 to evaluate the safety and tolerability of GEN6050X (NCT06392724). Two patients have received 5E13vg/kg GEN6050X till Oct 2024. The first patient has finished 3-month follow-up. The safety profile is good. The first muscle biopsy will be conducted in Feb 2025. All clinical manufacture has been finished, and IND filing will be expected at the end of 2024. Collectively, GEN6050X is a safe and effective gene editing drug candidate and may provide a cure for DMD exon 50 skipping patients.

438 GNT0004, Genethon's AAV-based gene therapy for Duchenne muscular dystrophy: long-term follow-up of ambulatory boys enrolled in the dose-escalation phase of GNT-016-MDYF.

Vincent Laugel[1], Silvana De Lucia[2], Jean Davion[3], Nathalie Daniele[4], Fei Ghoul, Manon Sanz, Laurine Buscara[5], Stephanie Blaie[6], Laurent Thibaut, Marie-Astrid Sagot[7], Amanda Rivière[7], Estelle CREOFF[8], Marielle LELAIT, **Arnaud Valent**[7], Gerald Perret[9], Serge BRAUN[10], Francesco Muntoni[11]
[1]Hospital Hautepierre, Strasbourg,, Strasbourg, Bas-Rhin, France, [2]Armand Trousseau Hospital, Institute of Myology, Paris, Paris, France, [3]Hospital of Lille, Lille, Nord, France, [4]GENETHON, Evry, Essonne, France, [5]GENETHON, Evry, Essonne, [6]genethon, Evry-Courcouronnes, Essonne, France, [7]GENETHON, EVRY, SA, France, [8]GENETHON, Evry, France, France, [9]Genethon, Évry-Courcouronnes, France, France, [10]AFM TELETHON / GENETHON, EVRY, Essonne, France, [11]Imperial College London, London, United Kingdom

Duchenne muscular dystrophy (DMD) is a severe disease caused by mutations in the dystrophin gene that leads to progressive muscle degeneration and early death.

GNT0004 is a gene therapy utilizing an adeno-associated virus serotype 8 (AAV8) vector, containing a shortened, functional dystrophin gene (hMD1) under the control of the Spc5.12 promoter, which is specifically designed to target skeletal and cardiac muscle tissues. GNT0004 is being evaluated in the international, all-in-one (phase 1/2/3) clinical trial GNT-016-MDYF. This trial includes a first-in-human dose escalation (Part 1), a placebo-controlled pivotal Phase 3 (Part 2), and a long-term follow-up (Part 3). The study considers ambulatory boys with DMD, aged 6 to 10 years, who have a stable or early decline in their North Star Ambulatory Assessment (NSAA) score. Participants are on stable corticosteroid treatment and have been followed for at least 6 months in the natural history (NH) study GNT-014-MDYF. Long-term data from Part 1 patients receiving Dose 2 ($3x10^{13}$ vg/kg, selected for the pivotal phase) are presented. A comparison with an external control group from the NH study was conducted to explore clinical efficacy. Five patients were enrolled in Part 1, three of whom received Dose 2. At week 8, biopsy results showed a mean of 53% hMD1-positive fibers in the Dose 2 group. A significant decrease in serum creatine kinase (CK) levels was observed post-dose, with levels remaining low from week 8 and up to 2 years, based on available follow-up data. In the Dose 2 group, at one year, the mean creatine kinase (CK) level was 5,306 IU/L, reflecting a mean reduction of 68% compared to baseline (mean 19,175 IU/L). Clinically, functional outcomes were stable or improving, clearly differentiating from the NH progression in favor of GNT0004-treated patients across all efficacy parameters analyzed (e.g., in the Dose 2 group, a delta of +4.7 points was observed on the NSAA scale, along with an improvement of 0.1 m/s in the Stride Velocity 95th Centile (SV95C) at one year) (Figure 1). At Dose 2, no serious adverse events (SAEs) were reported, nor were there any opportunistic or severe infections. Three adverse drug reactions (ADRs) were reported, all of which were mild and resolved without complications. GNT0004 at Dose 2 was well-tolerated and provided long-term stabilization of the sarcolemma, as evidenced by the notable and sustained low levels of CK, with a clear clinical benefit compared to the natural disease progression. These effects will need to be confirmed in Part 2, the pivotal phase of GNT-016-MDYF.

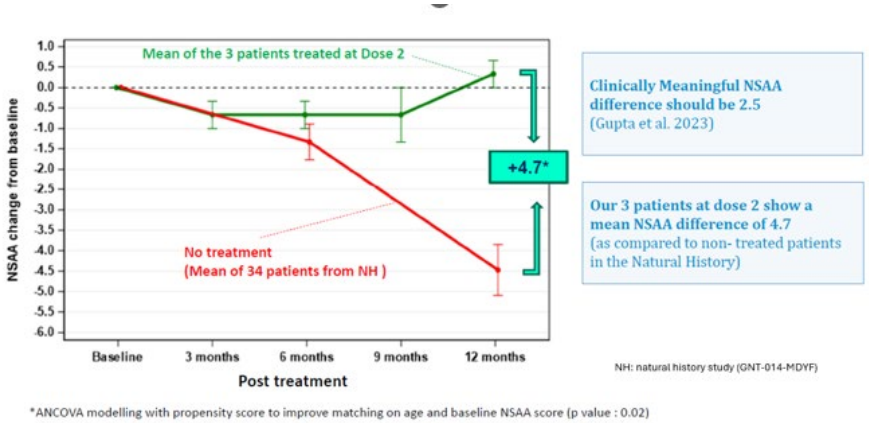

Figure 1. Early evidence of clinical benefit (Part 1, GNT-016-MDYF)

439 Determining the Effectiveness of a *FKRP/FST* Single AAV Dual Gene Vector for the Treatment of Limb Girdle Muscular Dystrophy type R9 (LGMDR9) at Different Ages

Deborah Zygmunt[1], Patricia Lam[2], Macey Bennett[3], Paul Martin[4]
[1]Abigail Wexner Research Institute at Nationwide Children's Hospital, Columbus, OH, [2]Nationwide Children's Hospital, Columbus, OH, [3]Abigail Wexner Research Institute at Nationwide Children's Hospital, [4]The Research Institute at Nationwide Children's Hospital, Columbus, OH

Limb Girdle Muscular Dystrophy Type R9 (LGMDR9) is an autosomal recessive dystroglycanopathy in which α-dystroglycan is not properly glycosylated due to loss of function mutations in the Fukutin-Related Protein (FKRP) gene. Patients with LGMDR9 have skeletal muscle damage causing weakness concentrated in the pelvic and shoulder girdles. LGMDR9 patients may also experience loss of ambulation, decreased respiratory function, and cardiomyopathy. FKRP gene replacement inhibits disease progression in animal models but will likely not recover muscle strength that has already been lost. We have developed a single AAV vector with dual FKRP/FST gene therapies to couple FKRP gene replacement with a muscle building follistatin (FST) therapy to rebuild lost muscle strength in LGMDR9 patients while simultaneously preventing subsequent disease. Here we compare the dual gene therapy to FKRP or FST therapy alone to determine the potential benefits of coupling these genes in a single AAV treatment. We also compare outcomes of treatment at different stages of the disease. $FKRP^{P448L}$ mutant mice were injected with AAV via tail vein at 4 weeks of age for necropsy at 28 weeks of age, or 52 weeks of age for necropsy at 70 weeks of age. One week before euthanasia ambulation was tested on a treadmill. Tetanic force and force drop during repeated eccentric contractions were measured in the TA muscles in situ. Using a custom automated analysis workflow, measures of muscle histopathology, including myofiber diameter, percent central nuclei, and non-muscle area were quantified. This workflow also calculated the intensity of matriglycan expression in IIH6C4-immunostained sections. Matriglycan is the glycan reduced in the disease state, thus allowing visualization of AAV-affected FKRP expression. At 28 weeks, all wild-type mice successfully completed the treadmill protocol, while ambulation time of PBS-treated $FKRP^{P448L}$ mice was reduced. Treatment with 5E+13 vg/kg rAAV.MHCK7.FKRP.pA.CMV.FST (FKRP.FST) restored ambulation to normal, while mice treated with rAAV.MHCK7.FKRP (FKRP) had some improvement. Mice treated with rAAV.CMV.FST (FST) had no improvement. FKRP.FST- and FST-treated mice showed an increase in absolute tetanic force, but only FKRP.FST-treated mice maintained a force deficit near wild type in repeated eccentric contractions. The percent myofiber central nuclei was increased in PBS-treated $FKRP^{P448L}$ mice compared to wild type, which FST treatment did not significantly improve. FKRP and FKRP.FST treatment reduced central nuclei. Myofiber diameter was significantly increased in mice treated with both FST and FKRP.FST. Immunostaining with IIH6 antibody showed significant increases in matriglycan expression in FKRPP448L mice treated with FKRP and FKRP.FST. At 70 weeks, no mice in any group were able to complete the treadmill protocol, and there was no significant difference in walking times between any of the groups. While muscles in mice treated with FKRP.FST were significantly larger than other groups, the absolute tetanic force was not improved. Myofiber diameter was only significantly increased in $FKRP^{P448L}$ mice treated with FKRP.FST. These results demonstrate the clinical usefulness of a single AAV dual gene therapy for treatment of LGMDR9 when treated at a young age. We continue to explore treatment with other promoters to optimize these effects and to dose mice at different ages and intervals to better understand the full potential of this therapy.

440 Cross-Species Comparison of AAV8, 9, rh74, and Six Myotropic AAV Variants in Murine and Canine Models Following Systemic Delivery

Matthew Burke[1], Jin Han, Xiufang Pan[1], Yongping Yue[1], Keqing Zhang[2], Lei Jin, Jun Li, Roland Herzog[3], Dongsheng Duan[4]
[1]University of Missouri, Columbia, MO, [2]University of Missouri School of Medicine, [3]IU School of Medicine, Indianapolis, IN, [4]Univeristy of Missouri, Columbia, MO

Recent advances in AAV capsid bioengineering have provided novel variants with promising performance in striated muscle and reduced liver tropism in mice and nonhuman primates. Several of the most potent muscle-directed, or "myotropic" AAV capsids feature a surface exposed Arg-Gly-Asp (RGD) motif. Myotropic AAV variants hold great promise to treat neuromuscular diseases such as Duchenne muscular dystrophy (DMD). Murine

and canine models are the most common animal models for DMD. To determine the best myotropic AAV capsids for DMD preclinical studies, we compared six myotropic AAV capsids with three AAV serotypes currently used in clinical trials (AAV8, 9, and rh74) in murine and canine models using a novel exonic barcode system. Unlike conventional short barcode systems, the exonic barcode system allows precise quantification of AAV delivery (vector genome (vg) copy number) and AAV-mediated expression (transcript copy number) by barcode-specific TaqMan qPCR. Barcoded but otherwise identical reporter AAV genomes expressing EGFP driven by the ubiquitous CAG promoter were packaged in each of the nine capsids. Barcoded AAV vectors were mixed in equal proportions and delivered intravenously to adult BL10 mice (n=10), adult mdx mice (n=10), and 1-week-old (n=3) and 1-month old (n=2) dogs. Mouse studies were performed in two different doses (3.0E+12 and 1.0E+13 vg/kg/AAV, n=5 mice/dose). Dog studies were performed using one dose (3.0E+12 vg/kg/AAV). Tissues (heart, liver, diaphragm, and various limb muscles) were collected at 1-month post-injection. DNA and mRNA were extracted. We first validated the barcode-specific TaqMan PCR by next-generation sequencing of RNA extracted from the quadriceps of BL10 mice. Linear regression analysis revealed a robust correlation between the two methods (r=0.988). Next, we quantified vg and transcript copy number in all tissues by TaqMan qPCR. In mice, we obtained consistent results from BL10 and mdx mice at both doses. Specifically, AAV8 and AAV-RGD-1 had the highest and lowest vg copy number in the liver, respectively. AAVrh74 and AAV-RGD-1 had the highest and lowest transcript copy number in the liver, respectively. AAV-RGD-3 had the highest vg copy number (in most samples) and the highest transcript copy number in cardiac and skeletal muscle. In dogs, 1-week-old and 1-month old dogs yielded consistent results. Specifically, AAV8 and AAVrh74 had the highest vg copy number and transcript copy number in the liver, respectively. Interestingly, while AAV-RGD-5 had the highest vg copy number in most samples, AAV-RGD-1 consistently yielded the highest transcript copy number in cardiac and skeletal muscle. Our results will help guide selection of the most appropriate AAV capsids for preclinical studies in murine and canine DMD models. (Supported by NIH NS90634, NS131416, and AI177600).

Engineered Immune Effector Cells for Solid Tumors

441 T cell engineering using V(D)J recombination allows tumor growth inhibition in mice

Miri Horovitz-Fried[1], Natalia Gritsenko[2], Iris Dotan[3], Ayelet Dangot[4], Carmel Pundak-Mintz[5], Daniel Nataf[5], Tal Veig[5], Lee Reicher[6], Katia Beider[7], Arnon Nagler[7], Carlo Cipriani[8], Debora Bublik[5], Daniela Cesana[9], Adi Barzel[10]

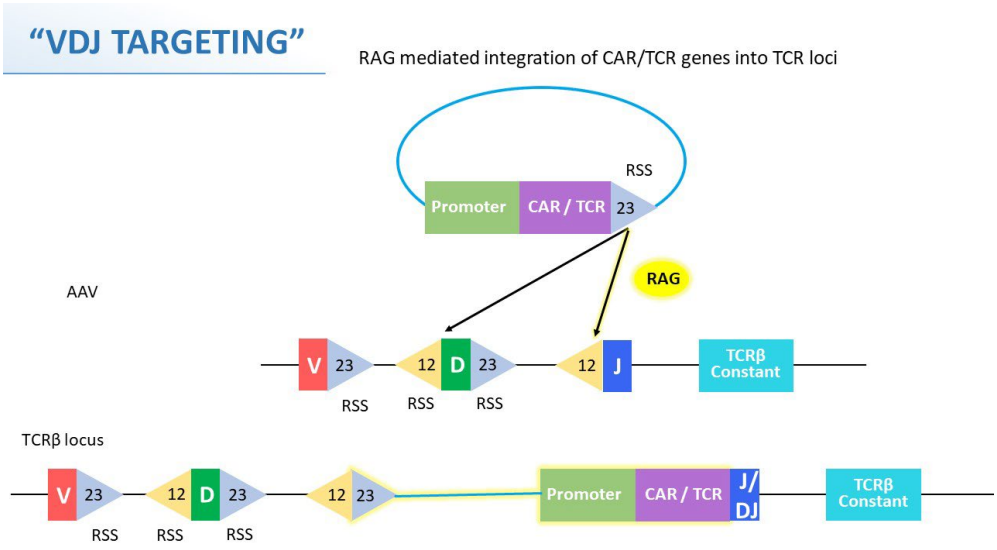
Introduction:
T cell therapies have shown clinical success in hematological malignancies, but they rely on prolonged, expensive *ex vivo* manipulations and their efficacy is hampered by early T cell exhaustion, promoted by the prolonged culturing required for the scarcely retrieved cells. We propose “VDJ targeting”: a novel immunotherapy approach targeting AAV-delivered immune genes into the genome using V(D)J recombination in developing T cells.

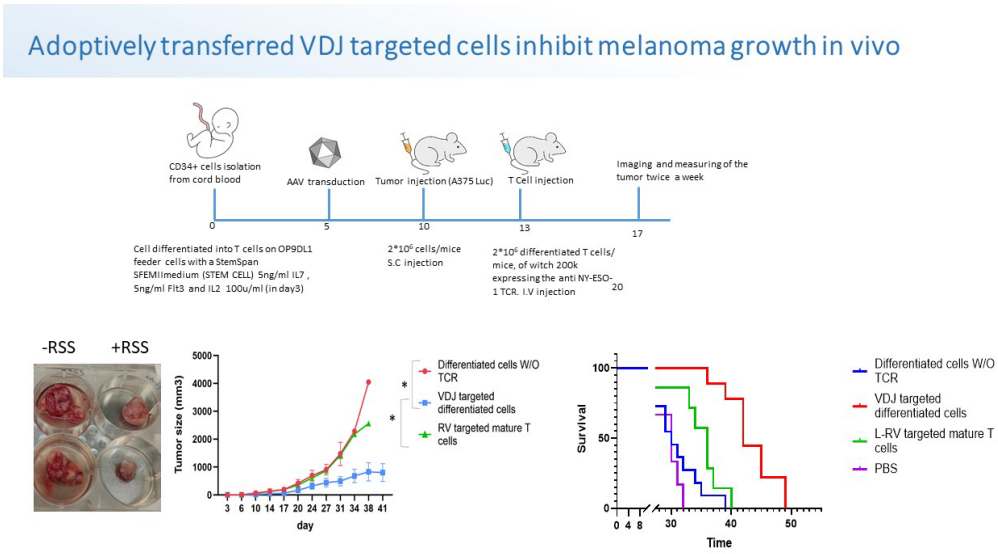
Material and methods:
We use AAV vectors coding for a transgenic TCR/CAR gene followed by a recognition signal sequence (RSS) for the recombination activating gene (RAG) complex, which is active only during T cell development) Fig 1). We targeted *ex vivo* differentiated T cells from human cord blood and bone marrow as well as from mouse bone marrow. Mouse bone marrow cells were grown on OP9DL1 feeder cells in IL-7 and FLT-3 containing medium for 5 days, and then transduced with 1e6 vector genomes per cell of an AAV-DJ vector coding for a CAR against CD19. Human cord blood or bone marrow derived HSPCs were grown on feeder cells with an SPEM-2 medium for

5 days and then transduced with a 7e5 vector genomes per cell of an AAV6 vector coding for either a CAR anti-CD19 or a TCR targeting an NY-ESO1 peptide presented on HLA-A*02.

Results and discussion:
Following transduction, mouse bone marrow-derived hematopoietic stem and progenitor cells (HSPCs) $CD3^+$ were found to express the CAR and were activated by CD19-expressing cancer cells. Similarly, human cord blood and bone marrow derived HSPCs $CD3^+$ cells successfully expressed the TCR and were activated by NY-ESO-1 expressing cancer cells. Importantly, human T cells, engineered by VDJ recombination to express the anti-NY-ESO-1 TCR, inhibited tumor growth and prolonged survival in immunodeficient mice implanted with a human NY-ESO-1^+ melanoma. Moreover, our VDJ-targeted T cells vastly outperformed conventionally engineered T cells, transduced with a lentiviral vector coding the anti-NY-ESO-1 TCR. (Fig 2)

Conclusion:
VDJ targeting produces potent naïve T cells that may be transplanted in lower numbers and have increased persistence compared to T cells engineered with state-of-the-art technologies. VDJ targeting is thus an efficient T cell engineering technology applicable in the autologous, allogeneic and *in vivo* engineering settings.





442 Sensitive HLA-independent T cell Receptors Overcome Tumor Antigen Heterogeneity in Solid Tumors

Sophie Hanina[1], Tyler Park[1], Michael Lopez[2], Vinagolu Rajasekhar[1], Jorge Mansilla-Soto[3], Sascha Haubner[4], Huiyong Zhao[1], Priyam Banerjee[5], Richard Koche[1], Pierre-Jacques Hamard[1], Zeynep Tarcan[1], Dennis Chi[1], John Healey[6], Elisa De Stanchina[6], Robert Motzer[1], Ritesh Kotecha[1], A. Ari Hakimi[1], Christina Leslie[1], Michel Sadelain[7]
[1]Memorial Sloan Kettering Cancer Center, New York, NY, [2]Columbia University Medical Center - New York, NY, Brentwood, NY, [3]H Lee Moffitt Cancer Center and Research Institute, Tampa, FL, [4]Columbia University Irving Medical Center, New York, NY, [5]Rockefeller University, New York, NY, [6]Memorial Sloan Kettering Cancer Center, [7]Columbia Initiative in Cell Engineering and Therapy, Columbia University Irving Medical Center, New York

Background:
Overcoming tumor antigen heterogeneity in solid tumors is a major challenge for cancer immunotherapies including chimeric antigen receptor (CAR) T cells. Unlike CD19 for B-cell malignancies(1), no target with pan-cellular expression in solid tumors and absence in normal vital cells has been identified(2–5). Thus, CAR T cell efficacy in solid tumors is compromised by heterogeneous target antigen expression and unacceptable toxicities in normal tissues. CD70 is a potential candidate due to its aberrant upregulation in a variety of solid tumors(6–12), whilst its physiological expression is restricted to immune cell subsets(13–15). However, CD70 expression in tumors is typically heterogeneous, with some tumor cells exhibiting high expression and others, often accounting for the majority of tumor cells, appearing low/negative(16–19). Not surprisingly, the clinical responses obtained in patients who were treated with CD70-targeted CAR T cells have been modest(20, 21).

Methods:
We developed patient-derived xenograft (PDX) orthotopic models of clear cell renal cell carcinoma (ccRCC), high grade serous ovarian carcinoma (HGSOC), and pancreatic ductal adenocarcinoma (PDAC), which recapitulate CD70 tumoral antigen heterogeneity observed in patients, to study the limitations of CD70-CAR T therapy. Flow cytometry, confocal/STED microscopy, transcriptional and chromatin accessibility profiling were used to characterize CD70 expression in PDX models. CD70 transcriptional and chromatin accessibility in ccRCC primary patient tumors were assessed by 10x Multiome. CD70 gene scores as a proxy of targetable expression were determined using a single cell atlas(22) of chromatin accessibility for 222 cell types adult normal human tissues.

Results:
We found that within CD70-heterogeneous tumors, apparent CD70-negative tumor cells do in fact express low levels of CD70, though not at a level high enough to be eliminated by conventional CAR T cells. Thus, we could leverage this pan-tumor cell expression of CD70 by adapting CAR design for more sensitive detection by using an HLA-independent T cell (HIT) receptor, which substitutes the antigen recognition domain of a T cell receptor with that of a CAR, thereby co-opting the downstream signaling of the CD3 complex. Unlike CD70-CAR T cells, CD70-HIT T cells completely eradicated CD70-heterogeneous tumor models of renal cell carcinoma, ovarian and pancreatic cancer. We further found that the CD70 locus in apparent-negative tumor cells is epigenetically silenced by Enhancer of Zeste Homolog 2 (EZH2)-mediated histone H3 lysine 27 trimethylation (H3K27me3), still allowing for very low expression. Given conventional methods are at their limit of sensitivity to detect very low CD70 expression, we harnessed chromatin accessibility to identify low-level but HIT targetable expression in our PDX models. We could then infer an epigenetic signature that predicted low-level expression in a cohort of primary patient samples and limited expression in normal tissues.

Conclusions:
Our works opens up the possibility that tumors comprising only a fraction of CD70-positive tumor cells may express CD70 in all or most tumor cells, and therefore may be targeted by a sensitive immunotherapy such as CD70-HIT T cells. Our findings position CD70 as a pan-cancer target and provide a model for uncovering additional stealth targets amenable to sensitive immunotherapeutic approaches in the face of apparent tumor antigen hete

443 IL-18 Metabolically Reprograms CAR-expressing Natural Killer T Cells and Enhancing Antitumor Activity Against Neuroblastoma

Gabriel Barragan Bravo[1], David de la Cerda[1], Elisa Landoni[2], Kshiti Dholakia[1], Piotr Humeniuk[1], Linjie Guo[3], Gengwen Tian[1], Xin Xu[1], Azlann Arnett[1], Che-Hsing Li[1], Xavier Rios[1], Amy Courtney[1], Gianpietro Dotti[4], Leonid Metelitsa[3]
[1]Baylor College of Medicine, Houston, TX, [2]UNC Lineberger Comprehensive Cancer Center, Chapel Hill, NC, [3]Baylor College of Medicine, Houston, TX [4]UNC Lineberger Cancer Center, Chapel Hill, NC

Invariant natural killer T cells (NKTs) have intrinsic anti-tumor properties that make them promising candidates for CAR-based immunotherapies. GD2-specific CAR (GD2.CAR) NKTs co-expressing IL-15 have shown promising results in patients with relapsed/refractory neuroblastoma (NB, NCT03294954). We also recently demonstrated that CAR-NKTs armed with a membrane-bound form of the proinflammatory cytokine IL-12 further enhance CAR-NKT antitumor activity without added toxicity in mice. Herein, we hypothesized that co-expressing IL-18, another proinflammatory cytokine, alone or with IL15 would further boost the therapeutic potential of CAR-NKTs. To test this hypothesis, we generated retroviral constructs expressing IL-15 and/or IL-18 with the inducible caspase 9 (iC9) safety switch and co-expressed them in human NKTs with a GD2.CAR using dual retroviral transduction. After repeated *in vitro* tumor challenge, IL-18 or IL-15.IL-18 co-expressing GD2.CAR-NKT retained higher functionality (proliferation, cytotoxicity, and cytokine secretion) compared with IL-15 or no cytokine controls. Transcriptomic analyses showed significant enrichment of lymphocyte activation as well as proliferation- and metabolism-related processes in IL-18-expressing CAR-NKTs when compared to IL-15 expressing cells. Targeted metabolomics analyses revealed that GD2.CAR/IL-18 NKTs produced significantly elevated levels of glycolysis (glyceraldehyde 3-phosphate and phosphoenolpyruvate) and citric acid cycle (cis-aconitate and succinate) metabolites compared to GD2.CAR/IL-15 NKTs. *In vivo*, GD2.CAR-NKTs co-expressing IL-18 or IL-15.IL-18 demonstrated superior antitumor activity in a xenograft model of metastatic NB, though mice treated with IL-15.IL-18 cells showed signs of toxicity, accompanied by an increased CAR-NKT expansion in blood and elevation of human cytokine concentrations in serum. These effects were ameliorated by triggering the iC9 safety switch. In contrast, mice treated with GD2.CAR/IL-18 cells did not show signs of toxicity and survived significantly longer than all other groups ($p<0.001$). These results provide support for using IL-18 for clinical development of the next generation of cytokine-armed CAR-NKT cancer immunotherapy.

444 Adoptive cell therapy with genetically engineered T cells for Epithelial Ovarian Cancer

MARIA CHIARA MAFFIA[1], Eliana Ruggiero[2], Elena Tassi[3], Anna Simioni[4], Zulma Magnani[5], Alice Bergamini, Giorgia Mangili, Giorgio Candotti, Luca Bocciolone, Giacomo Pavone, Emanuela Rabaiotti[1], Carlotta Sabini[1], Massimo Candiani[1], Miriam Sant'Angelo[1], Claudio Doglioni[5], Birgit Schultes[6], Aaron Prodeus[6], Chiara Bonini[7]
[1]Ospedale San Raffaele, MILANO, Milano, Italy, [2]Ospedale San Raffaele, Milano, Italy, [3]IRCCS Ospedale San Raffaele Scientific institute, Milano, Milano, Italy, [4]Università San Raffaele, Milano, Milano, Italy, [5]San Raffaele Scientific Institute, Milan, Italy, [6]Intellia Therapeutics, Cambridge, MA, [7]Università Vita Salute San Raffaele, Milan, Italy

The limited clinical benefits of immunotherapy in epithelial ovarian cancer (EOC) highlight the urgent need for innovative treatment strategies to improve outcomes. This study employs a dual-pronged strategy to promote EOC immunotherapy, focusing on tumor-specific T-cell receptor (TCR)-redirected T cells.

Cancer cells derived from the ascites of EOC patients were analyzed to determine the expression of selected tumor-associated antigens (Mesothelin, HER2, NY-ESO-1, and WT1) and membrane-bound inhibitory receptor (IR) ligands. These antigens, critical for tumor progression, were selected as targets for our T cell products. Using TCR gene editing techniques, T cells with HLA-A*02:01-restricted receptors specific for these antigens were generated, drawing from both our laboratory's library and relevant literature. In clinically relevant models using patient ascites-derived primary cultures (PC), T cells engineered with WT1-, MSLN-, and NY-ESO-1-specific TCRs exhibited potent and specific elimination of target cells, with WT1-TCR emerging as the most promising candidate for further development. We hypothesized that disrupting IR pathways could shield engineered T cells from

immunosuppression within the tumor microenvironment (TME), thereby enhancing their therapeutic efficacy. To explore this, T-cell products were engineered to express WT1-TCR while incorporating gene disruptions of specific IRs (TIM3 or LAG3) (IR_{KO} WT1-TCR). To assess the impact of IR disruption on anti-tumor efficacy, WT1-TCR and IR_{KO} WT1-TCR T cells were tested against WT1-positive, HLA-A*02:01-positive PC and tumor organoids (PDOs). Evaluations included cytokine secretion, T cell activation using flow cytometry, and apoptosis measured via Incucyte live cell imaging. IR_{KO} WT1-TCR T cells demonstrated superior cytotoxicity compared to WT1-TCR T cells, with $TIM3_{KO}$ WT1-TCR showing heightened effectiveness against tumor cells expressing TIM3 ligands. Co-culture experiments with PDOs further confirmed the increased induction of apoptosis mediated by $TIM3_{KO}$ and $LAG3_{KO}$ WT1-TCR T cells compared to their IR-competent counterparts. Finally, in vivo experiments were conducted to monitor tumor growth using IVIS live imaging and ultrasound. Considering the results of in vitro experiments, our primary focus was to analyze the efficacy of $TIM3_{KO}$ WT1-TCR T cells in comparison to $IR_{COMPETENT}$ WT1-TCR T cells. Both T cell products significantly inhibited tumor growth compared to control groups that received no T cell therapy. Ultrasound imaging revealed a reduction in the size of abdominal masses, with $TIM3_{KO}$ WT1-TCR treatment achieving the most pronounced decrease in mass diameter, particularly in the intermediate size range (4-8 mm).

These findings support the hypothesis that TIM3 knockout enhances the anti-tumor efficacy of WT1-TCR-engineered T cells for EOC.

445 Multimodal T cell immunotherapy CAR-TA (B7-H3 CAR and PRAME Tumor Antigen cells) for pediatric brain and solid tumor patients

Kajal Chaudhry[1], Samantha Murphy[2], Nana Owusu-Tieku[3], Chase Mccann[4], Haili Lang[5], Conrad Russell Cruz[6], Patrick Hanley[6], Amy Hont[7], Catherine Bollard[8]*
[1]Children's National Medical Center: Children's National Hospital, Washington, DC, [2]Children's National Hospital, Alexandria, VA, [3]Children's National Hospital, Washington DC, Washington, DC, [4]Children's National Hospital, Washington, DC, [5]Children's National Medical Center, Derwood, MD, [6]Children's National Medical Center, Washington, DC, [7]Washington, DC, [8]The George Washington University, Washington, DC.
**Corresponding Author*

While tumor-associated-antigen cytotoxic T-cell (TAA-T) therapies have shown a robust safety profile and a signal of efficacy in pediatric patients with solid tumors, previous clinical trials did not observe any objective clinical responses. This lack of response is likely due to potent tumor-induced immune evasion tactics. We hypothesized that gene engineering TAA-T cells with a dominant negative TGF-b receptor (DNR) and combinatorial approaches with a B7H3-targeted chimeric antigen receptor (CAR) T-cell product would overcome multiple tumor immune evasion strategies including: antigen loss (targeting intracellular and extracellular antigens with TAA-T and CAR-T), MHC downregulation (with a CAR) and cytokine (TGF-B) suppression. Hence our objective was to evaluate whether this multimodal therapeutic (CAR-TA) would elicit enhanced anti-tumor responses in vitro compared with the single modalities.

Methods:
We engineered T cell products (CAR-TA) from two donors that comprised B7H3 CAR-engineered T-cell and DNR-transduced TAA-T products at a 1:1 ratio. Experiments were performed with the combined product, single products, and untransduced (Un-T) and/or non-specific T cells as controls.

Results/Discussion:
We first demonstrated that TAAT targeting PRAME elicited potent anti-tumor activity against tumor cells (36.92% ± 1.07% target lysis at 48 hours of co-culture). In contrast, the co-culture of tumor cells with non-specific T-cells resulted in tumor proliferation by 24.33% ± 3.109% (Mean tumor growth difference TAAT vs Un-T: 67.76% ± 6.94%; p=0.0006). We also confirmed that DNR-transduced T-cell products obviated TGF-b downstream signaling in vitro (addition of exogenous TGF-b to DNR-T cells resulted in only modest upregulation of 38.65% ±8.56% in pSMAD2/3 expression compared to 66.25% ± 4.03% upregulation in Un-T). We next determined whether CAR-T-cells upregulate MHC on tumor cells. Using D556 medulloblastoma tumor lines, we observed an upregulation of MHCI (57.4% increase when co-cultured with CAR-T cells compared to 14% when co-cultured

with Un-T cells). We also observed a 90.3% increase in MHCII expression in D556 tumor cells when cultured with CAR-T cell compared to a 17.4% in the Un-T cell co-culture condition. Finally, we determined whether the combined CAR-T & DNR-TAAT product (CAR-TA) elicited enhanced anti-tumor activity in vitro compared to the individual components alone. CAR-TA products elicited 53.52% ± 5.86% clearance of HLA-matched tumor significantly higher than 36.13% ± 2.87% for CAR-T alone (p=0.0099) within 21 hrs of co-culture while we observed no tumor clearance for DNR-TAAT, TAAT or Un-T alone. Additionally, we observed antigen spreading when CAR-TA products (n=2) were repeatedly stimulated with HLA-matched tumor cell lines (Ewing Sarcoma and D556 cells). Specifically, after repeated stimulation, CAR-TA products targeting PRAME and B7H3, promoted expansion of T cells targeting other tumor associated antigens (MAGE3/4, WT1, Survivin, and SSX2) in vitro. This "antigen-spreading response" was not observed with the CAR-T or TAA-T or non-specific T cell products. In summary, we have developed a novel T-cell therapy (CAR-TA) that addresses multiple tumor immune evasion strategies in a single product for the treatment of children with relapsed/refractory solid tumors. We are currently testing more donors and will validate this T-cell therapeutic in preclinical in-vivo models before translating to clinical trials

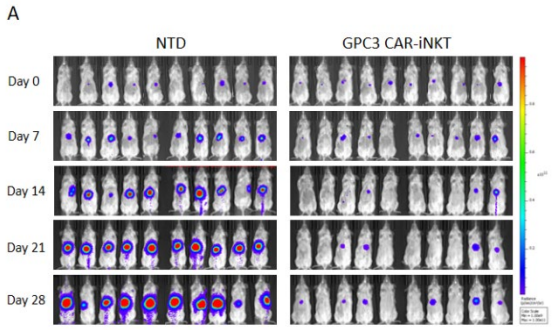
**Corresponding Author*

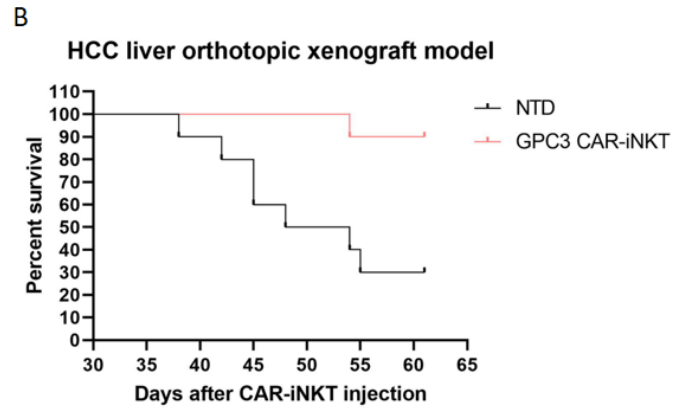
Background:
Hepatocellular carcinoma (HCC) is recognized as the sixth most common malignant tumor worldwide, with a five-year survival rate of only 22%. Invariant natural killer T (iNKT) cells, a rare subset of innate-like immune cells, exhibit unique features: they kill targets by co-expressing natural killer (NK) lineage receptors and a semi-invariantly rearranged T cell receptor (iTCR) that recognizes glycolipids presented by CD1d, modulating the immune microenvironment in both TCR-dependent and independent manners, all without the risk of Graft versus Host Disease (GvHD).

Methods:
Allogeneic CAR-iNKT cells were generated from peripheral blood mononuclear cells (PBMCs) that derived from healthy donors. After purification, iNKT cells were genetically engineered to express a third-generation CAR targeting GPC3 through genome editing. The CAR construct also includes secretory components IL-15 and IL-21 to increase the proportion of memory cell subsets and enhance anti-tumor activities. The CAR template was integrated into the β2M locus through ribonucleoprotein (RNP)-based CRISPR/Cas editing. HCC intraperitoneal (IP) xenograft model, HCC liver orthotopic xenograft model and xenogenic GvHD model engrafted with human CD3- PBMCs in B-NDG mice were employed to evaluate the efficacy and the safety of cell products.

Results:
The CAR-iNKT cells demonstrated a final product purity averaging around 95%, β2M knockout efficiency around 90%, and CAR expression varying between 60% and 90%. In the IP xenograft model, three weeks after the injection of CAR-iNKT cells, complete clearance of tumor cells was observed and there were no signs of tumor recurrence up to the seventh week (week 3: NTD vs. GPC3 CAR-iNKT, $P < 0.001$; week 7: NTD vs. GPC3 CAR-iNKT, $P < 0.001$). Additionally, CAR-iNKT cell product showed superior anti-tumor activity in liver orthotopic xenograft model (Fig. A & Fig. B): treatment with GPC3 CAR-iNKT cells significantly suppressed tumor growth (week 6: NTD vs. GPC3 CAR-iNKT, $P < 0.001$) and extended the survival time of mice (medium survival: NTD, 51 days; GPC3 CAR-iNKT, undefined). At last, iNKT cells demonstrated higher safety compared to T cells in the xenogenic GvHD model, with almost no infiltration of human T cells in vital organs (week 6: histological analyses of lung, liver and spleen) and cytokine secretion levels similar to those in the negative control group (ELISA analyses of IFN-γ production from week 6: T cells vs. iNKT cells, $P < 0.001$; PBS vs. iNKT cells, $P = 0.4263$; PBS vs. T cells, $P < 0.001$).

Conclusions:
Our GPC3 CAR-iNKT cells demonstrated exceptional anti-hepatocellular carcinoma potency in mouse models. These findings strongly support the continued preclinical and clinical development of this innovative cell therapy for patients with relapsed or refractory hepatocellular carcinoma.





447 ADI-270, an Armored Allogeneic Anti-CD70 CAR γδ T Cell Therapy, Demonstrates Robust CAR-Directed and -Independent Anti-Tumor Activity Against Hematologic and Solid Tumor Models Compared to Conventional CAR αβ T Cells

Melinda Au[1], Yogendra Verma[1], Nitya Ramadoss[1], Gauri Lamture[1], Yvan Chanthery[1], Michael Salum[1], Jie Zhang[1], Alexander Teague[1], Pranav Murthy[1], Morgan Smith-Boeck[1], Ramandeep Kaur[1], Smitha Gundurao[1], Aruna Azameera[1], Jonathan Wong[1], Elizabeth Speltz[1], Katherine Wang[1], Marissa Herrman[1], Arun Bhat[1], Shon Green[1], Kevin Nishimoto[1], Blake Aftab[1]
[1]*Adicet Bio, Redwood City, CA*

Background
CAR-engineered γδ T cells represent a promising therapeutic platform for addressing the challenges associated with the treatment of refractory solid and hematologic malignancies. Unlike conventional αβ T cells, γδ T cells possess both innate and adaptive immunity that enable targeting and killing of tumors in an MHC-independent manner. Together with their natural tissue tropism and anti-tumor activity, γδ T cells have the potential to effectively traffic to tumor sites and reduce antigen escape. To leverage these distinct effector functions of γδ T cells, we developed ADI-270, a novel allogeneic γδ T cell product engineered with a third-generation CAR targeting CD70 using its natural receptor (CD27). In addition, ADI-270 is armored with a dominant negative TGFβ receptor (dnTGFβRII) to resist the immunosuppressive effects present in solid tumor microenvironments.

Methods
Vδ1 T cells engineered to express an anti-CD70 CAR and dnTGFβRII were generated from healthy donor human PBMCs. To expand on the potential of ADI-270 to treat solid and hematologic malignancies, we compared the functionality of ADI-270 to clinically relevant benchmarks representing allogeneic scFv-based anti-CD70 αβ CAR T cell approaches. Cell-based in vitro assays were used to evaluate the cytotoxicity of these products against hematologic and solid tumor cell lines with low to negative CD70 expression. CITE-seq was used to profile gene

and surface expression levels from single ADI-270 cells. Human tumor xenografts in NSG mice were used to assess in vivo trafficking and efficacy of ADI-270 against various cancer models.

Results
ADI-270 exhibited potent in vitro cytotoxicity against a panel of cancer cell lines expressing varying levels of CD70 and maintained effector function in the presence of TGFβ1. In contrast to αβ CAR T cell benchmarks, ADI-270 was associated with increased potency against low CD70 expressing cells and in $CD70^{+/-}$ cell mixtures, and demonstrated activity against $CD70^{-}$ tumor cells, suggesting both CAR-directed and CAR-independent killing mechanisms. Despite this increased potency, ADI-270 demonstrated a lower inflammatory cytokine profile when co-cultured with $CD70^{+}$ cells compared to αβ CAR T benchmarks. Additionally, ADI-270 showed rapid tumor homing in vivo and significantly inhibited tumor growth in all $CD70^{+}$ human tumor xenografts tested, including those with low and heterogenous CD70 expression. Analysis of transcriptomes obtained by scRNAseq (10X) using UMAP dimensionality reduction and cluster analysis confirmed ADI-270 cell population homogeneity.

Conclusion
These results support the enhanced potency of ADI-270 against multiple CD70-low to CD70-negative-expressing tumor cell models compared to relevant scFv-based αβ CAR T cell benchmarks. The anti-tumor activity of ADI-270, which involves CAR-directed and CAR-independent mechanisms against both hematologic and solid tumors, highlights the potential to overcome the challenges associated with antigen heterogeneity. These favorable preclinical efficacy and safety characteristics support the clinical development of ADI-270 to address multiple $CD70^{+}$ cancers.

Lipid Nanoparticles III

448 Multi-Objective Machine Learning-Guided Optimization of mRNA Lipid Nanoparticles for Cell-Selective Transfection

Statement of Purpose:
Lipid nanoparticles (LNPs) have emerged as promising non-viral gene delivery vectors. However, they require extensive development across a vast and complex design space—a task where heuristic and brute-force screening approaches have proven inefficient. Here, we build and deploy a machine learning (ML)-guided iterative screening platform to accelerate the optimization of LNP compositions for cell-selective gene delivery. Starting from sparse initial library screens of LNP transfection against on-target and off-target cell types, we select, train, and refine high-performing ML models that predict transfection outcomes as a function of LNP design features. We then leverage multi-objective (MO) search algorithms and experimental validation to create a build-test-learn-design iterative loop that generates de novo LNP compositions aimed at *maximizing on-target and minimizing off-target transfection*. Our *in silico*-guided approach accelerates the design of LNP formulations with high cell-selective transfection properties.

Methods:
Human RAMOS-B cell line, a canonically hard-to-transfect cell type, were chosen as the *on-target* cells. Human THP-1 monocytes were used as the *off-target* cells. To generate a foundational LNP library for initial ML training, we utilized DLin-MC3-DMA as the ionizable lipid (IL), along with cholesterol, DMG-PEG2000 (PEG), and DSPC as the helper phospholipid (HL). We varied the combined molar percentage of IL and HL, the molar ratio of cholesterol to PEG, the molar ratio of IL to HL, and the molar ratio of lipids to mRNA. 81 LNP formulations were screened separately in each cell for *in vitro* transfection efficiency using luciferase reporter mRNA. For each cell, a panel of tree-based, linear, and partial least squares regression ML models were trained to predict LNP transfection and were optimized using the scikit-learn Python package (1.2.2). For each cycle of MO iterative optimization, our

Gaussian process-based Bayesian Optimization via Scikit-Optimize (0.9.0), fed with our best Ramos B and THP-1 ML models, suggested 12 *de novo* LNPs that maximized Ramos B and minimized THP-1 transfection, utilizing expected improvement (EI) to balance exploration and exploitation of the design space.

Results:
LNPs designed to maximize transfection in *on-target* B cells and minimize *off-target* THP-1 cells (B-skewed LNPs) were developed through an ML-guided Build-Test-Learn-Design loop (Fig. 1A). After just 4 iterations, B-skewed LNPs achieved 50-fold higher transfection in B cells (RLU~ e^7) compared to THP-1 cells (RLU~ e^4) at the same dose (Fig. 1B). In a 50:50 coculture of B and THP-1 cells treated with GFP encoding mRNA LNPs, we observed that our B cell-skewed LNPs transfected 60% of B cells and were highly selective for B cells, with over 75% of the transfected cells being B cells (Fig. 2A–C). Compared to commercially available and top grid-search LNPs, B-skewed LNPs achieved significantly higher GFP expression per cell and a higher percentage of GFP+ cells in the B cell population than in the THP-1 cell population (Fig. 2D, E).

Conclusion:
An iterative automated ML-guided platform was developed to accelerate the MO optimization of LNPs. Our platform successfully identifies LNPs that achieve better and more selective transfection in *on-target* B cells than in *off-target* THP-1 cells *in vitro* compared to both conventional grid-searched and commercially available LNPs.

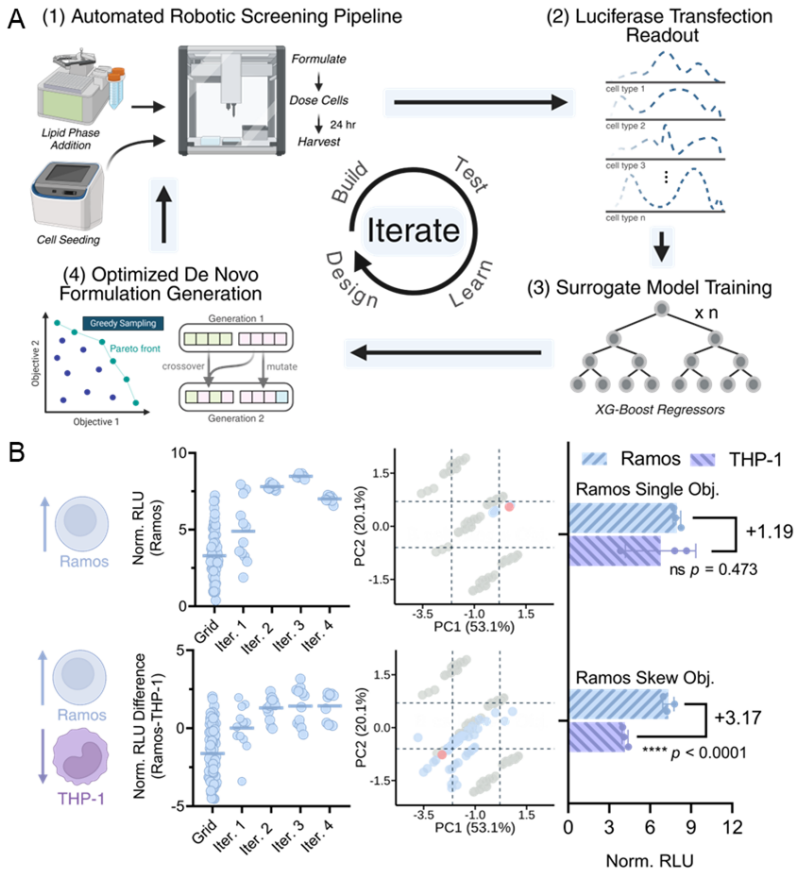

Figure 1. Iterative strategy for machine learning (ML)-driven optimization of cell-type selective mRNA-LNPs. (A) The Design-Build-Test-Learn loop for iterative screening. (B) Four rounds of iterative screening were to either only optimize Ramos B cell transfection alone (single objective) or Ramos B cell selective transfection by maximizing the difference between Ramos B and THP-1 cell transfections (multi-objective).

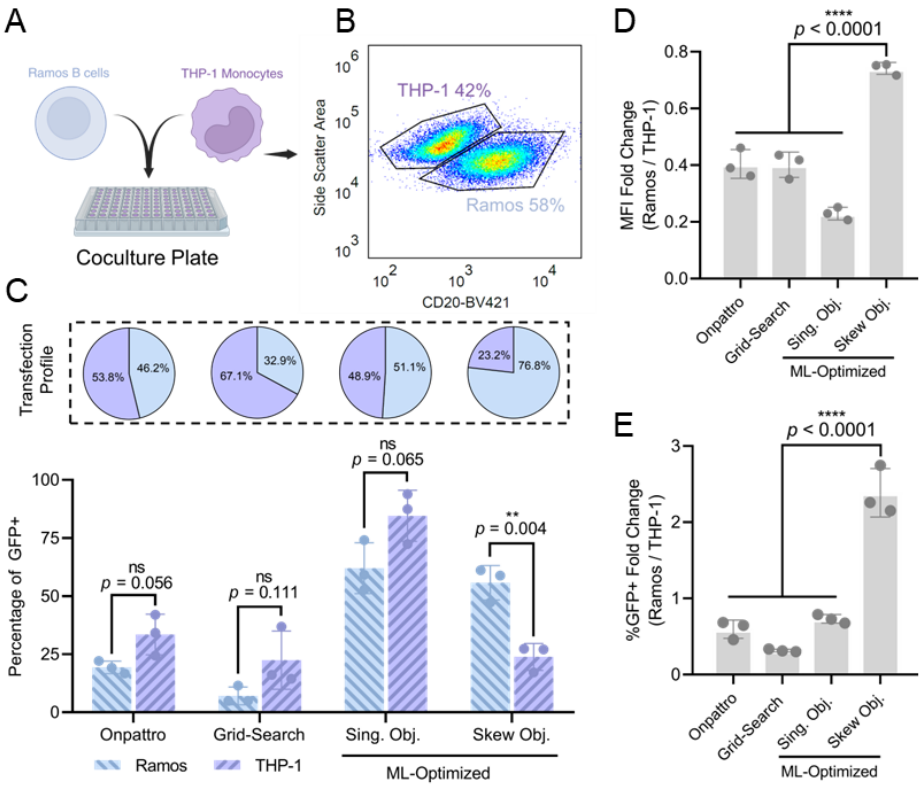

Figure 2. A) Ramos B cells and THP-1 monocytes were seeded together at equal cell concentration and treated with 1) Onpattro formulation, 2) the top grid-searched LNP, and the top ML-optimized LNPs from 3) single objective and 4) dual-objective skewed approaches. LNPs were formulated using GFP reporter mRNA. **B)** Representative flow gating of cell populations in the coculture via CD20 stain. **C)** Overall transfection profile and GFP+ percentage of Ramos and THP-1 cells after 24 hours. **D–E)** Transfection fold change (Ramos/THP-1) in both GFP+ percentage and mean fluorescence intensity (MFI) of transfected cells.

449 Gene Replacement Therapy for Pulmonary Lymphangioleiomyomatosis

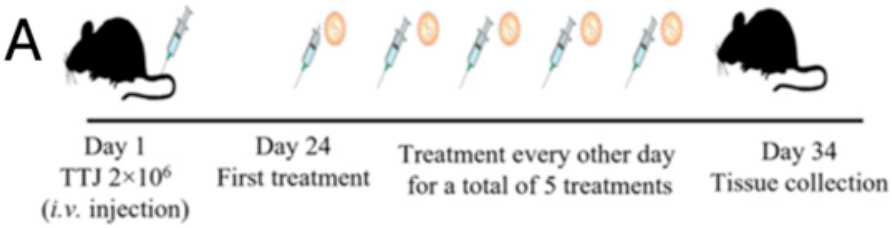
Yan Tang, Brigham and Women's Hospital, Boston, MA

Pulmonary lymphangioleiomyomatosis (LAM) is a rare genetic lung disease that is characterized by aberrant mTORC1 hyperactivity caused by inactivating mutations of the tumor suppressor genes tuberous sclerosis complex 1 or 2 (Tsc1 or Tsc2) genes. Rapamycin (sirolimus), an mTORC1 inhibitor, is FDA-approved for the treatment of LAM, although ongoing loss of lung function and need for lung transplantation can still occur. Thus, there is an urgent need to develop new therapies for the treatment of LAM. Given that LAM is caused by mutations in a single gene, either TSC1 or TSC2 (more common), gene replacement therapy presents a potential therapeutic strategy by introducing functional TSC1 or TSC2 genes into affected cells. Achieving safe and effective systemic delivery of messenger RNA (mRNA) to specific organs and cells in vivo remains a significant challenge in the development of mRNA-based gene replacement therapy. To date, systemically administered lipid nanoparticles (LNPs) co-formulated with mRNA have predominantly targeted the liver and spleen. Through a library screening approach, we identified the specific modifications on the functional lipids and route LNP to the lung. Furthermore, by modifying the head-group structure of LNPs, different pulmonary cell types can be precisely targeted.

In this study, we demonstrate the efficacy of LNP-based mRNA therapy in a preclinical model of LAM. Our lung-targeting LNPs efficiently delivers mouse Tsc2 mRNA to restore TSC2 tumor suppressor function in tumor nodules,

resulting in a significant reduction in tumor burden. This research establishes mRNA-loaded LNPs as a promising therapeutic platform for the treatment of LAM.

Fig. 1. Lung-targeting LNP. (B) Representative *ex vivo* image of tdTomato fluorescence in edited Ai14 mouse organs.



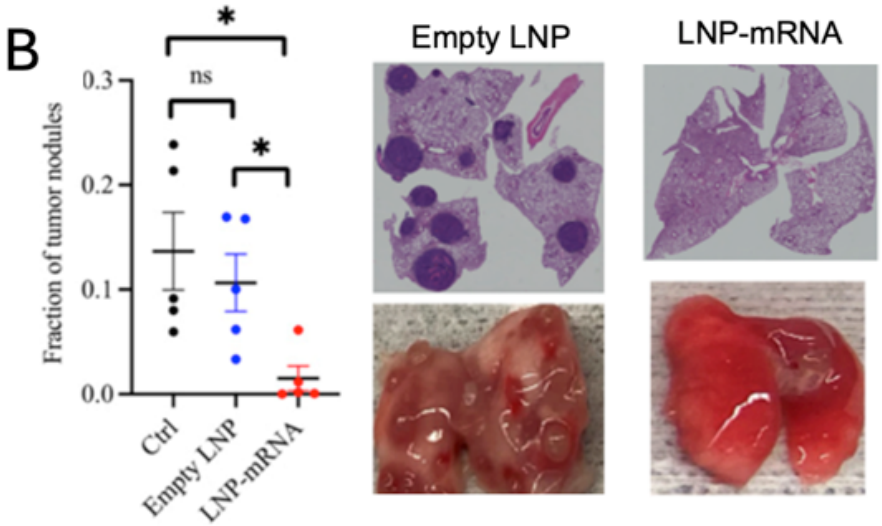


Fig. 2 Therapeutic effect of Tsc2 mRNA-loaded LNP in antitumor growth. (A) Treatment design. Syngeneic C57BL/6J mice were tail vein injected with 2 million Tsc2-deficient cells to form tumor nodules in the lung. On day 24 after tumor cell inoculation, mice were randomly assigned to three groups: untreated control, empty LNP treatment, and LNP-mTsc2 treatment. Mice were treated every other day for a total of five times (n = 5). (B) Fraction of tumor nodules per lung in the three treatment groups (left), and representative H&E and image of lungs collected from empty LNP and LNP-mTsc2 treated groups (right).

450 Ionizable Lipid Development and LNP Formulation Optimization Enable the Use of RNA Gene Writers for *In Vivo* Treatment of Genetic Diseases in Liver

Gun Su Han[1], Xiaowei He[1], Mengxia Sun[1], Sharvik Shirodkar[1], Gulen Tonga[2], Ada Cid[1], Meghna Tupal[1], Ana Maria Castillo[1], James Rottman[2], Jeff An[2], Erin Spofford[1], Zuhua Cai[1], Thomas Colace[1], Matthew Kim[1], Michael Hahn[1], Philip Zakas[1], Befikadu Mekonnen[2], Minhyoung Lee[1], Aayush Rastogi[1], Yiru Jin[1], Joseph Milano[1], Morgan Stilgenbauer[1], Zsanett Jancso[1], Annie Chivatakarn[1], Gang Sun[2], William Salomon[1], Bill Querbes[1], Michael Holmes[3], Hari Pujar[1], Jane Wang[1]*, Apiwat Wangweerawong[1]*
[1]Tessera Therapeutics, Somerville, MA, [2]Tessera Therapeutics, Inc., [3]Tessera Therapeutics, Cambridge, MA
**Corresponding Author*

In recent years, RNA-encapsulated lipid nanoparticles (LNPs) have been developed into FDA-approved siRNA therapeutics and prophylactic mRNA vaccines. Yet, while several clinical trials are in progress, the application of LNPs for *in vivo* gene editing remains a challenge, owing to both the development of complex payloads which are harder to deliver at a therapeutically relevant dose and the need for well-tolerated lipid compositions. To address this challenge and enable *in vivo* gene editing for genetic diseases in the liver via an intravenous (IV) administration, we have developed novel ionizable lipids (iLipids) and LNPs to safely and efficiently deliver RNA Gene Writers to hepatocytes.

We applied our RNA Gene Writer to address phenylketonuria (PKU) by editing the human *PAH* gene. To achieve high levels of gene writing along with a desirable safety profile, we screened known iLipids and LNP formulations, while independently developing our own proprietary iLipid library and LNP formulations in parallel. We designed, synthesized, and tested novel iLipids from various cores to identify multiple promising core structures, then optimized iLipid structures for each genus via iterative screenings based on our structure-activity relationship (SAR) model. We successfully discovered a highly potent proprietary iLipid and LNP formulation that delivered RNA Gene Writer to an estimated average of 54% of hepatocytes in a *hPAH* transgenic mouse model, while exhibiting a desirable tolerability profile based on serum chemistry assessments. Upon evaluating potent LNP formulations, we observed that the iLipid identity has a large influence on the safety profiles of the resulting LNPs.

We also applied our RNA Gene Writer to edit the disease-causing PiZ allele in Alpha-1 antitrypsin deficiency (AATD) through a similar iLipid discovery campaign. After screening our own iLipids and LNP formulations, we identified multiple proprietary iLipids and LNP formulations that exceeded the anticipated curative levels of *SERPINA1* gene correction in the hepatocytes of a transgenic mouse model (*hSERPINA1*$^{E366K/E366K}$ mouse). We then further optimized a lead LNP formulation that achieved an estimated average of 79% of hepatocytes in non-human primates (NHP) after a single IV administration, resulting in the production of 84% of the correct mRNA transcripts on average. When we evaluated the biodistribution profile of our RNA-LNP formulation in *hSERPINA1*$^{E366K/E366K}$ mice at a saturating dose, we observed high levels of intended gene editing in the liver and minimal to undetectable levels of gene editing in off-target tissues, suggesting a high degree of liver tropism of our LNP formulation. We further evaluated the safety of the LNP formulation by investigating its pharmacokinetics (PK) profile, where we observed that the LNP formulation was cleared from the blood quickly relative to other LNPs and iLipids. This profile of high on-target delivery and relatively rapid clearance is highly desirable for further translation to the clinic.

Taken together, we demonstrated that our LNP delivery platform can be applied to efficiently and safely correct different genes in hepatocytes at therapeutically relevant doses with a single IV administration. Through successful iLipid discovery campaigns and LNP formulation optimizations, we enabled the use of our RNA Gene Writers for editing multiple disease targets in liver hepatocytes.

451 Targeted Gene Editing in the Fetal Brain via In Utero Intracerebroventricular LNP mRNA Delivery

Rosa Choi[1], Marco Carpenter[2], Nicole Kus[1], Ana Maria Dumitru[3], William Johnston[1], Andrew Mudreac[1], Alanis Perez[1], Hooda Said[1], Mohamad-Gabriel Alameh[4], William Peranteau[1]*

Many genetic disorders affecting the central nervous system (CNS) begin during prenatal development, resulting in permanent damage. CRISPR-Cas9 gene editing has the potential to provide a one-time curative treatment, provided the therapeutic agents reach the appropriate cells and tissues. Despite the potential, obstacles like the blood-brain barrier (BBB) and the limited regenerative ability of neurons have slowed the advancement of therapies aimed at the CNS. While non-viral ionizable lipid nanoparticles (LNPs) are recognized for their safety and effectiveness in mRNA delivery to the liver, data on the cell-type-specific biodistribution throughout the CNS following ICV administration are limited. Fetal gene editing via ICV administration addresses disease processes before they manifest and leverages the distinctive biological characteristics of the developing fetus to enhance therapeutic delivery to the brain. To optimize fetal ICV mRNA delivery to neurons, we evaluated three different LNP formulations containing CRE recombinase mRNA in a GFP reporter mouse model. To quantify mRNA delivery, GFP expression was analyzed in neurons, endothelial cells, and microglia in the cortex, cerebellum, and spinal cord via flow cytometry. Among the tested formulations, one LNP (LNP2) demonstrated notable efficiency in delivering mRNA to endothelial cells (~80%), macrophages (~15%), and neurons (~35%) in fetal recipients when compared to negligible mRNA delivery observed in postnatal recipients. Similar results were observed in the cerebellum and spinal cord. Together, these results indicated that the fetal environment provides unique conditions that enhance the uptake and distribution of LNP-delivered mRNA in the CNS. Building on these findings, we quantified the differential binding of LNP2 to proteins commonly found in cerebrospinal fluid, which provided insights into strategies for enhancing brain-specific drug delivery. Finally, we used LNP2 to conduct CNS gene editing in a mouse model of Friedreich Ataxia (FRDA). To this end, we delivered SpCas9 mRNA and single guide RNA (sgRNA) targeting the mutation via ICV at the 14th gestational day. We observed low levels of gene editing in the brain of FRDA fetal recipients, and no quantifiable editing in the postnatal recipients. These preliminary results highlight the feasibility of in utero gene therapy to address the genetic basis of FRDA and provide a foundation for further exploration. Overall, this study highlights the potential of leveraging fetal biology to optimize LNP-mRNA delivery for CNS-targeted therapies, paving the way for innovative in utero treatments for neurological disorders.

452 Multi-stage-mixing to create a core-then-shell structure improves DNA-loaded lipid nanoparticles' transfection by orders of magnitude

Jia Nong[1], Xijing Gong[2], Quang Minh Dang[3], Vladimir Muzykantov[4], Jacob Myerson[2], Zhicheng Wang, Jacob Brenner[2]
[1]University of Pennsylvania, Philadelphia, PA, [2]University of Pennsylvania, [3]University of Pennsylvania, Wayne, PA, [4]Philadelphia, PA

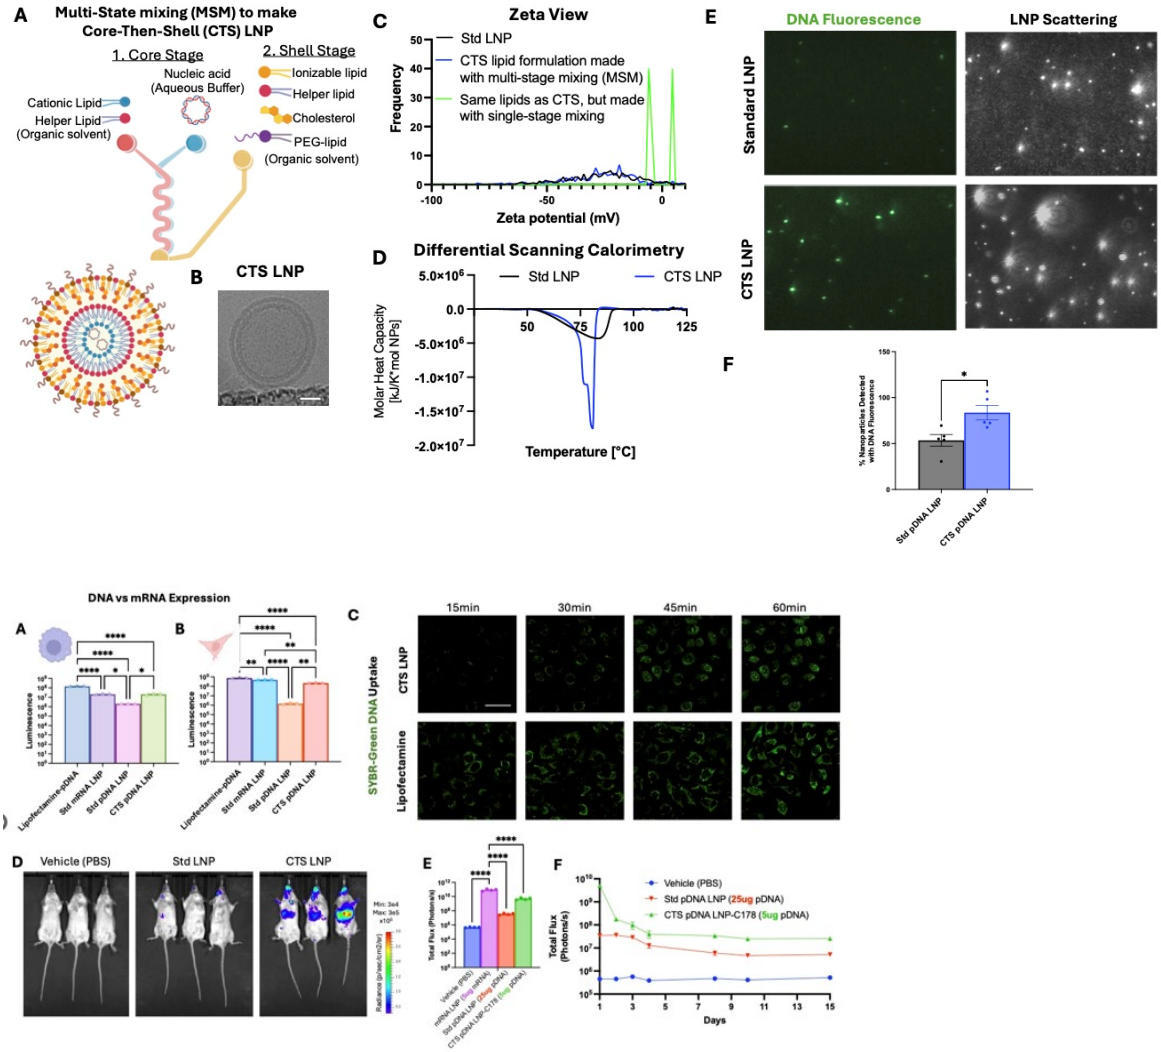
DNA-loaded lipid nanoparticles (LNPs) offer unique advantages for treating chronic diseases, including months-long expression and cell-type-specific targeting through genetic promoters. However, their clinical translation has been limited by poor protein expression levels that are orders of magnitude lower than mRNA LNPs. Here, we introduce multi-stage mixing (MSM) microfluidics to create core-then-shell (CTS) structured DNA LNPs that dramatically improve transfection efficiency. In MSM synthesis, DNA is first mixed with cationic and zwitterionic lipids to form a compact core, which is then immediately encapsulated by standard LNP lipids before aggregation can occur, forming a stabilizing shell (**Fig 1A**).

Physical characterization reveals that CTS LNPs possess a distinct architecture from conventional LNPs that are produced by rapid mixing aqueous phase containing nucleic acids and organic phase containing lipid mixture. Cryo-electron microscopy shows a well-defined central region with two distinct outer shells, contrasting with standard LNPs' amorphous structure (**Fig 1B**). Single-particle zeta potential measurements show similar zeta distribution of CTS LNPs vs. standard LNPs (**Fig 1C**). Differential scanning calorimetry confirms the unique internal organization of CTS LNPs (**Fig 1D**). Notably, CTS LNPs exhibit two sharp thermal transitions (75°C and 85°C) versus one broad transition in standard LNPs, indicating more ordered structural domains. Nanoparticle tracking analysis demonstrates superior nucleic acid loading, with 83% of CTS LNPs containing detectable DNA compared to 53% of standard LNPs (**Fig 1E-F**).

In vitro studies show that CTS dramatically improves DNA transfection efficiency. CTS LNPs achieve >10-fold higher expression than standard LNPs in RAW macrophages (**Fig 2A**) and ~150-fold higher in HeLa cells (**Fig 2B**), reaching levels comparable to mRNA LNPs. The delivery of DNA into nucleus by CTS LNPs is on a very similar time course to that of Lipofectamine (**Fig 2C**). The enhancement extends to traditionally hard-to-transfect primary cells, with CTS LNPs outperforming the gold standard Lipofectamine in mouse embryonic fibroblasts and primary cortical neurons.

In vivo, CTS DNA LNPs demonstrate remarkable improvements in both efficiency and safety. When co-loaded with the STING inhibitor C-178, CTS DNA LNPs reduce DNA induced mortality to from 100% to 0%, and achieve peak expression levels approaching those of mRNA LNPs but with sustained expression over months rather than hours. Notably, this is accomplished with a 5-fold lower DNA dose compared to standard LNPs while eliminating toxicity concerns (**Fig D-F**).

This work advances both materials science and therapeutic applications by demonstrating how microfluidic control over nanoparticle assembly kinetics can access otherwise unattainable particle architectures. The development of CTS DNA LNPs represents a significant step toward realizing the potential of DNA-based therapeutics for chronic diseases, offering the unprecedented combination of high expression levels, sustained duration, and cell-type specificity in a single delivery system. This innovation opens new possibilities for treating numerous common chronic diseases where current genetic medicine tools face limitations.



Vector Product Engineering, Development and Manufacturing (excluding AAV)

453 Optimization of Cell Expansion Phase Parameters for a Cost-Effective Lentiviral Vector Perfusion Process

Marta Arrizabalaga Cascallana[1]*, Parameswari Singh[2], Holger Laux[3], Qasim Rafiq[4]

Impact/Novelty
This pioneering study optimizes cell expansion phase conditions to enhance the efficiency of lentiviral vector (LVV) production via perfusion process, employing a Design of Experiments (DoE) methodology.

Introduction
The demand for high-quality, high-yield LVV production processes is growing rapidly. Perfusion technology emerges as a promising solution, offering reduced processing time, enhanced vector quality and lower costs. Despite its potential, the establishment of an effective perfusion process remains underexplored, particularly in the cell expansion phase. A typical perfusion process comprises two phases: the cell expansion phase, aimed at achieving a target cell density, followed by a steady-state production phase. While existing literature predominantly focuses on optimizing the production phase, this study addresses the overlooked potential of optimizing the cell expansion phase. By refining key parameters in this phase, we ensure the entry of high-quality, productive cells into the production phase, while minimizing media consumption and reducing process time.

Methods
A DoE approach was employed to investigate the interactions amongst three critical parameters: batch duration, seeding cell density, and induction reagent concentration. A three-level factorial design was used and analyzed with JMP 18 software. Inducible producer HEK293T cells, adapted for serum-free, suspension growth, were employed for LVV production. A total of 29 experimental runs were conducted in shake flasks under pseudo-perfusion conditions through daily centrifugation over 8-11 days. Optimal conditions identified through the DoE were subsequently validated in benchtop stirred-tank reactors using an ultrasonic cell retention device under fully continuous perfusion conditions.

Results and discussion
Our findings indicate that a lower induction reagent concentration in the N-1 shake flask led to earlier induction, reducing cell growth due to VSV-G cytotoxicity but enhancing early cell productivity. Additionally, the timing of perfusion initiation, in conjunction with appropriate seeding cell density, proved critical. Premature initiation of perfusion could hinder cell growth, while delayed initiation could result in glucose depletion and reduced cell productivity. Principal Component Analysis (PCA), conducted using DoE software and Python, provided deeper insights into the interactions between cell expansion parameters and their impact on key responses such as cell growth rate, specific productivity, expansion phase duration, glucose consumption, and space-time yield. By optimizing these parameters, we achieved higher cell productivity, reduced media consumption, and a shorter overall process time, ensuring the health and productivity of cells entering the production phase. This optimization was successfully validated in benchtop stirred-tank reactors, demonstrating a significant improvement in perfusion efficiency and cost reduction.

Conclusion
This study underscores the critical importance of optimizing the cell expansion phase in LVV perfusion manufacturing. By fine-tuning key parameters, we enhanced process efficiency, reduced media usage, and shortened processing time, thereby laying the foundation for more cost-effective and scalable LVV production.

454 Advancing Lentiviral Vector Manufacturing: a Platform for Commercial Cell Therapy Success

Bojiao Yin[1], Jimmy Xin[2], Chyan-Jang Lee[3], Nicholas Redmond[4], Briana Orlando[4], Nhi Tran[4], Christine Beaudry[5], Emily Sinclair[1], Arianna Spooner[4], Michael Giffin[4], Debaditya Bhattacharya[4], Mercedes Segura Gally[1]
[1]ElevateBio, Waltham, MA, [2]Elevate Bio, East Weymouth, MA, [3]Elevate Bio, Waltham, MA, [4]ElevateBio, Waltham, [5]ElevateBio - Waltham, MA, Waltham, MA

The demand for efficient strategies to advance lentiviral vector (LV)-based therapies from early development to commercialization is growing. LVs are efficient tools for delivering genetic material to cells and are widely used in *ex vivo* cell therapy clinical trials, but their commercial success depends on robust, well-characterized LV manufacturing processes. We have previously reported the development and scale-up of a transient transfection, suspension culture-based LV production process that consistently achieves upstream infectious titers exceeding 1E8 TU/mL and purified final titers of 1E9 TU/mL, with particle-to-infectious titer ratios below 200 and 2–3 log reductions in residual DNAs and host cell proteins (HCPs). These outcomes were demonstrated using TCR (NYESO) and CD19 CAR model cargos and have since supported clinical manufacturing of additional cargo constructs.

GMP manufacturing data demonstrates the platform's scalability, with a single batch capable of producing enough vector to treat up to several hundred patients, depending on titer, transduced cell numbers, and MOI dosing. Process development studies investigated the expanded operational ranges for parameters such as buffer pH in chromatography, cell density, plasmid quantities during transfection, and in-process hold times, to enhance process flexibility. Additionally, a GMP-compliant HEK 293 working cell bank (WCB) was established, demonstrating comparability to the master cell bank (MCB). To accelerate commercial readiness, a 2L scale-down model (SDM) was evaluated across multiple LV products to mirror the 25L production scale used in process development (for Tox-grade material) and GMP manufacturing (for clinical material). A Quality Target Product Profile (QTPP) with product-independent quality criteria for ex vivo applications was established, along with risk assessments for Critical Quality Attributes (CQAs), raw materials, and process parameters, providing a foundation for process characterization. This comprehensive approach integrates robust process design, clinical insights, and risk-based analysis, providing a clear pathway for commercializing LV-based therapies.

455 Serum Free Suspension HEK293 Cells Stably Expressing Gag/Pol /Rev /VSVG for Efficient Production of Lentiviral Vectors

Glenda Dickson[1], Ruby Quartey-Papafio[2], NAHID ZAREIAN, David Darling[3], Farzin Farzaneh[4]
[1]ViroCell Biologics, 12-18 Theobalds Road, London, WC1X 8SL, UK, LONDON, London, United Kingdom, [2]ViroCell Biologics, London, London, United Kingdom, [3]ViroCell Biologics, London, Greater London, United Kingdom, [4]King's College London, London, United Kingdom

Several groups have generated serum free suspension HEK293T cells with regulated expression of the integrated helper plasmids. The same is not true of the HEK293 parent cells without the SV40 Large T antigen. Anticipating future regulatory requirements that may include avoidance of bovine serum, Large T antigen, and antibiotics, we have developed a new lenti producer cell line with tightly regulated expression of VSVG.

First, HEK293 cells were selected based on their ability to proliferate as suspension adapted serum-free cells. Promising oligoclonal cells were further adapted to highly efficient proliferation in serum free suspension culture. This was followed by screening for transfection efficiency and efficient production of LV after transfection with the vector and helper plasmids (4 plasmids). The most promising of these oligoclonal populations of serum-free suspension cells also proliferate rapidly in adherent culture and can readily transit between a suspension and an adherent phenotype.

The most efficiently transfectable suspension populations were expanded adherently and transfected to express stable Gag/Pol and Rev in a single step. To achieve this, Gag/Pol encoding pMDL.RRE was linearized and paired

with a novel Rev/Puromycin construct. The linearization provided cohesive ends that were compatible with the linear pMDL.RRE. Different Gag/Pol to Rev ratios were concatemerized and transfected into the serum-free suspension HEK293 cells. Selection of these cells in low concentration of puromycin enabled the isolation of a mixed population of cells that stably expressed a broad range of different levels and ratios of Gag/Pol and Rev. This original population was used to sort cells with the optimum levels of Rev expression. This population was used in turn used to identify individual clones of cells able to support the production of high titre lenti by transient transfection of plasmids encoding VSVG and the vector. These clones were further modified with a tightly regulated and inhibitable VSVG cassette. The new cells grew in the presence of appropriate inhibitors to regulate both Protease and VSVG toxicity. Following the removal of Protease and VSVG inhibitors, infectious LV could be readily produced by transfection of the vector plasmid. This strategy, based on the expression of optimised levels and ratios of Gag/Pol and Rev, in combination with a tightly regulated VSVG, which is rapidly degraded in the absence of a small molecule stabilizer, allows the generation of stable LV producer cells. Clonal populations of stable, high-titre, producer cells are now being characterised.

Data presented here supports our hypothesis that we could generate a stably expressed Gag/Pol/ Rev, partnered with a novel regulated VSVG. The VSVG can be constitutively expressed based on the addition of the desired inducer and removal/dilution of the stability molecule. The resulting vector is non-infectious until the "stop signal" is removed and the protein is stabilised. This cell line combines the flexibility of suspension or adherent culture, with Stable Gag/Pol, Rev, and a tightly regulated VSVG expression.

456 A to Z of replication-competent free adenovirus production from gene to manufacturing process intensification

Emilie Gateau[1], Solène Arnoult[2], Sylvain Fauquenoy[3], Tiago Albano[4], Cedric Meeus[3], Simon Paquet[3], Dmitrii Sorokin[4], David Mainwaring[5], Amita Kala[5], Byron Rees[5], Vasily Medvedev[4], **Hanna Lesch[6]***

**Corresponding Author*

Adenoviral vectors are versatile tools used for their high transduction efficiency, immunogenic properties and easy manufacturing across various applications. Non-replicating adenoviruses are widely used in gene therapy and vaccination, delivering therapeutic genes without the risk of viral replication. However, safety concerns remain regarding unintended recombination and creation of replication-competent adenoviruses (RCA). This study examines the intensified production of non-replicating adenoviruses using CAP® cells (Cytiva's amniocyte production cells), a suspension-adapted human cell line engineered for efficient and safe viral vector manufacturing.

Transfection conditions of the adenovirus cosmid vector were optimized to generate adenovirus seed stock in suspension CAP cells. To accelerate screening, we developed a rapid identification method using flow cytometry, initially with a GFP reporter gene and later extended to the therapeutic gene of interest. We achieved a transfection efficiency of 21% and a virus yield of 1.93×10^9 VG/flask surpassing our 1×10^5 VG/flask needed for clonal selection.

To ensure correct gene insertion, we used standard plaque picking for adherent HEK293 cells. For suspension CAP cells, we developed a cloning method using limited dilution in plate format to ensure single viral particle infection per well (0.1 ifu/well) and screening the clones by infecting CAP and adherent HEK293 cells analyzed by qPCR and cytopathic effect, respectively. . Selected clones were then expanded under optimized conditions over multiple generations and tested for RCA absence.

With the virus seed, we established a scalable production process. Optimization of key parameters—including cell density at infection (CDI), multiplicity of infection (MOI), and medium exchange strategies—significantly improved adenovirus yields. Perfusion-based fed-batch systems were evaluated to sustain cell viability and productivity, increasing the final yield.

We tested two perfusion-enabled bioreactor technologies: the iCELLis nano fixed-bed bioreactor and the BioBlu 1c stirred-tank bioreactor connected to an ATF system. The perfusion rates were studied measuring key metabolites, such as glucose consumption. This approach increased cell density and led to at least a 5-fold improvement in titer compared to an optimized batch process.

These results highlight CAP cells as a versatile and efficient platform for adenovirus production across different upstream technologies, particularly in meeting the growing demand for gene therapy and vaccine manufacturing. The intensified adenovirus production process using CAP cells represents a major advancement in bioprocessing, offering a scalable, high-yield, and RCA-free platform.

457 Establishing a Versatile Platform for Intensified Lentiviral Vector Manufacturing

Chris Brown[1], Yeonji Kim[2], Charles Hill[3], Keen Chung[4], Jing Zhu[1], Xiaojun Liu[1]*
[1]ReciBioPharm, Watertown, MA, [2]Boxborough, MA, [3]Repligen, Waltham, MA, [4]Repligen Corporation, Waltham, MA

Lentiviral vectors (LVVs) have become important tools in cell and gene therapy, valued for their ability to efficiently modify both dividing and non-dividing cell types. This, combined with their ability to integrate into the host genome for long-term expression, have made LVVs increasingly attractive for treating a wide range of diseases. However, current LVV production methods face significant challenges, including low titers, limited scalability, and high manufacturing costs – leading to a high cost of goods (COGs) and limiting adoption of these vectors. Through this work, we aim to develop a flexible, intensified LVV manufacturing process by systematically evaluating key process parameters and implementing effective process intensification strategies such as TFDF perfusion to improve LVV production performance.

In this work, we first evaluated LVV production via transient transfection in suspension at a small scale to develop a baseline production platform. This entailed the screening of several commercial LVV production systems, and the selection of the system which performed best on the basis of LVV functional titer and quality. We further refined the packaging plasmid system used, and transfection conditions were optimized to increase LVV productivity, resulting in a 10-fold increase in functional titer. This optimized process was then successfully scaled to 2L benchtop bioreactors, maintaining comparably high productivity to the small-scale runs, with titers exceeding 2.0x108 transduction units per milliliter (TU/mL).

Further, process intensification was achieved through the implementation of Repligen's Tangential Flow Depth Filtration (TFDF) technology. TFDF combines both tangential flow and depth filtration principles through the use of a tubular depth filter with a 2-5 µm pore size operated in tangential flow mode. Use of this system resulted in a greater than 3-fold increase in cell density at time of transfection, increasing from 4.0x106 cells/mL in our batch process to over 13.0x106 cells/mL in perfusion while maintaining high cell viability. TFDF operation also enabled the continuous harvest of LVV for the duration of the study while retaining cells and cell debris within the bioreactor volume. Overall, this intensified process resulted in a significant increase in yield compared to our non-intensified process, with total titers harvested from the 2L perfusion bioreactor exceeding 1.9x1012 TU. Space yield in the bioreactor increased more than 4-fold from 2.0x108 TU/mLBR in batch operation to nearly 9.0x108 TU/mLBR in TFDF-mode operation, indicating an increase in cell-specific LVV production. This intensified process demonstrates significant potential to improve access to high-quality lentiviral vectors, allowing for equivalent LVV production at smaller scales and potentially obviating the need to scale beyond 200L, thereby reducing overall manufacturing costs and time. Future work will focus on further optimization of the TFDF perfusion process and its integration with downstream purification to develop a fully continuous LVV manufacturing platform.

458 Efficient and Scalable Chromatographic Purification of Clinically Relevant Lentiviral Vectors

Alicia Powers[1], Oluwadara Bewaji[2], Vijay Dasari[3], Timothy Lockey[1], Frank Fazio[3]
[1]St. Jude Children's Research Hospital, Memphis, Tennessee, [2]St. Jude Children's Research Hospital, Bartlett, TN, [3]St. Jude Children's Research Hospital, Memphis, TN

Lentiviral vectors are an important tool in gene and cell therapy due to their ability to transduce both dividing and nondividing cells. However, manufacturing challenges hamper the application of these vectors, particularly due to the lack of an efficient, scalable purification method. Historically, yields of over 50% have been achieved using a 5 mL Mustang Q membrane, but this yield decreases to 10-15% when a larger Mustang Q membrane is used for purification of lentiviral vector produced from suspension cells in serum free media. In this work, we compare chromatographic purification methods for a clinically relevant lentiviral vector including a Sartobind D membrane, Capto DEAE, and tangential flow filtration (TFF) to increase the load over a 5 mL Mustang Q membrane. We also compare differences in yield when using a process development focused AKTA Avant or a GMP appropriate AKTA Ready 450.

A 5L shake flask is inoculated with $1x10^6$ cells/mL in 1.5 L of media (80% Freestyle™ 293 Expression Media, 20% LV-MAX™ Production Media). Transfection occurs one day after inoculation, and Benzonase is added on the following day. The culture is harvested 48 hours after transfection and filtered through a 0.45 µM final filter before proceeding to chromatography. All methods conclude with a TFF step to bring the final volume to 2% of the culture volume and buffer exchange the purified product into X-VIVO 15 media.

While purification of lentiviral vector over a 5 mL Mustang Q membrane using an AKTA Avant 150 generated a yield of 55%, purification using the GMP appropriate AKTA Ready 450 gave a yield of 30% (857 mL load). Using TFF (500 kDa Pellicon Mini) to concentrate 4.5 L of supernatant to 500 mL before loading on the AKTA Ready 450, gave a similar yield of 27% showing that tangential flow filtration prior to chromatography does not significantly decrease lentiviral vector yield and increases the potential load volume of the membrane. This yield is significantly higher than the yield of 10-15% seen using the Mustang Q 10 mL during previous runs.

Lentiviral vector was also purified with an AKTA AVANT using a 3 mL Sartobind D membrane (50% yield), and Capto DEAE resin (11x90 mm, 21% yield). While further work is needed to verify scalability of these methods, they each show an improved lentiviral yield in a theoretically scalable format. As the need for clinical lentiviral vector has increased, efficient, scalable chromatography methods have lagged. This work presents potentially scalable methods for purification of lentiviral vectors.

459 Novel Lung Cell Penetrating Peptides Target Airway Epithelial Type 2 Cells

Maliha Zahid[1], Jin Wen[1], Gajalakshmi Singuru[1], Jeffrey Stiltner[2], Sanjay Mishra[2], Kyle Feldman[3], Kayla McCandless[2], Raymond Yurko[4], Kazi Islam[4], Ray Frizzell[2], Hisato Yagi[2], Jonathan Brown[5]
[1]Mayo Clinic, Rochester, MN, [2]University of Pittsburgh School of Medicine, Pittsburgh, PA, [3]Yale New Haven Hospital, New Haven, CT, [4]University of Pittsburgh, Pittsburgh, PA, [5]MPEG LA, Los, MD

Background:
Cell-penetrating peptides (CPPs) are 5-30 amino acid peptides capable of crossing cell membranes without transfection reagents while delivering large cargoes in an intact, functional form. Our previous phage display studies identified a unique, non-naturally occurring 12-amino acid peptide, termed the cardiac-targeting peptide. Through alanine scanning, we identified two robust lung-targeting peptides (LTPs): S7A and R11A. This study details the identification, biodistribution, comparison of linear and cyclic version, uptake mechanism, and targeted cell types of LTPs. We further demonstrate LTP as delivery vectors for siRNA targeting SARS-CoV-2 proteins in an air-liquid interface model of viral infection using human lung cells.

Methods:
Wild-type CD1 mice were injected with Cy5.5-labeled LTPs, and the biodistribution was analyzed via imaging at various circulation times. Lung uptake was assessed via cross-staining of lung sections post-injection, as well as single cell isolation followed by immunostaining with various lung cell markers followed by FACS. Human bronchial epithelial cells (HBECs) were incubated with linear or cyclic LTPs, and FACS measured uptake intensity. Endocytosis mechanisms were explored via FACS analysis of cyclic R11A (cR11A) uptake in HBECs treated with endocytosis inhibitors (Pitstop2, Amiloride, and Nystatin) and via confocal microscopy tracking co-localization with transferrin or the lysomal marker LAMP1. For siRNA delivery, cR11A was conjugated to siRNA duplexes using a DTME linker and confirmed by MALDI-TOF analysis. Anti-viral efficacy against SARS-CoV-2 was tested in an air-liquid interface model of human lung infection.

Results:
Alanine scanning identified S7A (APWHLSAQYSRT) and R11A (APWHLSSQYSAT) as potent LTPs with minimal heart uptake. Intravenous injection of LTPs into mice demonstrated robust lung accumulation of both S7A and R11A, with minimal liver and kidney uptake and a favorable lung-to-liver ratio. Peak lung uptake occurred at 15 min, with fluorescence intensity decreasing in the liver over time (Fig.2). cR11A significantly enhanced cellular uptake (~100-fold increase) compared to linear R11A. FACS analysis showed Pitstop2 significantly reduced cR11A uptake, while Amiloride and Nystatin had no effect, suggesting clathrin-mediated endocytosis. Confocal imaging showed early lysosomal localization of cR11A, followed by cytosolic release within 120 min, confirming lysosomal escape, which was further validated by the lack of co-localization between LTPs and Alexa-488-transferrin in serum starved conditions. Further, FACS analysis of lung single-cell and confocal images revealed that cR11A selectively targeted ATII cells, p63+ basal cells, and ionocytes. Notably, cR11A-siRNA conjugates targeting SARS-CoV-2 effectively inhibited viral replication in an air-liquid interface model of human lung cells, with EC_{90} values of 0.64 ± 0.2 μM (cR11A-S1) and 1.04 ± 0.2 μM (cR11A-E2), compared to 0.019 μM for Remdesivir.

Conclusions:
We identified two novel LTPs, R11A and S7A, that targets ATII, basal cells and ionocytes after an intravenous delivery in as little as 15 min. Cyclization enhanced transduction efficiency in vitro and in vivo by enhancing serum stability. Uptake occurs via clathrin-mediated endocytosis, followed by endosomal escape. Finally, we successfully conjugated cR11A to siRNA and demonstrated a potent anti-viral effect in an air-liquid interface bronchial epithelial cell culture.

Oncolytic Virus Therapies

460 CRAd657-CD40L as a Potent Oncolytic and Immune-stimulatory Treatment for Hepatocellular Carcinoma

Rosa Diaz[1], Shao-Chia Lu[2], Jason Tonne[2], Jill Thompson[3], Thanich Sangsuwannukul[2], Benjamin Kendall[1], Alexa Veliz-Rios[4], Alex Chen[4], Mark McNiven[4], Satdarshan Monga[5], Mitesh Borad[6], Lewis Roberts[1], Mitchell Ho[7], Sidney Hopps[8], Mary Barry[2], Michael Barry[2], **Richard Vile[2]**
[1]Mayo Clinic Minnesota, [2]Mayo Clinic, Rochester, MN, [3]Mayo Clinic Minnesota, Rochester, MN, [4]Mayo Clinic, Rochester, [5]University of Pittsburgh, Pittsburgh, [6]Mayo Clinic Cancer Center, Scottsdale, AZ, [7]Laboratory of Molecular Biology, CCR, NCI, NIH, Bethesda, Maryland, [8]Adze Biotechnology, Coral Gables, FL

The αPD-L1 antibody atezolizumab – as an Immune Checkpoint Blockade (ICB) - in combination with the vascular endothelial growth factor (VEGF)-targeting antibody bevacizumab, has been approved as standard-of-care (SOC) for hepatocellular carcinoma (HCC). However, only a subset of patients responds to ICB therapy, possibly associated with tumors which already have an immune infiltrated ("hot") Tumor Micro Environment (TME) and a weak anti-tumor T cell response which can then be expanded and de-repressed by ICB. Oncolytic viruses (OV) are a promising method to convert poorly immune infiltrated tumors ("cold") into "hot" tumors by inflaming the TME with virus induced cytokines which may also lead to the priming of anti-tumor T cells. In this respect, we developed CRAd657-CD40L, a live, conditionally replicative adenovirus derived from the species C human adenovirus serotype 6 (Ad6). CRAd657-CD40L encodes the CD40L transgene. CD40, a member of the tumor necrosis factor superfamily, is a costimulatory factor on antigen-presenting cells (APCs) which, when bound by its ligand CD40L triggers APC maturation and enhances the generation of anticancer cytotoxic T lymphocytes. CRAd657-CD40L is conditionally replicative because it carries two deletions in the E1A region, *dl*1101/1107, and the hyper variable region (HVR) involved in viral capsid neutralization has been replaced with the HVR of the adenovirus serotype 57 (Ad57). Here, we tested the efficacy of CRAd657-CD40L against a Sleeping Beauty model of HCC in which anti-PD-L1 ICB is partially effective. *In vitro* studies showed that replication of CRAd657-CD40L is tightly restricted to human tumor cells. Direct iv delivery of the virus alone improved significantly upon ICB treatment alone despite a relatively poor ability of the virus to replicate in murine tumor cells. Therapy was dependent upon CD8+ T cells. To alleviate concerns regarding adenovirus delivery to the liver, we also showed that the virus could be effectively delivered to HCC tumors using pre-loading of GPC-targeting CAR T cells – thereby allowing us to reduce the dose of virus given i.v. Finally, as a prelude to clinical translation of CRAd657-CD40L into patient trials for both HCC and melanoma, we have performed extensive toxicity studies in an adenovirus permissive Syrian hamsters, which have shown an excellent safety profile for this virus.

461 Mechanisms of synergy between TGF-beta inhibitor and IL12 expression from the systemically deliverable clinical oncolytic immunotherapy VET3-TGI

Steve Thorne, Kalivir, Pittsburgh, PA

Oncolytic vaccinia virus therapies actively recruit T-cells towards the tumor microenvironment. These can be combined with IL-12 expression to help enhance the immune response by stimulating Th1 cells. However, IL-12 mediated induction of IFN-gamma was also found to increase TGF-beta signaling within the tumor microenvironment.

TGF-beta mediated resistance is one of the major mechanisms of immune suppression utilized across multiple solid tumor types. Blockade of TGF-beta (TGFBi) will therefore likely improve response to immunotherapy. Combining TGF-beta inhibition with IL-12 expression can maximize therapeutic benefits through simultaneously reducing immunosuppression and enhancing anti-tumor immune response. Current studies describe a vaccinia-based immunotherapy, VET3-TGI, combining enhanced systemic virus delivery to tumors and locally expressed IL-12 and TGFBi within the tumor microenvironment, for efficient control of multiple tumor models. *In vivo* mouse studies demonstrated potent therapeutic activity, including many CRs, even at doses several logs below equivalent clinical

doses after systemic (intravenous) delivery. In addition, toxicity studies demonstrated the safety of VET3-TGI in mouse models. This data led to the selection of VET3-TGI as a lead clinical candidate and clinical testing has begun.

462 Fusogenic onclytic vaccinia virus armed with immunostimulatory cytokines improves tumor immune microenvironments systemically and induces complete response in mice bearing bilateral tumors and orthotopic tumors.

Motomu Nakatake[1], Emi Kaitsurumaru[2], Ryo Ishiguro[2], Mami Takahashi[3], Hajime Kurosaki[4], Takafumi Nakamura[1]*
[1]Division of Genomic Medicine, Tottori University, Japan, Yonago, Tottori, Japan, [2]Division of Genomic Medicine, Graduate School of Medical Sciences, Tottori University, Yonago, Japan, Yonago, Tottori, Japan, [3]National Cancer Center Research Institute, Chuo-ku, Tokyo, Japan, [4]Tottori University, Japan, Yonago, Tottori, Tottori, Japan

Oncolytic virus has great immunotherapeutic potential for treatment of various refractory tumors. It induces systemic antitumor immune response following local oncolysis. We have developed two distinct oncolytic platforms, MAPK-dependent recombinant vaccinia virus (MDRVV) and fusogenic oncolytic vaccinia virus (FUVAC). MDRVV achieved tumor-specific virus replication by deleting two viral growth factors, VGF and O1L. FUVAC has been isolated from the MDRVV as a mutant clone which induces cell-cell fusion due to the nonsense mutation of viral fusion inhibitor, K2L. Cell-cell fusion of FUVAC enhances viral oncolysis leading to higher antitumor immune response compared to non-fusogenic MDRVV. FUVAC changed tumor immune microenvironment from “cold” to “hot”, through decreasing tumor associated immunosuppressive cells locally and increasing cytotoxic T cells systemically.

However, it was insufficient to treat distant untreated tumors such as metastatic tumor region. Most oncolytic viruses are treated directly via intratumoral route; then it decreases antitumor effects against untreated tumors because of the lack of direct oncolysis. To remodel tumor immune microenvironment systemically, we have developed FUVAC-IL12/CCL21 armed with two immunostimulatory cytokines, interleukin 12 (IL12) and C-C motif chemokine ligand 21 (CCL21). In mice bearing bilateral subcutaneous CT26 colorectal tumors, unilateral intratumoral injection of FUVAC-IL12/CCL21 more prolonged the survival of mice than it of FUVAC and MDRVV-IL12/CCL21. FUVAC-IL12/CCL21 achieved 72% complete response in both tumors compared to 0% for FUVAC and 29% for MDRVV-IL12/CCL21. Pharmacokinetic analysis showed that viral replication, IL12 and CCL21 productions were mostly accumulated in the treated tumors while IFN-γ was systemically elevated by FUVAC-IL12/CCL21. FUVAC-IL12/CCL21 significantly increased the IFN-γ secretion of splenocyte T cells stimulated with MMC-treated CT26 tumor cells rather than UV-irradiated vaccinia viruses. Furthermore, tumor immune microenvironment was analyzed by single cell RNA-seq. FUVAC-IL12/CCL21 clearly improved the immune microenvironment of distant untreated tumors, by increasing effector memory $CD8^+$ T cells while decreasing the exhausted T cells. TCR repertoire analysis revealed that FUVAC-IL12/CCL21 increased the TCR diversity through its cell-cell fusion induction. Thus, FUVAC-IL12/CCL21 elicited robust antitumor immune responses by infiltrating effector memory T cells including diverse tumor-reactive clones. FUVAC-IL12/CCL21 was also evaluated in the orthotopic pancreatic ductal adenocarcinoma (PDAC) KMPC tumor model. KMPC cells were cloned from PDAC tumor tissue of Pft1a-Cre/LSL-KrasG12D mouse and induced clinically relevant stromal infiltration in cold pancreatic tumors by intrapancreatic transplantation. Intraperitoneal injection of FUVAC-IL12/CCL21 significantly prolonged the survival of mice compared to mock or FUVAC treatment. Moreover, the tumor microenvironment was analyzed by spatial transcriptomics and immunostaining. FUVAC-IL12/CCL21 enhanced infiltration of $CD4^+$ and $CD8^+$ T cells while decreasing tumors and stromal infiltration.

In conclusion, fusogenic oncolytic vaccinia virus armed with IL12 and CCL21 augmented the antitumor immunotherapeutic potential through improving tumor immune microenvironments systemically. FUVAC-IL12/CCL21 would have the potential to overcome oncolytic virus-resistant tumors which limit the clinical benefits.

463 Stroma Modulating Recombinant Oncolytic Vesiculovirus Shrinks Pancreatic Tumor and Increases Immune Response

Khandoker Usran Ferdous[1], Mulu Tesfay[1], Aleksandra Cios[2], Isabelle Miousse, Bolni Nagalo[3]
[1]University of Arkansas for Medical Sciences, Little Rock, AR, [2]UNIVERSITY OF ARKANSAS FOR MEDICAL SCIENCES (UAMS), LITTLE ROCK, AR, [3]UAMS, Little Rock, AR

Vesicular stomatitis virus is one of the most studied oncolytic virus candidates used in preclinical and clinical cancer research. A newly developed synthetic chimeric vesiculovirus, VMG, has been tested across multiple cancer types including pancreatic ductal adenocarcinoma (PDAC) in vitro and in vivo. While the VMG virotherapy seems promising, the presence of hyaluronic acid (HA) and collagen (CN) in the tumor stroma elevates tumor stiffness and interstitial fluid pressure, which incapacitate the effectiveness of oncolytic virotherapy by hindering the penetration of oncolytic viruses/drugs or immune cells into the tumor. We have engineered and evaluated the efficacy of VMG expressing collagenase (CNase) or mouse hyaluronidase (mPH20) or special enzyme (Enz) having both CNase- and PH20-like effect in preclinical PDAC model. The genetic modification of VMG virus did neither compromise its oncolytic/cytotoxic activity nor its replication ability in vitro which are evident from the MTS cell viability assay and viral kinetics assessment respectively. We then tested the efficacy of VMG vectors in the Pan02 in vivo PDAC mouse model. The result show that out of all the synthetic VMG vectors, the VMG-Enz significantly reduced tumor volume. IHC staining and QPLI data demonstrate that the hybrid VMG vectors effectively infected the tumor and were able to digest stromal components such as HA and CN to help viruses duplicate within the tumor. Furthermore, flow cytometry data confirm us that there was an increase in $CD8^+$ T cells, granzyme B^+ T cells, dendritic cells, natural killer cells and a reduction in M-MDSCs which are the hallmarks of successful onco-immunotherapy. However, there was also an increase in immune checkpoint markers including PD-1, PDL-1, PDL-2 and anti-viral resistance genes for IFN-α, IFN-β and Mx-1 which provide us an evidence of resistance built up against the VMG virotherapy. We conclude that, the VMG-Enz was able to increase immune response and significantly abate tumor growth by curtailing stromal hyaluronic acid and collagen level. In future, studies should focus on evaluating the potential of VMG-Enz as an arm of combination therapy with immune checkpoint inhibitors or type I IFN antagonists in increasing survival benefits in experimental animal.

464 Redressing the Balance Between Immunodominant Antiviral and Immunosubdominant Antitumor T Cell Responses to Enhance the Efficacy of Oncolytic Viroimmunotherapy

Benjamin Kendall[1], Jill Thompson[2], Olivia Liseth[3], Thanich Sangsuwannukul[3], Rosa Diaz[1], Jason Tonne[3], **Richard Vile**[3]
[1]Mayo Clinic Minnesota, [2]Mayo Clinic Minnesota, Rochester, MN, [3]Mayo Clinic, Rochester, MN

Oncolytic viruses (OVs) are engineered specifically to replicate in, and kill, tumor cells. The current paradigm proposes that OV tumor cell killing induces immunologic cell death which triggers innate responses culminating in the priming of adaptive T cell responses against tumor associated antigens (TAA). However, the distracting effect of the (immunodominant) antiviral T cell response upon generation of an effective (immuno-subdominant) antitumor response is a major potential impediment to efficacy of OV immunotherapy. Therefore, here we directly addressed the impact of oncolytic virotherapy on the host antitumor T cell response. We show that the immune response stimulated by highly immunodominant viral antigens immunologically distracts from the priming of antitumor CD8 T cells recognizing weak immuno-subdominant TAA and consequently restricts therapeutic efficacy. Thus, in the syngeneic B16 and CT26 models the highly inflammatory VSV was unable to stimulate an antitumor T cell response in C57 mice unless armed with a TAA (VSV- TAA). Moreover, treatment with the virus led to the ablation of pre-existing active antitumor T cells, and a shift of the tumor-reactive T cell landscape toward exhaustion. Furthermore, combination with anti-PD1 ICB therapy significantly improved mouse survival only in mice treated with VSV-TAA compared to VSV-wt. However, by expressing mutated, altered-self versions of a TAA we identified a goldilocks affinity threshold of TAA recognition by T cells which generated T cells which cross reacted with unaltered, SELF TAA expressed by the tumor and correlated with improved tumor control. Taken together, our data challenge the paradigm that immunogenic viruses alone function as *in situ* tumor vaccines. However, we offer a potential strategy to enhance antitumor T cell responses which retains the acute antitumor therapy provided by antiviral innate and T

cell responses, whilst alleviating the antiviral T cell distraction that diminishes the induction of curative tumor-specific T cells.

465 Oncolytic Vaccinia Virus Expressing Non-Secreted Decoy-Resistant IL-18 Mutein Elicits Potent Antitumor Effects with Enhanced Safety

David Bartlett[1], Zuqiang Liu[2], Junjie Ye[2], Lingjuan Chen[2], Sefali Patel[2], Pingpo Ming[2], Chunyan Li[2], Julia Waltermire[2], Jinshun Zhao[2], Jinghua Ren[3]

Cytokines are promising for cancer treatment but face challenges like short half-lives, high dose requirements, and systemic toxicity. Oncolytic viruses provide an ideal platform to overcome these limitations by delivering cytokines directly to tumor sites, enabling high local concentrations within the tumor microenvironment (TME). This study utilized an oncolytic vaccinia virus (oVV) to deliver interleukin-18 (IL-18) and its variants and assessed their antitumor effects across different tumor models. The non-secreted mature IL-18 mutein (nsmDR-18)-expressing oVV demonstrated potent antitumor efficacy with reduced systemic toxicity. It increased the expression of antitumor factors, including IL-2, IFN-γ, granzyme B, and perforin, while expanding tumor-reactive $CD39^+CD103^+CD8^+$ T cells and reducing severely exhausted $PD\text{-}1^+TIM\text{-}3^+CD8^+$ T cells, thereby transforming immunologically "cold" tumors into "hot" tumors. However, nsmDR-18-expressing oVV treatment also elevated regulatory T cells (Tregs) and upregulated immune checkpoint molecules (PD-1, PD-L1 and CTLA-4). Combining nsmDR-18-expressing oVV with anti-CTLA-4 antibody significantly improved overall survival and induced systemic, tumor-specific antitumor immunity. These results highlight the potential of nsmDR-18-expressing oVV as a therapeutic strategy, supporting further exploration in clinical trials.

466 Enhanced Tumor Microenvironment (TME) Immunomodulation Through Repeat Dosing with a Synthetic Vesiculovirus Library

Natalie Elliott[1], Benjamin Kendall[2], John Vant[3], Alexander Baker[4], Richard Vile[5], Mitesh Borad[6]
[1]Mayo Clinic, Scottsdale, AZ, [2]Mayo Clinic Minnesota, [3]Arizona State University, Tempe, AZ, [4]Accession Therapeutics, OXFORD, UK, United Kingdom, [5]Mayo Clinic, Rochester, MN, [6]Mayo Clinic Cancer Center, Scottsdale, AZ

Intravenous (IV) delivery is the ideal route of administration for oncolytic virotherapy for the treatment of advanced metastatic cancers. However, IV delivery yields diminished vector to the tumor due to neutralizing antibodies and absorption by the reticuloendothelial system. As such, most efforts in the clinic have not been successful at attaining clinical regressions. Vesicular stomatitis virus (VSV), a negative strand oncolytic RNA virus, has yielded anti-tumor activity in <10% of patients in clinical trials. In most patients, replication competent virus is cleared within 48 hours and long term anti-tumor immunity is established in varying degrees. Given the delivery limitations with single administrations, extended dosing could provide an approach that parallels other anti-tumor modalities. Towards this end, we have developed a library of replication competent synthetic vesiculovirus vectors displaying distinct glycoproteins that evade antibody cross neutralization. Herein we show an *in vivo* model in which tumor bearing animals with pre-existing anti-vesiculovirus immunity can be treated with IV oncolytic vesiculovirus therapy, efficiently delivering virotherapy to the tumor and inducing anti-tumor immunity.

Utilizing seven novel vesiculovirus glycoproteins we generated chimeric vesiculovirus vectors using the clinically characterized oncolytic VSV vector backbone. We established *in vitro* replication kinetics, high titer production, and oncolytic capacity on a panel of tumor cell lines. We confirmed the vectors' ability to evade antibody cross neutralization by employing patient derived polyclonal antibody populations obtained from a clinical study with VSV-IFNβ (NCT01628640). We applied *in silico* modeling to identify antibody epitope regions to two monoclonal antibodies, 8G5F11 and 1E9F9, and noted sequence hypervariability amongst vesiculovirus glycoproteins in these regions, suggesting a mechanism of immune evasion. Next, we used an *in vivo* model of a syngeneic B16-OVA-$IFNAR^{-/-}$ melanoma tumor in C57BL/6 mice. Following IV immunizations with our novel vectors we treated mice with IV doses of VSV expressing OVA antigen. We confirmed delivery of the virus to the tumor by isolating live

virus as shown by plaque assays and further validated with viral genome qPCR. We assessed antibody responses and demonstrated unique antibody populations against each viral vector. Evaluation of inflammatory cytokines indicated antigen re-exposure only in our murine group both vaccinated and treated with the identical VSV vector. Examination of the tumor microenvironment indicated significant improvement of immune cell infiltration in groups immunized and then treated with alternative vesiculovirus vectors over repeated VSV vector delivery. Antigen specific tetramer staining identified both anti-viral and anti-OVA tumor antigen specific T cell populations, with tumor antigen specific T cell responses aligning with overall survival and decrease in tumor burden. In conclusion, we provide evidence that a library of novel vesiculovirus vectors both evade prior antibody generated immunity and allows delivery of a therapeutically significant secondary dose of an oncolytic vesiculovirus vector. This study lays the groundwork for further development of repeat dosing strategies in the clinic with oncolytic vesiculovirus vector libraries.

Innovation in Alternative Cell Therapy Sources

467 CAR-Engineered HSCs for Treating B-cell Acute Lymphoblastic Leukemia

[1]CHU Sainte Justine, Montréal, QC, [2]Research Center of CHU Ste-Justine, Montreal, QC, [3]Charles-Bruneau Cancer Center, CHU Sainte-Justine Research center, Montréal, QC, [4]CRCHUSJ, Montreal, QC, [5]Charles-Bruneau Cancer Center, CHU Sainte-Justine Research center, Montréal, [6]Sainte-justine Hospsital Reserach Center, Montreal, QC, [7]UCLA, Los Angeles, CA, [8]Aimostem Technologies, Lausanne, Vaud, Switzerland, [9]CHU Sainte-Justine, Montréal, QC, [10]CHU Sainte-Justine

The adoptive transfer of T and NK cells modified to express chimeric antigen receptors (CARs) has emerged as a promising therapy for the treatment of B-cell acute lymphoblastic leukemia (B-ALL). However, challenges such as poor proliferation, loss of engineered cells, and cell exhaustion limit its efficacy. To address these issues, we hypothesized that transducing CAR in hematopoietic stem cells (HSCs), instead of mature immune cells, could provide a continuous supply of CAR-modified cells. To test this approach, NSG (NOD/SCID/IL2Rγ null) mice were humanized with HSCs transduced with a CAR targeting CD22 under the control of the human elongation factor-1 (EF1)-α promoter. We demonstrated that CAR expression in T-cell progenitors disrupted T-cell development, resulting in the absence of peripheral CAR-T cells. Additionally, constitutive CAR expression across the hematopoietic compartment increased the risk of proto-oncogene activation. To address these challenges, we developed a bioinformatic pipeline to identify enhancer regions of the genome that can function as cell-specific promoters when paired with minimal promoter elements. Leveraging this pipeline, we designed a synthetic T/NK-specific promoter to restrict CAR expression to mature T and NK cells. Using a Green Fluorescent Protein (GFP) reporter gene under the synthetic promoter's control, we validated its specificity in T and NK cells after in vitro and in vivo HSC differentiation. Next, we humanized mice with HSCs transduced with a CAR-CD22 driven by the T/NK-specific promoter. Substituting the EF1-α promoter with the T/NK promoter overcame the CAR-T differentiation blockade, enabling the generation of HSCs derived mature CAR-T cells.

When challenged with B-ALL cells, mice engrafted with CAR-engineered HSCs under the T/NK promoter exhibited delayed leukemia progression and significantly improved survival. Interestingly, mice engrafted with HSCs under the EF1-α promoter also showed improved survival, despite the absence of CAR-T cells, suggesting a role for CAR-NK and/or CAR-macrophages in leukemia control. This raises the question of which cell types should be targeted for CAR expression in a context of CAR HSCs, when persistence of CAR-expressing cells is no longer an issue. To investigate, we have developed a high-throughput method to screen a large number of lineage-specific promoters. A lentiviral library of fifty promoters controlling GFP expression was used to transduce T, B, NK cells, and macrophages isolated from human peripherical blood. GFP^+ populations, containing cells with active promoters, were sorted *via* fluorescence-activated cell sorting. Long-read nanopore sequencing were then used to determine the enrichment of each promoter sequence in the GFP^+ T, B, NK cells, and macrophages. The sequencing results showed a strong correlation with those obtained from individual promoter transduction experiments in human peripheral blood mononuclear cells, confirming the robustness and reliability of the approach. To extend this

strategy, we are applying it to HSCs by transducing them with the lentiviral promoter library and generating humanized mice for *in vivo* validation.

The improved survival observed with the T/NK-specific promoter highlights the potential of CAR-HSC therapy. Expanding the repertoire of available cell-specific promoters will allow further evaluation of each cell type's contribution to B-ALL control, paving the way for more efficient CAR-HSC strategies.

468 Revitalizing aged CAR T cells with anti-inflammatory cytokine IL-37

Chimeric antigen receptor (CAR) T cell therapies have shown remarkable clinical efficacy against B-lineage leukemias and lymphomas, but over 50% of patients receiving CD19-targeted CAR T cell therapy will relapse within the first two years of receiving treatment. As all FDA-approved CAR T cell products are autologous, the fitness of a patient's T cells is a critical factor in final efficacy of the drug. It has been proposed the poor fitness of elderly patients, coupled with the biological decline of T cell function with age, can impact CAR T cell therapy outcomes. Therefore, there is a clinical need to improve CAR T cell therapies for older patients diagnosed with B-lineage hematological malignancies. Interleukin-37 (IL-37) is a newly discovered anti-inflammatory cytokine in the interleukin-1 family. IL-37 reduces inflammation by inhibiting downstream activation pathways and reducing the production of proinflammatory cytokines. We hypothesize that modifying aged CAR T cells to constitutively express IL-37 cytokine will reinvigorate these cells and improve anti-tumor outcomes.

Published studies have shown supplementation of systemic recombinant IL-37 (rIL-37) in vitro restores proliferative capacity and cytokine production as well as reduces surface expression of immunoinhibitory proteins, like PD-1 and TIGIT. We engineered CD19-directed CAR T cells to secrete IL-37 using healthy donor samples over the age of 60. Construct validation revealed successful transduction of primary human T cells, cytotoxicity against CD19-expressing tumor cells, and secretion of functional IL-37. Aged healthy donor CAR T cells armored with the anti-inflammatory IL-37 cytokine exhibit more stem-like phenotype by CD62L surface expression compared to second-generation CAR T cells. Aged IL-37-secreting CAR T cells express fewer inhibitory molecules and secrete less pro-inflammatory cytokines compared to parental CAR T cells after CAR manufacturing. Further, engineered IL-37-expressing CAR T cells show robust proliferative capacity compared to second-generation CAR T cells after repeated antigen stimulation in vitro. Previously published work demonstrated that treatment with systemic rIL-37 improves the anti-tumor efficacy of aged CD19-targeting CAR T cells in both syngeneic and xenograft mouse models of B-cell acute lymphoblastic leukemia (B-ALL). We found aged, > 65 years, IL-37-secreting healthy donor CAR T cells significantly decrease tumor burden and improve overall survival of tumor-bearing mice in a xenograft mouse model of B-cell lymphoma. To address these findings in a clinically relevant model, we manufactured armored CAR T cells using T cells from elderly patients, > 65 years, diagnosed with chronic lymphocytic leukemia (CLL). Like data collected from healthy donors, CLL patient-derived IL-37-expressing CAR T cells are characterized by a decreased exhausted phenotype and demonstrate enhanced cytotoxicity against CD19-expressing tumor cells compared to parental CAR T cells.

Ongoing work will determine how IL-37 expression alters aged patient-derived CAR T cell function as well as investigate the expression of IL-37 by aged CAR T cells in syngeneic mouse models of B-cell malignancies. We anticipate the findings of our research will improve our understanding of aging-associated immune function in the context of cellular immunotherapy and enhance the development of novel CAR T cells specifically for patients with advanced age or chronic inflammation.

469 In Vivo Self-Renewing HSC-Based CAR-NK Cell Factory

Despite high response rates, target-antigen positive relapse remains the largest challenge post-CAR T cell therapy in adult oncology patients, mostly following progressive decline over time of the infused gene-modified cells. CAR NK cells potentially have a larger therapeutic window given absence of cytokine release syndrome toxicity, but the limitations of persistence are even more severe. We hypothesized that genetic engineering of the self-renewing pluripotent hematopoietic stem cells (HSCs) will enable constant production of in vivo “CAR-effector cell factories", thus overcoming challenges of persistence in cell therapy. To avoid potential toxicity and potential pro-tumor immunosuppressive effects of a pan-hematopoietic CAR expression precluding clinical applicability, *we developed a gene-modified HSC platform in which CAR expression is precisely controlled and induced only upon NK cell differentiation*.

We generated an integrated computational pipeline using primary human immune cell subset ATACseq/RNAseq datasets to identify candidate NK-specific regulatory DNA elements. From 198 non-redundant potential NK-specific elements, we designed 117 unique assemblies – each combining 1 to 3 elements with a minimal promoter. Assemblies were synthesized and cloned upstream of a GFP reporter in a third-generation self-inactivating (SIN) lentiviral (LV) vector, thus lacking endogenous viral LTR transcriptional activity upon transgene integration in the genome, and dependent on our synthetic regulatory element assemblies (Fig. 1A–E). We screened this library in primary NK and $CD34^+$ cells purified from adult peripheral blood mobilized donors in vitro. Most combinations resulted in similar NK and $CD34^+$ cell reporter expression (Fig. 1F-G, e.g. assembly NK005); however, we identified a small number of lead regulatory element combinations driving massive preferential expression in NK cells (Fig. 1F–G, e.g. NK022, NK026). The in vitro screen was independently repeated four times, from different donors, every time identifying the same lead candidates. Importantly, in vivo regulated expression in NK cells was confirmed following mouse humanization with LV-transduced HSCs and comparison of various differentiated immune subsets by multicolor Flow cytometry analysis (Fig. 2). We further combined 5 lead elements and identify an optimized, compact NK-specific regulatory element combination. Finally, we demonstrated that this NK-specific assembly could induce strong and functional expression of the Cilta-cel (Ciltacabtagene autoleucel) anti-BCMA CAR. Developmentally controlled CAR expression through an HSC platform represents a promising strategy to generate unprecedented CAR persistence that we hypothesize will facilitate long-term disease control. Combining HSC self-renewal with NK cell-specific expression uniquely enhances prospects for safety, therapeutic window, and feasibility of translation. We envision that this regulated HSC-CAR approach will pave the road to novel durable synthetic immune cell therapies.

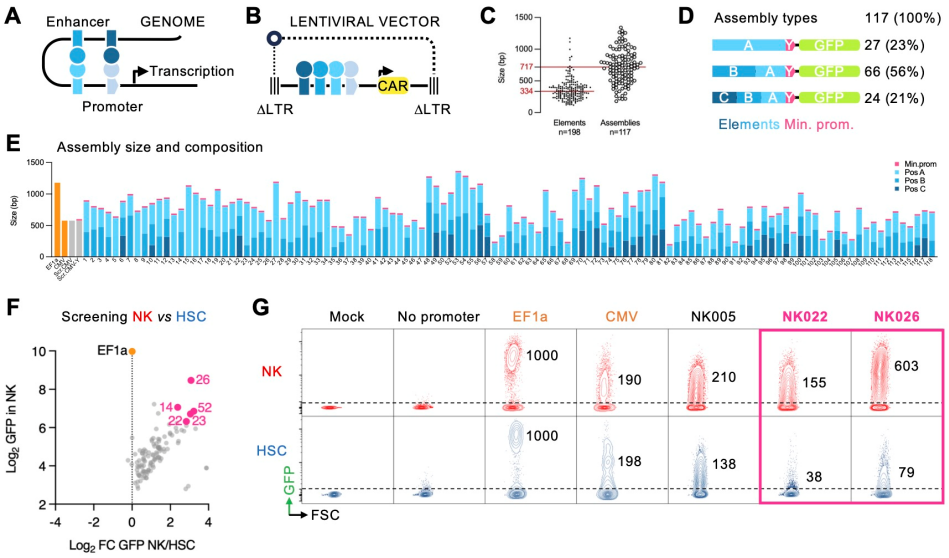

Figure 1. Identification of NK-specific promoters. (**A**) Schematic of distant regulatory elements in the genome (enhancers and promoter) driving specific gene transcription. (**B**) Schematic of a compact assembly of regulatory elements in a 3rd generation lentiviral vector to drive specific expression of a CAR. **Δ**LTR signifies the deletion in the long terminal repeat that define a self-inactivating (SIN) LV and render transcription activation dependent on the synthetic regulatory elements/minimal promoter, and not a viral element. (**C**) Size of 198 selected NK-specific elements selected from ATAC-seq data and 117 assemblies (success of production 117/118 assemblies; 99%). (**D**) Diagram of the different assembly types with 1, 2 or 3 elements associated with a 25-bp minimal promoter Y (YB_TATA). The annotations A, B and C indicate the relative position of each element from the minimal promoter Y. (**E**) Size and element composition of each assembly compared to constitutive promoters (EF1a and CMV) and control scrambled CMV sequences. (**F**) Screening results representative of four independent experiments comparing the activity (GFP expression) of each assembly in NK cells and peripherally mobilized and isolated CD34+ cells (HSCs). Data were normalized to EF1a for each cell type. Five assemblies showing the highest expression in NK cells (Y-axis) and highest fold-change compared to HSCs (X-axis) were selected (highlighted in the graph). (**G**) Representative Flow cytometry analysis of GFP expression in NK cells and HSCs. Enumerated values indicate normalized geometric mean fluorescence (MFI) of GFP+ cells (relative to EF1a=1000). NK005 is an example of a non-specific candidate, representative of a majority of tested assemblies, whereas NK022 and NK026 represent a minority of assemblies exhibiting preferential expression in NK cells. Of note, background HSC expression of GFP for control and NK regulatory assembly candidates is likely to be artificially increased in this in vitro assay by the short-term nature of this approach, proximity to LV transduction, and differences in HSCs in cell culture with required cytokine support *vs* in vivo results. This difference in vitro is noted *vs* post-HSC engraftment and hematopoietic differentiation where lower "leakiness" was observed in non-NK cells in vivo (Figure 2).

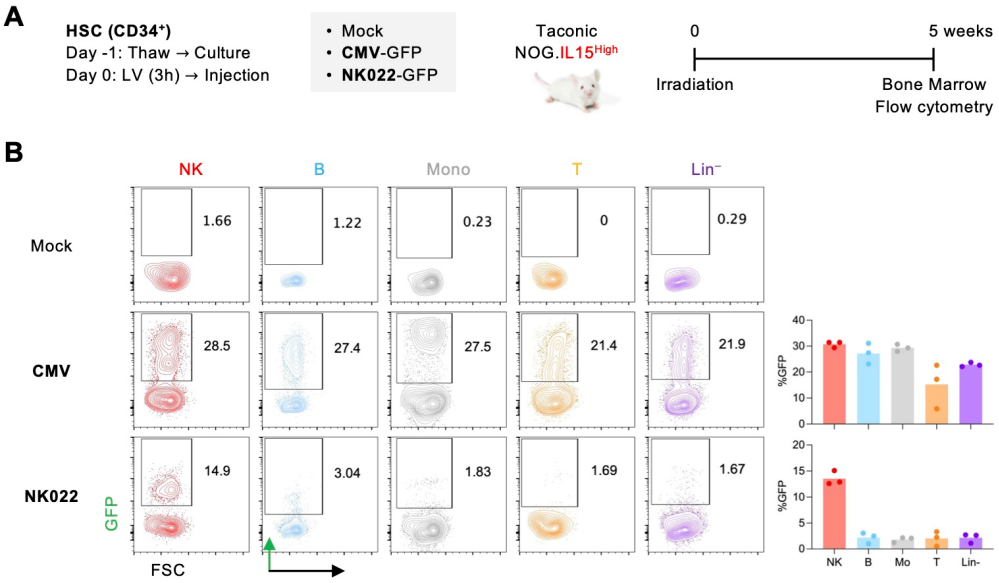

Figure 2. In vivo NK-specific promoter activity of NK022 candidate. (**A**) Schematic of the experimental procedure for the testing of in vivo NK-specific promoter activity of the NK022 assembly. Human HSCs were lentivirally transduced with CMV-GFP or NK022-GFP constructs and injected into irradiated (200 Rad) NOG-hIL15 (Taconic Biosciences®, supra-physiologic IL-15) mice (n=3 per group). After five weeks, mice were euthanized, and the bone marrow was harvested for flow cytometry analysis. (**B**) Plot of the percentage of GFP$^+$ cells in differentiated NK (CD3$^-$ NKp46$^+$), B (CD19$^+$), monocytes (CD14$^+$), (emerging) T cells* (CD3$^+$ NKp46$^-$) and lineage-negative (Lin$^-$) cells. *Of note, in this model, T cells could only be observed in a few experiments and might not represent fully matured T cells at this timing. Quantification in individual mice is shown on the right panel.

470 Phase 1 Translational Assessment of an Off-The-Shelf CAR NK Cell Armed with Alloimmune Defense Technology for Conditioning-free Therapy

Trever Greene[1], Seth Peng[1], Cara Bickers[1], Alan Williams[1], Daniel Morales-Mantilla[1], Rina Mbofung[1], Veronika Bachanova[2], Matthew Lunning[3], Premal Lulla[4], Adhinav Deol[5], Michael Byrne[6], Don Stevens[7], Deepa Patel[1], Ramzey Abujarour[1], Tom Lee[1], Raedun Clarke[1], Betsy Rezner[8], Jode Goodridge[1], Rebecca Elstrom[1], Bob Valamehr[1], Lilly Wong[1]

[1]Fate Therapeutics, Inc., San Diego, CA, [2]University of Minnesota, Minneapolis, MN, [3]University of Nebraska Medical Center, Omaha, NE, [4]Baylor College of Medicine, Houston, TX, [5]Karmanos Cancer Institute, Wayne State University, Detroit, MI, [6]Tennessee Oncology, Nashville, TN, [7]Northon Healthcare, Louisville, KY, [8]Fate Therapeutics

Autologous chimeric antigen receptor (CAR) T-cell therapy has revolutionized the treatment of hematological malignancies; however, its scope of application is limited by manufacturing complexity, cost of treatment, and patient accessibility. Allogeneic strategies to overcome such limitations include the use of induced pluripotent stem cell (iPSC)-derived CAR T or NK cell therapies that can be uniquely manufactured "off-the-shelf" for broad patient access. Unlike donor-derived allogeneic approaches, iPSC-based cell therapies are highly amenable to genetic engineering, can be consistently produced in a cost-effective manner, and reliably available for on-demand treatment.

Intense conditioning chemotherapy (CCT), often consisting of cyclophosphamide and fludarabine, is commonly administered to patients prior to treatment with CAR therapies, although CCT is associated with severe toxicities. We developed FT522, a next generation iPSC-derived CAR NK cell therapy, that is designed to confer therapeutic benefit without requiring the administration of CCT. FT522 builds off the success of our previous CAR NK cell therapy (Ghobadi et. al., 2025) and incorporates five synthetic controls of cell function: a CD19-targeted CAR; a high-affinity non-cleavable CD16 (hnCD16) Fc receptor to maximize antibody-dependent cellular cytotoxicity; an IL-15/IL-15 receptor fusion protein to offer cell-intrinsic cytokine support and enhanced function; a

CD38 knockout to enhance metabolic fitness; and an alloimmune defense receptor (ADR) targeting 4-1BB to promote functional persistence in the absence of CCT.

Preclinical studies were performed to evaluate whether FT522 could maintain anti-tumor activity while under threat by alloreactive immune cell populations. FT522 effectively culled allogenic responses *in vitro,* and uniquely eliminated tumor cells better than control CAR NK cells without ADR *in vivo* (2000-fold lower tumor burden at study endpoint, p=0.016). A Phase 1 multicenter clinical study of FT522 in relapsed/refractory B cell lymphoma (NCT05950334) is currently ongoing, where FT522 is administered either with or without CCT. Preliminary clinical data showed that when combined with CCT, FT522 induced deep and lasting CD19+ B cell depletion, and clinical responses in both indolent and aggressive lymphoma were observed. In addition, FT522 attenuated activated (4-1BB+) T-cell recovery (7-fold fewer CD4 T cells at day 8 post infusion, n=3), suggesting that treatment with FT522 can target both tumor cells as well as activated host alloreactive T cells. Importantly, when administered without CCT, FT522 did not result in the expansion of activated (4-1BB+) T cells. Furthermore, a dose-dependent increase in FT522 persistence, which outpaced that of prior CAR NK cells without ADR, was observed (16-fold greater AUC at 50% the dose n=3). No evidence of either cellular or humoral responses against FT522 was detected, suggesting that ADR can protect FT522 from host immune response in the absence of CCT. Collectively, our preclinical and early-stage translational data from our Phase 1 study of FT522 demonstrate that ADR is capable of enabling anti-tumor activity, promoting functional persistence, and avoiding immune rejection without requiring administration of CCT to patients.

471 Generation of iPSC-derived CD4$^+$ and CD8$^+$ CD19 CAR αβ T cells with *in vivo* tumor control and cell expansion comparable to healthy donor T cells.

Successful development of off-the-shelf CAR-T cell therapies requires complex engineering to i) prevent graft vs host disease (GvHD) and rejection by the patient's immune system, and ii) equip the cells with anti-tumor capabilities, such as a chimeric antigen receptor (CAR). Induced pluripotent stem cells (iPSCs) provide an ideal platform; engineered clones can be characterized and banked for future differentiation due to the unique ability of these cells to both self-renew and retain the potential to make any cell in the adult body. Using a scalable feeder-free method, we report the generation of allogeneic iPSC-derived CAR T cells with comparable function to primary T cells. iPSCs were engineered with a CD19 CAR and allo-evasion edits designed to combat cellular and humoral responses. A fully characterized clone was selected and differentiated using a novel process that generated a mix of CD4$^+$ and CD8$^+$ T cells. scRNA-seq analysis of cells at different stages of this process confirmed that cells follow a trajectory matching normal thymocyte development to αβ T cells. Upon in vitro tumor challenge, these iPSC CAR T cells displayed Ag-dependent cytotoxicity, proliferation, and cytokine production, including IL-2. A single infusion of Century iPSC-CAR-T cells demonstrated tumor control in an established NALM6 tumor model without the need for exogenous cytokines or cytokine engineering. Importantly, iPSC-CAR-T cells persisted in peripheral blood for at least 21 days, trafficked to the bone marrow, and measurably proliferated upon tumor rechallenge in an in vivo model. Both in vivo proliferation and tumor control were at least comparable to primary T cell controls. These data are a significant advance in the field of allogeneic iPSC CAR T cells and support the use of this platform for the development of scalable, accessible CAR T cell medicines.

472 Combinational "Off-the-Shelf' CAR T Cells: A Unified Front Against AML Heterogeneity

Christos Georgiadis[1]*, Renuka Kadirkamanathan[2], Arnold Kloos[3], Roland Preece[4], Oliver Gough[5], Michael Heuser[6], Waseem Qasim[7]

Most chimeric antigen receptor (CAR) T cell trials to date have employed autologous T cells and have avoided the hurdles of allogeneic immunity. As an alternative to autologous CAR T cells, effectors can be generated from donors through an "off-the-shelf" approach and used without HLA matching following appropriate genome editing steps. Cytidine deaminase editors mediate irreversible C>U>T edits for multiplexed knockout of αβ T cell receptor (TCRαβ) to avoid graft-versus-host disease (GvHD), shared antigens to evade self-targeting through CAR, and CD52 to confer resistance to serotherapy or HLA to directly avoid rejection. In the context of heterogeneous disease such as acute myeloid leukaemia (AML), multiple targeting moieties are required for complete coverage of blast populations and an approach using combinations of "off-the-shelf" CAR T cells was investigated.

We generated 'universal', TCRαβ depleted BE-CAR7, BE-CAR33 and BE-CARCLL-1 CAR T cells and evaluated their application against highly heterogeneous and aggressive AML. BE-CAR33 and BE-CARCLL-1 demonstrated potent anti-leukaemic effects against HL-60, MOLM-14, U-937 and Kasumi-3 cell lines and CLL-1^{+}CD33^{+} primary AML samples *in vitro*. To model disease heterogeneity, NSG mice engrafted with CRISPR-engineered CLL-1^{-} CD33^{+} and CD33^{-}CLL-1^{+} HL-60 cells were treated with BE-CAR33 and BE-CARCLL-1 either alone or in combination. Disease progression could be inhibited more effectively in combined BE-CAR infusions over monotherapy strategies. Compatibility of BE-CAR7 and BE-CAR33 after removal of CD7 was also confirmed in a humanised patient derived xenograft (PDX) model of AML with effective clearance of CD7^{dim}CD33^{bright} disease.

In addition, BE-CAR T cells against CD70 were developed as an emerging candidate in immunotherapy for haematological malignancies such as AML. BE-CAR70 cells quadruple base edited for TCRαβ, B2M, RFX5 and CD70, to minimise self-targeting effects, and magnetically depleted of residual TCR, HLA-I and II, were able to eliminate AML cell lines *in vitro* and sustain durable disease control over a period of 38 days in a humanised murine model of AML, demonstrating uncompromised functionality compared to conventional single TCRαβ-edited versions. Importantly, a clear advantage in evading host rejection, attributed to quadruple editing of BE-CAR70 was overserved in *in vitro* mixed lymphocyte reactions. Therapeutic strategies envisage 'pick and mix' applications of base edited universal CAR T cells in combination, ultimately determined by disease specific antigen profiles for individual patients. Pre-manufactured and ready to use allogeneic combinations should enable timely interventions against AML where disease can otherwise evolve and progress rapidly.

473 Development of a Feeder-Free Maturation Method for TCR$^{-/-}$ CAR iT Cells

Mame Diop[1], Vera Alexeeva[2], Pieter Lindenbergh[3], Isabelle Riviere[4], Frances Weis-Garcia[5], Michel Sadelain[6], Sjoukje Van Der Stegen
[1]Columbia Initiative in Cell Engineering and Therapy, Columbia University Irving Medical Center; Cancer Center Amsterdam, Amsterdam UMC, Amsterdam, NL, New York, NY, [2]CZ Biohub New York, New York, NY, [3]Columbia Initiative in Cell Engineering and Therapy, Columbia University Irving Medical Center, New York, NY, [4]Takeda, Cambridge, MA, Cambridge, MA, [5]Antibody & Bioresource Core Facility, Memorial Sloan Kettering Cancer Center, New York, [6]Columbia Initiative in Cell Engineering and Therapy, Columbia University Irving Medical Center, New York

Induced pluripotent stem cells (iPSC) are a renewable source for the generation of allogeneic, off-the-shelf, chimeric antigen receptor (CAR) T cell therapy and are currently under evaluation in clinical trials for both $CD19^+$ hematological malignancies as well as systemic lupus erythematosus. However, large scale T cell differentiation is challenged by the reliance on xenogeneic reagents, including bovine sera and murine feeder cells, and their requirement to grow in adherent cultures. Protocols have been established to support T cell differentiation utilizing immobilized recombinant proteins, with positive selection mimicked through TCR engagement with antibodies or mitogens. For allogeneic application, avoidance of GvHD through elimination of the TCR at the iPSC level requires TCR-independent maturation protocols. We previously reported that stimulation of double-positive (DP), $TCR^{-/-}$ anti-CD19 CAR^+ iT cells (*TRAC*-1XX-iT) with CD19 and 4-1BBL expressed on irradiated feeder cells facilitates positive selection and proliferation, generating single-positive (SP) CD8ab *TRAC*-1XX-iT cells. We hypothesized that antibody-mediated CAR and 4-1BB stimulation could support a xenograft-free maturation method of functional SP antigen-specific cytotoxic iT cells. To induce CAR signaling we developed anti-idiotype (anti-ID) antibodies, which were selected for CAR specificity and ability to induce CAR activation. Two antibodies were identified, one with anti-CD19 CAR specificity and the other with pan-CAR specificity. Immobilized but not soluble anti-ID antibody was able to induce iT cell maturation in a dose-dependent manner. However, CAR engagement alone was not able to induce proliferation. Similar to the feeder-based method where proliferation required additional 4-1BB engagement. To provide 4-1BB costimulation, we tested both soluble and immobilized recombinant protein and agonist antibodies. Proliferation only occurred with the addition of a soluble 4-1BB agonist. The specificity and potency of the plate-bound matured iT cells combined with 4-1BB engagement was demonstrated using in vitro cytotoxicity and intracellular cytokine assays. Additionally in vivo, the resulting *TRAC*-1XX-iT cells showed enhanced tumor control compared to feeder-based maturation. To eliminate the requirement for anti-ID antibody immobilization, we aimed to generate soluble methods for CAR stimulation through bead coating or antibody crosslinking to promote clustering of CAR molecules on the iT cells' surface. Antibody crosslinking combined with soluble 4-1BB agonist resulted in T cell maturation and robust proliferation. In vitro, the feeder-free matured iT cells display a phenotype and cytotoxicity similar to feeder-matured iT cells. In a systemic mouse model of leukemia, a single dose of feeder-free matured iT cells demonstrated potent tumor control and significantly increased survival when evaluated against feeder-matured iT cells. In sum, we established a soluble feeder-free and TCR-independent method for $TCR^{-/-}$ CAR^+ iT cell maturation through antibody-mediated CAR and 4-1BB engagement that produces potent cytotoxic CAR iT cells for therapeutic application.

HSC Transplantation and Gene Therapy

476 Dilanubicel Improves Single Cord Blood Transplantation: Updated Results with a Larger Cohort

Filippo Milano[1]*, Jenna Pedersen[1], Laura Roberts[1], Brandon Hadland[2], **Francesco Mazziotta[1]**, Ann Dahlberg[1], Colleen Delaney[3]
[1]Fred Hutchinson Cancer Center, Seattle, WA, [2]Fred Hutchinson Cancer Research Center, Seattle, WA, [3]Deverra Therapeutics, SEATTLE, WA
**Corresponding Author*

Background:
Recent clinical data suggest that third-party donor granulocyte transfusions can enhance donor CD8 T cell expansion and induce remission in relapsed AML patients undergoing cord blood transplant (CBT). Accessibility to CBT could improve by eliminating the need for a second CB unit without added risk. Dilanubicel, a cryopreserved, non-HLA-matched progenitor cell therapy product that is derived from the proprietary ex vivo expansion of cord blood CD34+ cells isolated from 6-8 pooled CB units, has shown clinical safety, early myelomonocytic recovery support, and contains antigen-presenting cells. This study evaluates dilanubicel as an adjuvant, transient graft to enhance graft-versus-leukemia effects and remove the need for a second CB unit.

Methods:
From March 2022 to January 2025, 22 patients with hematologic malignancies were enrolled in a single-center Phase II trial to assess the safety of dilanubicel in augmenting single CBT. Conditioning regimens included FLU/TBI/CY (n=11) or FLU/TBI/CY/Thiotepa (n=11). CB units required ≥4/6 HLA matching, while dilanubicel was used off-the-shelf without matching. The selected donor CB unit had to contain ≥2.5×10^7 TNC/kg and 1.7×10^5 CD34/kg pre-freeze. Dilanubicel infusion followed CB infusion by 4 hours, delivering 800×10^6 total CD34+ cells. Chimerism studies were performed from day 7 to one-year post-HCT. GVHD prophylaxis included cyclosporine and mycophenolate mofetil.

Results:
The median age was 33 years (range, 10-63), and 50% were ethnic minorities. Most patients had acute leukemias (AML=10, ALL=10, CML=1, MPAL=1), with 6 (27%) having minimal residual disease pre-HCT. Most (n=16) received a 4/6 HLA-matched CB unit. Median infused TNC and CD34 per kg were 3.14×10^7 and 2.53×10^5, respectively. All patients engrafted neutrophils at a median of 18 days (range, 14-30) and platelets at 31 days (range, 26-42). Early (day 7) myelomonocytic recovery was derived from dilanubicel confirmed by chimerism analysis and by day 14 myelomonocytic recovery transitioned to the primary CB donor (unit). A transient early lymphocyte expansion was observed in all patients from day +8/9 (median 855/μL, range 100-1316/μL), preceding ANC recovery, and was derived exclusively from the primary CB unit. With a median follow-up of 13 months (range, 1-32), all patients remain alive with a single case of relapse (Figure 1). The infusion of a non-HLA-matched pooled donor product did not increase GVHD risk, in fact there have been no cases of grade III-IV or chronic GVHD observed to date.

Conclusion:
Relapse remains one of the main causes for treatment failure following stem cell transplant. The addition of Dilanubicel as an adjuvant transient graft in single CBT was found to be safe and led to excellent outcomes, including low relapse rate and no grade III-IV acute or chronic GVHD. Importantly, as a cryopreserved and off-the-shelf, non-HLA-matched allogeneic cell therapy, dilanubicel readily accessible for all patients and easily integrated into standard CBT. Further, pooled donor manufacturing eliminates the issues of donor-to-donor variability and is a highly scalable process, associated with very low cost of goods. With significant follow-up, the absence of relapse may be linked to third-party donor APCs activating donor T cell responses. These promising findings warrant further biological investigations and larger trials.

Figure 1. Disease-Free Survival at 3 years post Cord Blood Transplant. Median follow-up time 13 months.

T-cell antigen receptor (TCR)-based therapies utilize TCRs that specifically recognize distinct peptide-Human Leukocyte Antigen complexes (pHLA). If the TCR sufficiently binds to a given pHLA, the engaged T cell becomes activated and kills the target cell. A crucial concern following TCR discovery is assessing the potential for cross-reactivity to unintended targets. There are no standardized methods for preclinical safety assessment of TCRs. Prior failures of preclinical safety assessments of TCRs have led to severe toxicities and mortalities in the clinic. Each failure has prompted retrospective assessments, resulting in improvements in preclinical safety methodologies. However, most studies have focused on a single TCR, or a small panel of TCRs often with the same pHLA target, lacking a robust strategy applicable to a wide range of TCRs. Therefore, urgent need for improved methods to predict and identify potential epitopes recognized within healthy tissues in humans is highlighted.

We have developed a robust *in silico*/*in vitro* model to predict and validate TCR cross-reactivity by utilizing a diverse panel of TCRs. This panel of TCRs includes three primary categories: TCRs that have exhibited prohibitive clinical toxicities, TCRs that have been demonstrated to be clinically safe with some efficacy, and TCRs without clinical experience but expected to be innocuous. In order to produce a robust model that captures the diversity of the TCR intrinsic cross-reactivity potential, our panel of TCRs includes two pairs of naturally occurring TCRs that recognize the same pHLA and two pairs of affinity enhanced TCRs along with their wild-type counterparts, from which they were derived, that recognize the same pHLA.

In our predictive model, we deployed the X-scan technique to assess TCR-T cell activity following exposure to a panel of altered peptide ligands (APLs). This panel of APLs was derived from the target peptide by systematically substituting each amino acid position with all 19 alternative amino acids, while all other positions match the original target peptide. This technique allows us to evaluate the specificity of the TCR for the original pHLA and predict TCR degeneracy and cross-reactivity. We utilize primary human T cells engineered to express the TCR and assess whether each peptide in the X-scan assay triggered TCR-T cell activation by evaluating expression of activation markers, cytotoxic activity, and effector molecule secretion. The Xscan data combined with experimental testing of a list of candidate peptides identified within the human proteome was used to develop a machine learning model. We deployed XGBoost and random forest algorithm to predict cross-reactive peptides.

Our findings indicate the model was able to classify peptide cross reactivities and quantitatively predict peptide functionalities. The machine learning model achieves a high accuracy of 0.83 indicating the model can provides an effective computational tool to identify T cell responses against mutated epitopes.

The culmination of this dataset is to establish a robust lab-in-the-loop model to predict TCR cross-reactivity and help guide the development of a next-generation platform for derisking TCRs. The model advance personalized, cost-effective, and efficient TCR-based therapies. This approach has the potential to enhance TCR potency and safety, revolutionizing therapeutic applications in oncology and beyond.

Poster Talk Presentations

483 Mobilize LNPs: A Novel Platform for In Vivo Targeted Delivery of RNA Therapeutics to T Cells

Justin Fang[1], Amit Singh[2], Zhiwei Luo[3], Anthony Cura[2], Ting Lan[3], Feng Lin[3], Sanpeng Li[4], Bob Crooker[2], Fei Jiang[5], Wei Qin[5], Roxi Mitrut[2], Cassidy Purrington[6], Nikhita Khanna[2], Jack Norton[6], Alina Zhankulov-Nguyen[6], KieuDuyen Tran[2], Qiujie Cai[3], Rujia Wang[3], Annie Xue[6], Andrea Graham[6], Maria-José Araneda Rubio[2], Yongting Huo[3], Alex Wesselhoeft[2]
[1]Mote, Cambridge, MA, [2]Mote Therapeutics, Lexington, MA, [3]Mote Therapeutics, Dongguan, Guangdong, China, [4]Mote Therapeutics, Dongguan, Anhui, China, [5]Mote Therapeutics, Dongguan, China, [6]Mote Therapeutics, Lexington

Introduction:
Lipid nanoparticles (LNPs) have cemented their utility as efficient and effective delivery systems for RNA-based therapeutics with successful clinical translation as COVID vaccines (CORMIRNATY® and Spikevax) and hepatic delivery (ONPATTRO®). However, their usefulness in delivering to extra-hepatic tissues suffers several technological challenges and warrants further innovation. *Mobilize* is a versatile and modular extra-hepatic delivery platform that is designed to resolve these challenges through a simple but unique approach.

Methods:
Mobilize as a platform technology enables surface functionalization of LNPs with tissue specific ligands by inline micromixing as a single step to generate targeted delivery system (*Mobilize* LNPs). As proof of concept, we used Green Fluorescent Protein (GFP) encoding circular RNA (circRNA) as model reporter cargo for targeted delivery to T cells. The tLNPs were characterized for their size, polydispersity index (PDI), surface charge, encapsulation efficiency (EE), and stability. We evaluated the delivery efficiency of *Mobilize* LNP in multiple cell-based systems (Jurkat cells, human PBMC and T cells) before confirming *in vivo* targeted delivery capability in humanized mouse model and non-human primates (NHP).

Results:
Mobilize LNPs consistently demonstrated excellent physicochemical properties (size <100 nm, PDI <0.1 and EE >95%) and colloidal stability under refrigerated as well as frozen conditions. We validated activity of these LNPs in Jurkat, human PMBCs, and human T cells achieving ~100%, ~70% ~35% delivery respectively. We then tested *in vivo* delivery efficiency of the *Mobilize* LNPs in humanized mice and achieved nearly 55% positive quiescent T-cells at a very low dose. We finally dosed the *Mobilize* LNPs to non-human primates (NHPs) to achieve successful delivery in ~20% quiescent T-cells through a single dose with no overt toxicity at any tested dose.

Conclusions:
The *Mobilize* platform consistently demonstrates the ability to both (1) detarget the liver, (thus avoiding passive LNP sinks), and (2) specifically deliver to T-cells *in vitro* and *in vivo* in multiple models. The inherent design of the *Mobilize* platform elegantly addresses the challenges in functionalizing LNPs with targeting ligands for extra-hepatic delivery. The process behind *Mobilize* technology maintains platform versatility, stability, robustness, and delivery efficiency. Our data indicates that Mobilize has strong potential as an *in vivo* delivery platform of RNA therapeutics to extrahepatic tissues.

484 Treating Pancreatic Cancer with "Armed" Oncolytic Adenoviruses and Adoptive T-Cell Therapy

Brett Roach[1], Masato Yamamoto[2]
[1]University of Minnesota, Twin Cities, Minneapolis, MN, [2]University of Minnesota, Minneapolis, Minnesota

Introduction:
Pancreatic ductal adenocarcinoma (PDAC) is the third leading cause of cancer-related mortalities and is projected to become second by 2030. The survival rate for PDAC has not improved in nearly four decades. Two primary features make PDAC refractory: 1.) the highly immunosuppressive tumor microenvironment (TME) suppresses anti-tumor

immune cells and 2.) desmoplasia, which creates a fibrotic physical barrier for infiltration of anti-tumor immune cells and therapeutics. The goal of this project is to develop viro-immunotherapies against PDAC that target the immunosuppressive TME and desmoplasia by utilizing "armed" oncolytic adenoviruses (OAds) and adoptive T-cell therapy (CAR T-cells). Four transgenes were selected to "arm" the OAd constructs: i.) TGF-beta blocker, ii.) interleukin-7 (IL-7), iii.) interferon gamma (IFN-gamma), and iv.) unnamed effector. The top two transgenes were selected to be combined and analyzed further.

Methods:
"Armed" replication-deficient adenovirus (Ad) constructs were first generated to isolate transgene function from oncolytic activity. Anti-tumor effects were measured using a syngeneic mouse model harboring subcutaneous KPC cell tumors that were intratumorally treated with virus. Tumors were harvested at various time points and stained for immune cell infiltration and fibrosis. The top two transgenes that elicited the greatest anti-tumor effects (TGF-beta blocker and IFN-gamma) were combined into a single vector and analyzed for anti-tumor effects in a similar manner. Mesothelin-directed CAR T-cells (meso-CARTs) were injected (tail vein) into NSG mice bearing subcutaneous Panc1 tumors after intratumoral injection of Ad constructs.

Results:
Tumor growth was significantly inhibited in syngeneic mouse models in the presence of each "armed" Ad construct. Furthermore, significant tumor infiltration of anti-tumor immune cells was induced upon treatment as well as a decrease in fibrosis. When combining the top two transgenes into a single adenovirus vector (TGF-beta blocker and IFN-gamma), this vector induced a significant anti-tumor effect compared to all vectors harboring a single transgene. Abscopal effects were observed on contralateral tumors after injection of ipsilateral tumors. The vector expressing TGF-beta blocker and IFN-gamma showed the greatest abscopal effects as well as an increase in tumor infiltration of anti-tumor immune cells. Finally, combining meso-CARTs with IFN-gamma-expressing Ad induced the greatest anti-tumor responses compared to monotherapies.

Conclusions:
PDAC is very resistant to conventional therapeutics, so utilizing combination strategies seems essential. The findings in this study have broad implications in the field of pancreatic cancer by shedding light on how the TME can be manipulated to enhance anti-tumor effects to aid in the development of more efficient therapeutics against PDAC. Combining transgenes that enhance the immune system (IFN-gamma) and decrease the immunosuppressive features (TGF-beta blocker) of PDAC is a superior approach by enhancing therapeutic efficacy from multiple angles. Moreover, therapeutics inducing abscopal effects should be highly valued because most PDAC patients die from metastasis.

485 Supramolecular Assembly of Polycation/mRNA Nanoparticles and In Vivo Monocyte Programming

Yizong Hu[1], Leonardo Cheng[2], Stephany Tzeng[3]*, Jordan Green[4]*, Hai-Quan Mao[3]*
[1]Massachusetts Institute of Technology, Cambridge, MA, [2]Johns Hopkins University School of Medicine, Baltimore, MD, [3]Johns Hopkins University, Baltimore, MD, [4]Johns Hopkins University, Baltimore, Maryland
**Corresponding Author*

Introduction.
Conventional drug delivery vehicles employ nanoparticle sizes below 200 nm to reduce loss to phagocytic cells. Our work, instead, takes advantage of this size effect to achieve preferential messenger ribonucleic acid (mRNA) delivery to monocytes by engineering colloidally stable particles larger than 200 nm. Utilizing surface charge modulation as a generalizable strategy, we report assembly of poly(β-amino ester) (PBAE)/mRNA nanoparticles into supramolecular assemblies that are kinetically tunable between 200 and 1,000 nm and reveal an optimal size of 400 nm for safe and efficient transfection of monocytes following intravenous administration.

Methods.
When mixing the ethanol-dissolved PBAE with mRNA in a mildly acidic (pH 5.0) aqueous solution, PBAE/mRNA nanoparticles formed as a result of polyelectrolyte charge neutralization and hydrophobic interactions. Their

colloidal stability depends on competition between long-range electrostatic repulsion of residual positive charges on the surface and short-range van der Waals attractions among hydrophobic groups on PBAE. To allow further assembly of these initially stable nanoparticles to form submicron-and micron-sized particles, the excess positive charges of PBAE amines on the nanoparticle surface can be reduced by an increase in pH (to 7.4) that deprotonates amine groups and an increase in solution ionic strength (I = 0.205 M) that decreases the range of the electrostatic forces *via* Debye screening (Figure 1A). The assembly can be quenched (Figure 1B) by hydrophobic insertion of DMG-PEG2000 lipid onto the particle surface to stabilize any desired particle size, such as growing from 100 nanoparticles to 400 nm in size (Figure 1C).

Results.
Following *i.v.* injection of the 100- or 400-nm particles carrying Cy5-mRNA in C57BL/6J mice, they were quickly taken up by circulating Ly6C^{high} inflammatory monocytes. However, the 400-nm particles yielded a 10-fold higher uptake than the 100-nm particles (Figure 2A). To assess the gene expression profile, the assembled particles carrying mRNA encoding Cre recombinase (mCre) were *i.v.* injected into Ai-9 mice. At 72 h, a greater abundance of mature macrophages (F4/80^{+}CD11b^{+}) was detected in the liver and spleen compared to the untreated control mouse. Evaluation of transfection efficiency indicated that monocyte particle uptake and their subsequent differentiation were linked to successful transfection of the resulting macrophages, with 400-nm particles producing the highest level of tdTomato expression (Figure 2B). We tested the assembled 400-nm particles in a proof-of-concept therapeutic vaccine model for treating subcutaneously (*s.c.*) implanted ovalbumin (OVA)–expressing melanoma (B16-OVA). Statistically significant extensions of survival and delays of tumor growth were observed in the group that received the 400-nm particles loaded with mOVA or ODN as the sole functional payload but not in the group treated with the 100-nm particles (Figure 2C).

Conclusions.
Efficient transfection of monocytes by tumor antigen mRNA offers opportunities for cancer vaccines due to the ability of monocytes to differentiate into mature antigen-presenting cells that can mediate an antitumor response.

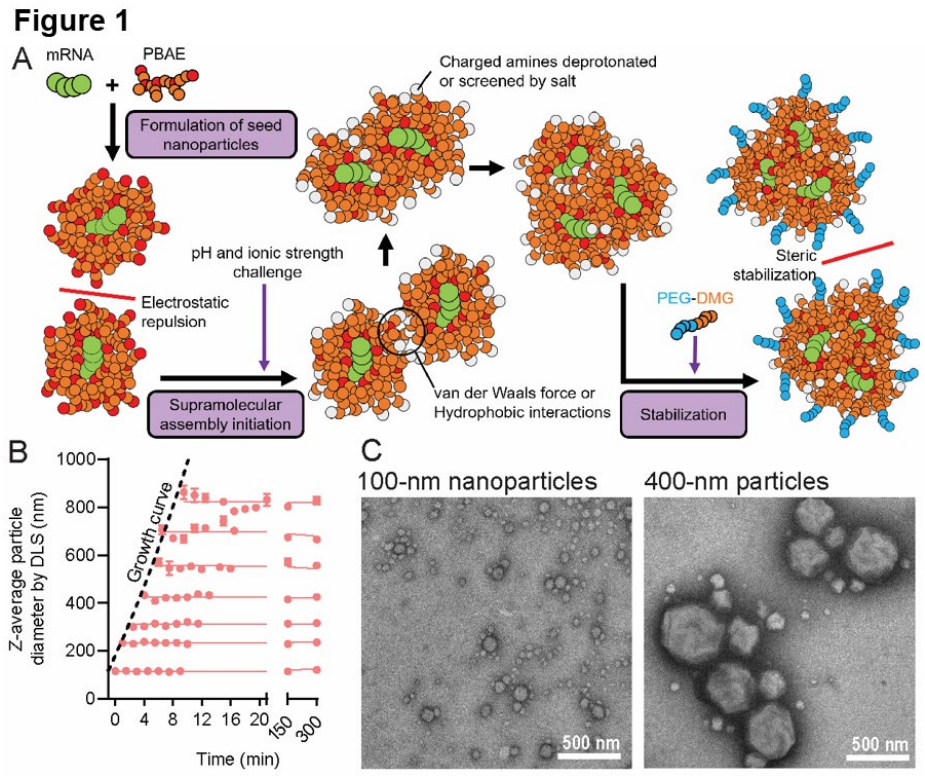

Figure 2

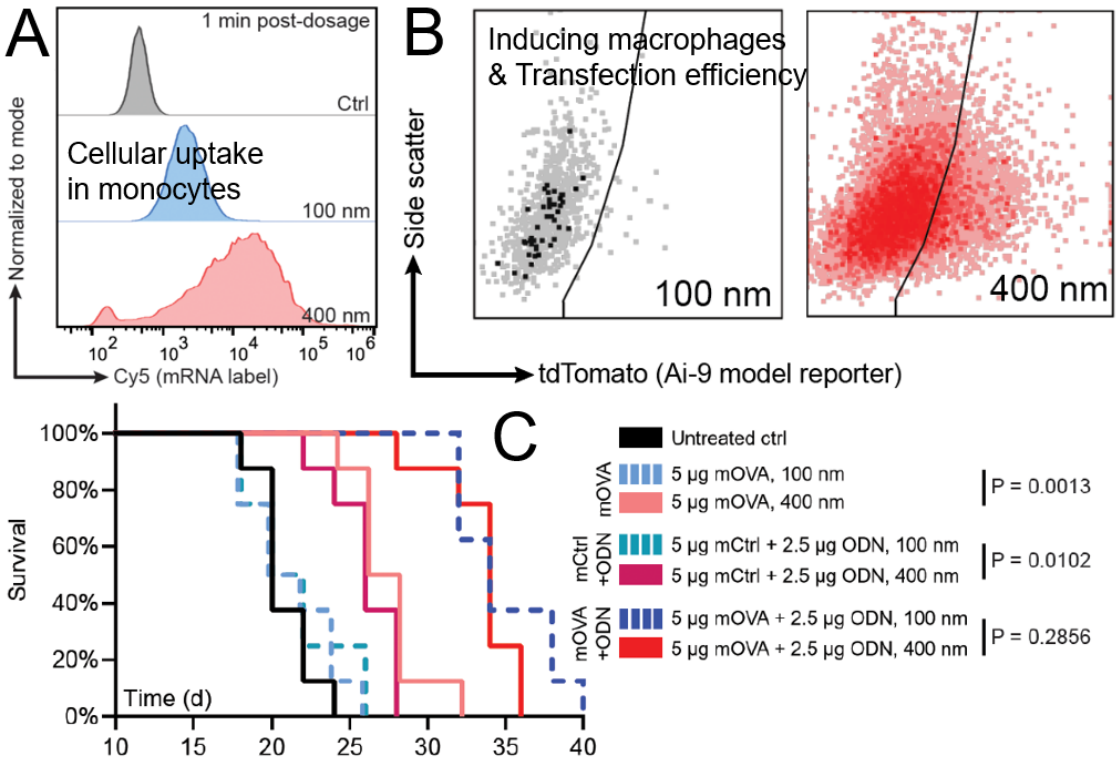


486 CS1 CAR Binds to Multiple Myeloma-Specific Isoform to Enable Precise Tumor Targeting

Vibhuti Vyas[1], Ryan Urak[2], Brenna Gittins[2], Zhiqiang Wang[2], Christian Huynh[2], Lawrence Stern[2], Daniel Rossi[3], Mary Clark[4], Stephen Forman[2], Xiuli Wang[2]
[1]City of Hope National Medical Center, Duarte, CA, [2]City of Hope, Duarte, CA, [3]Beckman Research Institute of the City of Hope National Medical Center, Duarte, CA, [4]City of Hope Beckman Research Institute

Multiple myeloma (MM) is a common hematological malignancy, with approximately 36,000 new cases diagnosed annually in the United States. Although novel therapies such as chimeric antigen receptor (CAR) T cells have shown promise in treating MM, achieving durable remission remains challenging. We developed CAR T cells targeting SLAMF7 (CS1) using a single-chain variable fragment (scFv) derived from the humanized monoclonal anti-CS1 antibody, HuLuc63 (elotuzumab). Although elotuzumab is a well-established therapy for MM, developing a CS1-targeting CAR platform has been hindered by fratricide during CAR T cell manufacturing due to expression of CS1 by a subset of T cells. However, our CS1-CAR T cells did not show evidence of fratricide, given their comparable expansion to mock-transduced T cells, and had potent anti-MM activity. Moreover, CD4/CD8 ratios remained stable, and a soluble version of our CS1 scFv did not bind to or induce cytotoxicity of T and NK cells from healthy donors or patients with MM. To investigate the specificity of our CS1-CAR, we incubated our soluble CS1 scFv with neoplastic MM cells from patient bone marrow and found that the CS1 scFv selectively bound to dominant light chain-positive MM tumor cells. We confirmed via co-immunoprecipitation that our soluble CS1 scFv bound to the MM cell line MM.1S, but not to other CS1-expressing cells, including peripheral blood mononuclear cells (PBMCs), CD19-targeted CAR T cells, or CS1-CAR T cells. Notably, there are 10 isoforms of CS1 generated by alternative splicing that vary in expression of constant (C-) and variable (V-) domains. Using a cellular microarray assay, we determined that our CS1-CAR specifically bound to CS1 isoform 6, which uniquely contains both C- and V-domains and is the isoform expressed by MM.1S cells but not PBMCs or T cells. For functional validation, we used CRISPR technology to knock out CS1 in MM.1S cells and subsequently re-expressed various isoforms. Our CS1-CAR T cells selectively targeted MM.1S cells expressing isoform 6 but not those expressing other CS1

isoforms. Through protein modeling, we determined that our CS1-CAR specifically binds to the C-domain of isoform 6 and that removing the V-domain causes conformational changes that prevent binding.

In conclusion, our CS1-CAR is highly selective for a tumor-specific CS1 isoform and does not induce fratricide during manufacturing. By targeting a tumor-specific CS1 isoform, this CAR spares normal T cells and enables the successful generation of clinical doses without CS1 knockout, which we are currently testing in a phase 1 clinical trial (NCT03710421). These findings provide valuable insights into CS1-CAR function, isoform-specific targeting, and broader considerations for CAR design in other cellular therapies.

487 A human cell-based platform for testing olfactory ensheathing cells as vectors for cancer gene therapy in hiPSC-derived brain-glioma assembloids

Elie Roumieh[1], Nicolas Bravo-Vasquez[2], Tianhe Xiao, Pierre Repiton[2], Emilio Di Ianni[2], Koen Breyne[3], George Scangas[4], D. Cristopher Bragg[1], Xandra Breakefield[1]
[1]Massachusetts General Hospital, Charlestown, MA, [2]Massachusetts General Hospital - Boston, MA, Charlestown, MA, [3]Massachusetts General Hospital and Harvard Medical School, Charleston, MA, [4]Massachusetts Eye and Ear Infirmary, Boston, MA

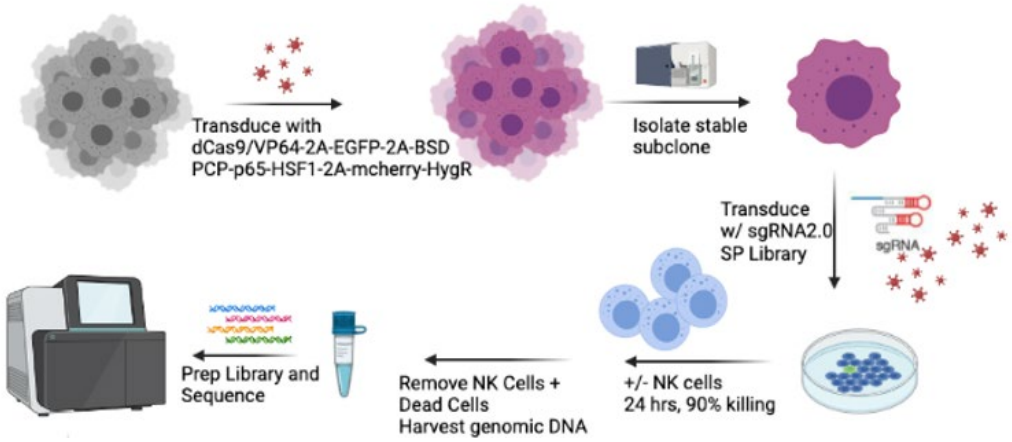
Olfactory ensheathing cells (OECs) are a hybrid glial cell population enriched in the olfactory bulb and nasal mucosa. Previous studies have reported that OECs may traffic through the brain and accumulate at sites of tumorigenesis, suggesting their potential to serve as vehicles for delivering therapeutic transgenes to CNS neoplasms. The goal of this study was to further characterize these properties in mucosal OECs, as these cells could potentially be obtained from patients and engineered for personalized cell-based therapies. As a first step, we confirmed the potential migratory capacity of endogenous mucosal OECs in a mouse model bearing glioma cells implanted within the brain. To selectively label mucosal OECs, Ai9 mice bearing a Cre-activated reporter received nasal injections of an AAV vector encoding Cre recombinase under the transcriptional control of *MPZ*, which encodes a canonical marker of OECs. Brains were collected and sectioned for analysis after 2 weeks post-inoculation. Within sections of brain parenchyma, we detected significant clustering of *MPZ*-Cre(+) cells surrounding the implanted tumors. Based on this observation, we next established a cell culture platform for evaluating human mucosal OECs in a human brain tissue model. Nasal biopsies from the superior turbinate were obtained from de-identified discarded tissue from human subject volunteers, and tissue was dissociated to generate mixed cultures of mucosal cells. The isolation protocol was validated in parallel by culturing olfactory bulbs dissected from 8–10-week-old mice. Immunostaining of the primary cultures from both human mucosa and mouse olfactory bulb revealed cells co-expressing known markers of OECs, including the canonical OEC markers, p75NGFR and MPZ, as well as S100beta, N-Cadherin, NCAM, and FAPB7. To isolate putative OECs, cultures were expanded over 2 weeks and then subjected to immunopanning with antibodies against either p75NGFR or MPZ. Both strategies successfully isolated mucosal and olfactory bulb cell populations that were double positive for both OEC markers. These primary OECs exhibited robust expansion in culture, successful cryopreservation and recovery, and efficient transduction with lentiviral vectors bearing transgene reporters of interest. To develop a human brain tissue model in which the effects OECs could be evaluated, a human induced pluripotent stem cell line derived from a healthy control individual was differentiated and matured over two months to generate cerebral organoids (Cos). At day 52, COs were co-cultured with glioma cells stably transduced with mCherry. After six days, the resulting assembloids were fixed and sectioned for image analysis, revealing significant invasion of the cortical organoid structure by the mCherry (+) glioma cells. Taken together, these brain-glioma assembloids provide a human cell-based platform for characterizing the time course by which mucosal OECs traffic through cortical tissue to accumulate around tumor cells, the nature of OEC:tumor interactions, and the efficacy of OEC-delivered therapeutic factors in limiting tumor growth. Functional studies to assess these parameters in OECs are currently ongoing.

488 Surfaceome CRISPR Activation Screens to Delineate Determinants of Natural Killer Cell Killing towards Cancer Cells

Xiaotong Wang[1], Ravi Dinesh[2], Imran Mohammad[3], John Sunwoo[2], Le Cong[4]
[1]Stanford University, Palo Alto, CA, [2]Stanford University, Stanford, CA, [3]Department of Otolaryngology—Head and Neck Surgery, Stanford University School of Medicine, Stanford, CA, [4]Stanford University Stanford, California

Major advances in tumor control have recently been achieved by targeting immune inhibitory signaling pathways. Natural killer (NK) cells are crucial for cancer immune surveillance due to their robust function and intrinsic anti-cancer activity. The responses of NK cells to cancer or infected cells are determined by integration of signals from germline encoded inhibiting and activating receptors engaged with cognate ligands on cancer cells. While NK cells offer protection against emerging tumors, they can also become dysregulated in response to signals from cancer cells and associated stroma in the tumor microenvironment. CRISPR screens have been applied to identify factors that control the sensitivity of cancer cells killing by NK cells. However, these studies were usually conducted on genome-wide scale, which is noisy to identify real hits, and in a loss-of-function way, which can only detect effect of genes that are expressed in the cell lines used.

Here we perform gain-of-function CRISPR screens in K562 and HGC27 cancer cells co-cultured with NK cells, using a surface protein gRNA library to uncover novel ligands across human cancers that can increase resistance or sensitization of tumor cells to NK cell killing. The Synergistic Activation Mediator (SAM) system was utilized to offer a high level of gene activation, and 3567 genes that have been shown through systemic analysis to comprise the cancer surfaceome were included in the library. We validate genes from our screen using arrayed cDNA overexpression in addition to knockouts in cell lines with endogenous factor expression and demonstrate a role for *SPN*, *CD4*4, *CD24*, and *PDPN* in mediating cancer cell resistance. Using NSG mice with transgenic expression of IL-15 (NSG-IL15) we further show that knocking out the above genes can enhance the NK cell killing towards tumor cells *in vivo*. Taken together, our results demonstrate the power of gain-of-function screening to identify novel targets for improved NK cell-based immunotherapy.



489 Attenuating Inflammation in Midbrain Dopaminergic Neurons through TNF-Responsive Synthetic Receptors

Joanne Lee[1], Hannah Brien[1], Nicole Marguerite[1], Nicholas Schulze[2], Ethan Lippmann[1], Jonathan Brunger[1]
[1]Vanderbilt University, Nashville, TN, [2]Washington University in St. Louis, St. Louis, MO

Introduction:
Parkinson's disease is a pervasive and damaging neurodegenerative disease, affecting more than 10 million worldwide, with treatment costs totaling to nearly $52 billion a year in the U.S. The main cause of Parkinson's disease is the death of dopamine producing cells, midbrain dopaminergic (mDa) neurons, in the brain. Current treatments involve Levodopa, a dopamine precursor medication that helps to replace this vital neurotransmitter, but over time, this medication loses its effectiveness. To address this, researchers have begun investigating transplantion of mDa neurons derived from induced pluripotent stem cells (iPSCs) to replace disease-related neuron loss. This

strategy has shown promise, but up to 90% of mDa neurons die within a week after transplantation due to inflammation caused by the transplantation process. A major cause of this is increased susceptibility of mDa neurons to the pro-inflammatory cytokine TNF-a (TNF). Here, we present an approach to ameliorate mDa neuron death by engineering them with TNF-sensitive synthetic receptors to combat inflammatory TNF in the environment through production of therapeutic proteins, like cytokine antagonists.

Materials and Methods:
Our system leverages a synthetic intramembrane proteolysis receptor (SNIPR) platform to program cellular responses to cues in their microenvironment. SNIPR is a synthetic receptor that regulates ligand-dependent transcriptional programs in cells through user-defined recognition motifs and transcription factors. By exchanging extracellular and intracellular domains, we can produce custom receptors that can sense a variety of ligands and respond in an orthogonal manner. Here, we engineered differentiated mDa neurons with SNIPR receptors to respond to TNF and produce therapeutic proteins.

Results and Discussion:
KOLF2.1J iPSCs were differentiated into mDa progenitor neurons through an established 11-day protocol. They were then lentivirally transduced with a TNF-sensitive synNotch receptor and a response element for either reporter outputs, like mCherry protein and firefly luciferase, or therapeutic outputs, like soluble TNF receptor 1 (sTNFR1), a TNF antagonist. After 72 hours of TNF treatment, engineered mDa neurons were fixed and stained for progenitor markers (Fig. 1A). Engineered neurons showed hallmarks of mDa progenitor differentiation after lentiviral transduction. The SNIPR receptor demonstrated potent reporter activation, in the form of firefly luminescence and mCherry fluorescence, in response to TNF treatment (Fig. 1B and 1C). Significant production of the therapeutic protein sTNFR1 was measured as well, demonstrating that a cytokine antagonist can be produced in response to a native inflammatory marker by an engineered mDa neuron (Fig. 1D).

Conclusions:
Here we present an innovative method to address transplantation-induced inflammation in mDa neurons through a TNF-sensitive synthetic receptor. We successfully engineered neurons that retained mDa progenitor markers and showed significant activation in response to a native cytokine. Up to 30 ng/mL of a cytokine antagonist was produced, which, based on prior work, could provide a measurable benefit. Further work will involve *in vitro* testing to quantify reductions in inflammation and cell death via inducible TNF antagonism as well as *in vivo* implantation of engineered mDa neurons.

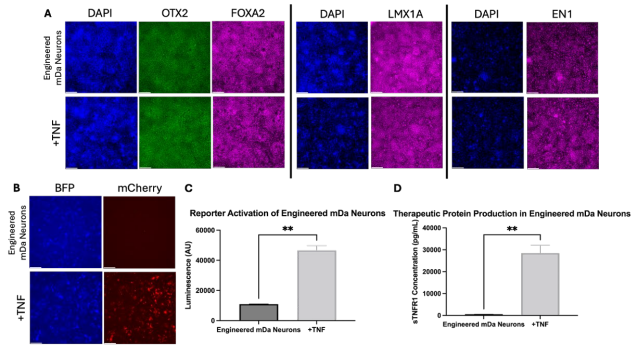


Fig. 1: A. Staining for the mDa neuron progenitor markers, OTX2, FOXA2, LMX1A, and EN1, for engineered mDa neurons with and without treatment with 50 ng/mL of TNF. A DAPI nuclear counterstain is included for visualization of cells. LMX1A and EN1 markers were stained and imaged in separate wells. B. mCherry reporter activation of engineered mDa neurons exposed to TNF. Neurons are engineered with a constitutive BFP marker for ease of visualization. C. Engineered mDa neurons treated with TNF show a significant increase in reporter firefly luminescence compared to control engineered neurons. D. Therapeutic protein, sTNFR1, production is significantly increased in engineered mDa neurons treated with TNF. Scale bar = 200 µm. (**p<0.01, Student's t-test with Welch's correction).

490 Oncolytic Herpes Simplex Virus and Radiation Therapy Synergize with IGF1R-Targeted Therapy to Enhance Glioblastoma Treatment

Alexandra Miller[1], Min Hye Noh[2], Jin Muk Kang[2], Grace Nguyen[2], Minxin Huang[1], Ji Yeon Kim[1], Amanda Kouaho[1], Yoshihiro Otani[3], Hiroshi Nakashima[4], E Chiocca[5], Tae Jin Lee[6]*, **Ji Young Yoo[6]***

**Corresponding Author*

Purpose:
We recently uncovered a novel mechanism of resistance to oncolytic herpes simplex virus-1 (oHSV) therapy, where infection stimulates the secretion of Insulin-like Growth Factor 2 (IGF2), subsequently activating Insulin-like Growth Factor-1 Receptor (IGF1R) signaling. This activation contributes to resistance against radiotherapy (RTx), establishing IGF1R as a key marker of poor RT response. In this study, we investigated the therapeutic potential of combining IGF1R blockade with oHSV and RTx to overcome resistance and enhance treatment efficacy.

Experimental design:
Western blotting, MTT assay, colony formation assay, and flow cytometry were performed to investigate the mechanism of IGF1R activation and its impact on cytotoxicity. Viral replication was assessed using Cytation imaging and plaque formation assays. The synergistic interaction of the triple combination therapy—including oHSV, RTx, and IGF1R blockade (e.g., OSI-906 or PPP)—was quantified using SynergyFinder analysis. Orthotopic mouse models were utilized to evaluate antitumor efficacy, with survival outcomes analyzed using Kaplan-Meier curves and the two-sided log-rank test.

Results:
oHSV treatment robustly activates IGF1R signaling in vitro and in vivo, thereby sensitizing tumors to IGF1R blockade. While IGF1R-targeting therapies show limited efficacy as monotherapy, their combination with oHSV significantly enhances cytotoxicity in all tested breast cancer and glioma cell lines and primary GBM cells compared to either agent alone. This effect is accompanied by a dose-dependent increase in PARP cleavage and caspase-3 activity. Additionally, RTx-induced IGF1 secretion further amplifies IGF1R activation, leading to increased phosphorylation of eIF2α and upregulation of YAP1 in combination with oHSV. The triple combination of oHSV, RTx, and IGF1R blockade exhibits strong synergy in breast cancer and glioma cells in vitro. It demonstrates enhanced anti-tumor efficacy in orthotopic breast cancer and GBM tumor models in vivo.

Conclusions: Our study provides preclinical evidence for the efficacy of a triple combination therapy of oHSV, RTx, and IGF1R blockade, supporting its potential for future clinical evaluation in patients.

491 Adenine Base Editing Rescues Dravet Syndrome in Mice

Andrew Nelson[1], Sophie Hill[2], Matthew Simon[3], Holt Sakai[4], Jun Xie[5], Alexander Sousa[4], Meirui An[6], Guangping Gao[5], Cathleen Lutz[3]*, Ethan Goldberg[7]*, David Liu[8]*

Dravet syndrome (DS) is a severe neurodevelopmental disorder characterized by drug-resistant epilepsy, temperature-sensitive seizures, cognitive impairment, and a high incidence of sudden unexpected death in epilepsy (SUDEP). DS is caused by loss-of-function variants in *SCN1A*, which encodes the voltage-gated sodium channel α subunit Nav1.1. Current approved treatments for DS are focused on symptom management and do not address its root cause. Here, we describe the use of adenine base editing (ABE) to directly correct $SCN1A^{R613X}$, a mutation documented in multiple DS patients. In cell culture, we identified ABE strategies to efficiently correct R613X in engineered homozygous $SCN1A^{R613X}$ HEK293T and Neuro-2a cells (72% and 92% correction, respectively). We used a dual-AAV9 approach to deliver an optimized ABE system to $Scn1a^{R613X/+}$ mice, which

recapitulate key DS pathologies. AAV9-ABE treatment resulted in high editing efficiency at both the genomic (59%) and transcriptomic (97%) levels in bulk brain cortices of P0 treated mice. Brain slice electrophysiological assays of ABE-treated mice revealed that parvalbumin-expressing inhibitory neurons displayed restored excitability and function, with an average 1.7-fold improvement in maximum instantaneous firing rate over untreated controls. Untreated *Scn1a*$^{R613X/+}$ mice undergo febrile seizures at P18-21 at an average core body temperature of 40°C, whereas ABE-treated mice do not experience febrile seizures up to 42.5°C (108.5°F; **Figure 1**). In a 45-day survival study, we observed substantial rescue from SUDEP in ABE-treated mice, with 90% survival at P45 compared to 30% in vehicle-treated control mice (**Figure 2**). These findings represent the direct correction of a common genetic cause of DS, establish a platform to correct *SCN1A* mutations with ABE, and suggest the potential of future precision genome editing treatments for DS.

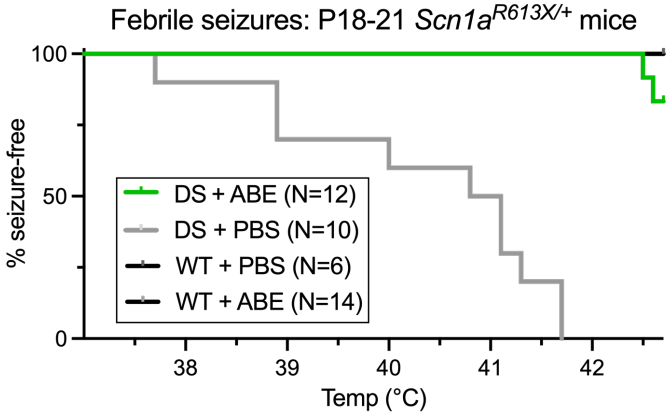

Figure 1 - Febrile seizures are ameliorated by ABE treatment. In heated cage assays, 10 of 12 ABE-treated DS mice did not experience seizures despite elevated core body temperatures. All vehicle-treated DS mice experienced febrile seizures at an average core body temperature of 40°C.

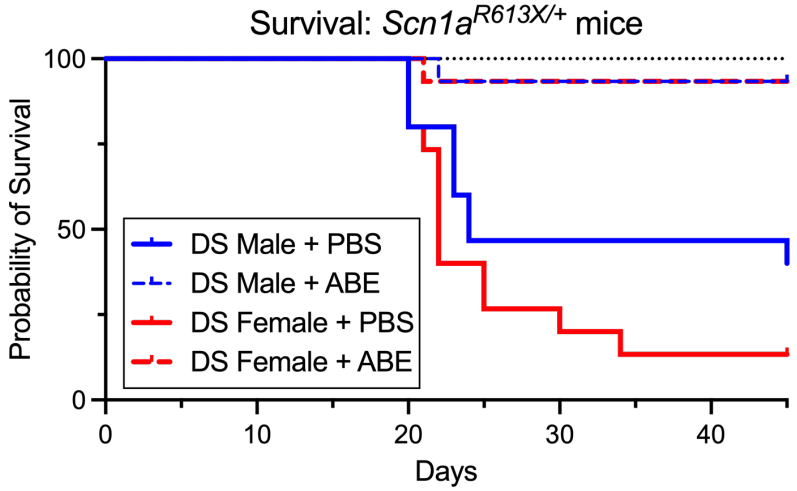

Figure 2 - ABE treatment rescues DS mice from SUDEP. Mice treated with AAV9-ABE or PBS at P0 by intracerebroventricular injection (N=15/group/sex).

492 Enhancing Truncation Event Prediction in AAV Vector Genome Designs Through Advanced Deep Learning

**Corresponding Author*

Truncation events in recombinant adeno-associated virus (rAAV) vector genomes remain a significant obstacle in gene therapy, leading to reduced therapeutic efficacy, increased toxicity, and higher production costs. These events are driven by complex sequence features, secondary structures, and replication dynamics, yet the underlying molecular determinants remain poorly understood. We hypothesized that a deep learning (DL)-based model leveraging diverse genomic features could predict truncation hotspots in rAAV genomes with high precision, enabling the rational design of more efficient and reliable vectors. To test this hypothesis, we curated a comprehensive dataset of rAAV sequences obtained from single molecule, real-time (SMRT) and nanopore platforms used to captured high-resolution, genome-wide truncation events. The vectors encompass single-stranded (ssAAV) and self-complementary (scAAV) vectors, diverse promoters, transgenes, and sequence lengths spanning from 2.5 kb to 5 kb.

A robust bioinformatics pipeline was employed to normalize sequencing data, filter palindromic reads that result from truncation events, and extract critical features such as GC content, free energy states of DNA secondary structures, and nucleotide composition. These refined inputs provided a strong foundation for training the predictive model. We developed a multi-output DL model integrating convolutional neural networks (CNNs) and bidirectional gated recurrent units (Bi-GRU) to simultaneously predict normalized truncation counts (regression) and classify truncation signals (classification). Rigorous evaluation demonstrated that the model was accurate at identifying truncation-prone regions across diverse vector designs, with predictions closely aligning with observed patterns in benchmark constructs.

Importantly, this work has the potential of highlighting molecular drivers that can be targeted for rational optimization of rAAV vectors. By advancing our understanding of truncation mechanisms, this study establishes a transformative approach to streamline vector development and enhance the reliability of next-generation rAAV-based therapies.

493 A New AAV Manufacturing Platform with *in Cellulo* Replication of Plasmid DNA in HEK293 Cells

Introduction:
Triple transfection of HEK293 cells is the most widely used method for producing recombinant adeno-associated virus (rAAV), a leading vector for human gene therapy. This process involves co-transfecting three plasmids at approximately equal molar or mass ratios: pHelper, which provides the human adenovirus serotype 5 (Ad5) helper genes; pRep/Cap, which expresses the AAV *Rep* and *Cap* genes; and pGOI, which harbors a therapeutic gene-of-interest (GOI) cassette flanked by AAV inverted terminal repeats (ITRs) **(Figure)**. Despite its tremendous success, this method faces several challenges, including high plasmid demand, suboptimal rAAV titers, and alarming vector impurities. Here, we introduce a new **AAV** manufacturing platform featuring **P**lasmid DNA *in* ***C****ellulo* **R**eplication in HEK293 cells (**AAVPCR**). AAVPCR comprises three plasmids: the same pHelper used in triple transfection; RP (replication plasmid), which expresses Ad5 polymerase (Pol) and precursor terminal protein (pTP) under the control of a bi-directional promoter (BiP), along with the meganuclease I-SceI directed by the CBA promoter; and TP (template plasmid), which carries I-SceI restriction site and Ad5 ITR-flanked *Rep/Cap* along with GOI **(Figure)**. Upon co-transfection into HEK293 cells, TP is linearized by I-SceI and *Rep/Cap* is replicated by the

Ad5 replication machinery consisting of Ad5 Pol, pTP, and DNA-binding protein (DBP) from pHelper *E2A* gene (DNA cannot be replicated without being linearized or flanked by Ad5 ITRs). By leveraging this *in cellulo* replication process, only a minimal amount of TP is needed to generate abundant *Rep/Cap* copies that support robust rAAV production, thereby greatly reducing the plasmid requirement **(Figure)**.

Results:
Using *EGFP* as a model transgene, we demonstrated that AAVPCR substantially reduced plasmid demand and improved vector purity compared with triple transfection: (1) *Rep/Cap* genome was amplified approximately 200-fold during the rAAV production phase, allowing a 33- to 100-fold reduction in TP mass input while still generating comparable rAAV titers; (2) The full capsid ratios in crude lysates, determined by ddPCR of the genome titer normalized to ELISA capsid titer, increased from 9.8% to 40.7% for rAAV2 and from 16.3% to 34.9% for rAAV5; (3) Prokaryotic backbone DNA encapsidation was reduced from 3.8% to 0.48% for rAAV2 and from 6.5% to 0.32% for rAAV5. Notably, AAVPCR effectively packaged non-permissive transgenes, such as *GPR78*, which are incompatible with triple transfection. AAVPCR boosted the AAV2.GPR78 titer by 16.4-fold, reaching 44% of *EGFP* control. Moreover, the full capsid ratio of AAV2.GPR78 at harvest was increased by around 10-fold, from 6.1% in triple transfection to 59.4% in AAVPCR.

Conclusion:
AAVPCR first demonstrates the proof-of-concept that plasmid DNA segments can be engineered to be selectively replicated by reconstituted Ad5 replication machinery during rAAV production phase. The strategy of *Rep/Cap* replication enables high-purity, high-titer rAAV production with an unprecedented low plasmid requirement. Since pHelper and RP are universally used in all rAAV preparations, and TP requires 33- to 100-fold less material than its triple transfection counterparts, AAVPCR significantly accelerates the rAAV production process and paves the way toward economical and robust off-the-shelf AAV manufacturing. Gene therapy involves introducing, removing, or modifying genetic material within a patient's cells to treat or prevent disease. Often the genetic material being delivered is a protein-coding transgene aimed to correct expression of a missing or mutated gene. One of the key challenges in gene therapy is achieving optimal expression of the protein-coding transgene, which can be partially addressed by codon optimization. This technique employs modifying the nucleotide sequence of the encoded transgene to reflect the codon usage patterns of the host species. Such modifications can enhance the efficiency and effectiveness of the gene therapy. While codon look up tables based on tRNA abundances have been historically used for determining codon usage, we aimed to address this issue using deep learning-based recurrent neural networks. We hypothesized that highly expressed genes might display the most efficient codon usage patterns. Algorithms were trained with coding sequences of >2,000 top expressed genes from mouse brain, liver, and muscle. Additional algorithms were also trained with transcripts of secretory genes to develop a codon-optimization pipeline for secreted transgenes. Once trained, these algorithms were then utilized to predict optimized coding sequences of randomly selected benchmark genes for evaluation of model performance. Predicted sequences showed novel codon usage patterns as compared to wildtype sequences and those obtained using a publicly available optimization tool. We observed that sequences predicted by our algorithms have an improved codon adaptation index, decreased usage of rare codons, and a selective pool of effective codon pairs. Additionally, we observed that our models result in sequences with lower CpG dinucleotide content, an unintended outcome that could be beneficial for therapeutic designs. Our algorithms also matched codon utilization with tRNA abundances without being trained with this information, pointing towards another hidden feature in codon usage of highly expressed genes. AAV9-serotyped vectors with DL-optimized EGFP versions enhanced transgene expression following intravenous and intramuscular administration in mice. Elevated expression and augmented biodistribution was observed in the liver, skeletal muscle, brain, heart, lung, and kidney. Codon optimization also improved expression in neurons and astrocytes of brains and in glomeruli of the kidney cortex and medulla. When applied to SMN1, the therapeutic transgene for spinal muscular atrophy (SMA), our muscle-optimized vector displayed higher expression as compared to the wildtype design, or those defined using publicly available optimization tools. For secreted factors, such as A1AT and factor IX, our algorithms produced similar enhancements in expression. Retaining the wild-type signal sequence, while codon-optimizing only the mature peptide, led to increased transgene production. These findings highlight the application of machine learning-based approaches to independently identify novel codon usage patterns merely from mRNA coding sequences, resulting in improved transgene expression that can be beneficial to the field of gene therapy.

495 Delivery of miRNA by Self-Complimentary AAV Provides ATXN1 Knockdown in SCA1 Mice and Supports Therapeutic Translation

Ryan Giovenco[1], Ellie Carrell[2], Shareen Nelson[1], Luis Tecedor[1], Elena Lysenko[1], Megan Keiser[3], Beverly Davidson[1]
[1]Children's Hospital of Philadelphia, Philadelphia, PA, [2]Virginia Commonwealth University, Richmond, VA, [3]Ohio State University, Columbus, OH

Spinocerebellar ataxia type 1 (SCA1) is a neurodegenerative disease caused by an expanded CAG trinucleotide repeat in the ATXN1 gene. The accumulation of mutant ATXN1 leads to progressive Purkinje cell degeneration and motor deficits. As a therapeutic approach, we have developed miS1, a microRNA (miRNA) targeting ATXN1 transcripts. Direct delivery of AAV encoding miS1 to the deep cerebellar nuclei has been shown to prevent and reverse disease phenotypes in multiple mouse models of SCA1[1-3]. In support of an IND application, we performed a

long-term study using AAV-miS1 in non-human primates. Unlike in mice, we observed cerebellar toxicity that was attributed to inverted terminal repeat (ITR) promoter activity. Interestingly, this activity was abolished in a dual therapy AAV where miS1 was co-expressed with the ATXN1 homolog, ATXN1L, supporting the remediation of toxicity by including a transgene driven by an RNA polymerase II promoter[4]. Here, we looked to optimize our approach further, testing miS1 in a self-complimentary AAV (scAAV) driven by an RNA polymerase II promoter and in multiple combinations with ATXN1L. Validation of scAAV-miS1 *in vitro* showed similar levels of knockdown and miRNA production to previous constructs. In SCA1 mice, scAAV-miS1 showed an improved reduction of ATXN1 compared to our previous AAV-miS1 virus and a reduction of inflammatory markers AIF1 and GFAP. Importantly, scAAV.miS1 packaged efficiently and generated high virus titers, reducing cost and mitigating any constraints on dosage. Combined with our extensive prior work, these results support a translatable SCA1 therapeutic and warrant further studies. References: 1. Keiser, M. S et al., Neurobiology of Disease 2013. 2. Pyruvate dehydrogenase (PDH) complex deficiency (PDHD) is a severe debilitating childhood mitochondrial disorder. PDH complex plays an integral role in glucose metabolism and comprises of three enzymatic subunits with the gene for the E1 α-subunit is located on the X-chromosome (*PDHA1*). Patients display developmental delay, hypotonia, hypertonia, dystonia, ataxia, and seizures. There are currently no disease-modifying therapies, leading to poor outcomes with mortality and morbidity. A brain-specific mouse model for PDHD has been reported, where the *Pdha1* KO mice display, neurological delay, ataxia, seizures, rapid weight loss, premature death by P21, neuropathology, abnormal metabolite levels, and reduced PDH enzyme activity.

AAVs have been used successfully in pre-clinical and clinical studies for severe neurological disorders. We have developed a novel gene therapy treatment for PDHD, using an AAV vector encoding human *PDHA1* gene driven by a CAG promoter. In this study we aimed to test AAV9 and AAV-F in a clinically relevant *Pdha1* KO mouse model, to assess the effects of AAV-mediated gene therapy on amelioration of the disease phenotypes. We administered titre-matched AAV9 and AAV-F gene therapy to newborn *Pdha1* KO mice via intracerebroventricular delivery. We observed 75% survival for AAV-F (n=8), 30% for titre-matched AAV9 therapy (n=10), and 0% for PBS control-treated *Pdha1* KO (n=10) mice over 100 days of development. In addition, we administered AAV9 at a higher dose (one log higher) and observed 80% survival, compared to 0% for PBS control-treated *Pdha1* KO (n=10) mice over 100 days of development. Behavioural assessment at P18 and P30 revealed no significant difference to wild-type (WT) controls however, by experimental endpoint (P100), the remaining AAV-F or AAV9 treated mice displayed a significant reduction in locomotion function compared to WT mice. Furthermore, we observed comparable PDH complex enzyme activity and relative metabolites in the brain for AAV-F and high dose AAV9 to WT control mice. Neuropathology assessment of the treated brains revealed a significant improvement in inflammation and neuronal loss in the olfactory bulb, prefrontal cortex and cortex in both groups. Cortical thinning was also significantly reduced after AAV-F and high dose AAV9 treatment. In addition, AAV-F revealed significantly lower transgene expression in the liver compared to high dose AAV9. We have shown by administering AAV-F one log lower to AAV9, we can observe a similar therapeutic effect in the CNS, whilst de-targeting the liver and therefore reducing potential off-target toxicities. Our proof-of-concept study so far has shown promising data for AAV-mediated therapy and as a potential treatment for patients with PDHD.

497 Safe and Efficient Editing of Novel CRISPR-Cas Ribonucleoprotein Complexes Delivered by Engineered Protein Delivery Vehicle

Bang Wang[1], Yuanwei Cao[2], Zihua Jiang[3], Miao Yu[2], Lawrence Ip[4], Ken Chau[4], Zongli Zheng[5]
[1]GenEditBio Limited, Hong Kong, Hong Kong, China, [2]Geneditbio Limited, Beijing, China, [3]Karolinska, Solna, Stockholm, Sweden, [4]Geneditbio Limited, Sha Tin, Hong Kong, [5]City University of Hong Kong, Hong Kong, Kowloon City, Hong Kong

Clustered regularly interspaced short palindromic repeats and associated proteins (CRISPR-Cas) system holds great promise to revolutionize genome editing and therapy in basic and translational settings. Various CRISPR-Cas systems have been explored and engineered, such as CRISPR-Cas9 and CRISPR-Cas12a that belong to Class 2 of CRISPR-Cas system. However, therapeutic applications of these tools are still limited due to potential off-target effects.

To address this limitation, we developed a novel Cas discovery platform combining a tailored protein-based delivery vehicle system. With this new platform, we identified and characterized dozens of novel type II Cas nucleases with diverse PAM restrictions and protein sizes. We next packaged high-fidelity Cas ribonucleoprotein (RNP) complex with an in-house tailored Protein Delivery Vehicle (PDV). The PDV encapsulated nucleases showed generally higher editing potency than plasmid modality delivered by lipofectamine at over ten endogenous loci, and with higher fidelities at tested sites as evaluated by GUIDE-seq. *In vivo* experiments demonstrated that the Cas RNP-PDV achieved saturating editing efficiency in mice's liver. Moreover, off-target profiling revealed a significant reduction in off-target effects in a hepatoma cell line compared to the conventional plasmid-based method. The transient nature of RNP delivery by PDV eliminated prolonged Cas9 exposure, reducing the risk of overloaded DNA double-stranded breaks. Biodistribution study in mice confirmed targeted delivery to the designated liver, with negligible accumulation in off-target tissues. This platform represents a significant advancement in *in vivo* genome editing, offering a safer and more efficient alternative to existing non-RNP-based delivery strategies for real clinical settings. Furthermore, our modular combination allows adaptation to diverse Cas nucleases encapsulated by PDV, broadening applications in cell and genome editing therapy.

498 Addressing the Manufacturing Bottleneck in Gene Therapies Through AAV Production in Whole *Nicotiana benthamiana* Plants

Pranav Mathur[1], Kevin Wong[1], Qingqinh Xie[2], Finley Burns[3], Katarina Dumar[3], Matthew Schafer[3], Jake Connors[3], Daniel Gibbs[1]
[1]Cirsium Biosciences, San Diego, CA, [2]Cirsiumbio, San Diego, CA, [3]Cirsium Biosciences, San Diego

Introduction:
The demand for adeno-associated virus (AAV) vectors is increasing due to their role in gene therapies for various genetic disorders. However, current production methods using mammalian and insect cell systems are costly, slow, and hard to scale, limiting accessibility. High production costs result in multi-million-dollar price tags for approved gene therapies, which are often unaffordable for patients, especially in low- and middle-income countries. With thousands of gene therapies in development, traditional cell culture-based production struggles to meet the growing demand, as it requires specialized facilities and lengthy scale-up times. Moreover, inconsistent vector yields and quality impact clinical reliability, especially for progressive genetic disorders where timely treatment is critical. To address these challenges, we have developed an innovative, plant-based AAV production system that is cost-effective, scalable, reliable, and faster, ensuring wider accessibility to life-saving treatments. We utilize a split-Rep and split-Cap system, where the VP1, VP2, and VP3 capsid proteins, along with the Rep78 and Rep52 proteins, are split across separate plasmids. This approach enhances AAV production efficiency, genetic stability, and scalability while minimizing the toxic effects of high Rep expression levels.

Methods:
Plasmids for AAV9-CMV-GFP production were generated by splitting Cap and Rep proteins across separate plasmids. These plasmids were introduced into *Agrobacterium tumefaciens*, which was used to deliver the vectors into *Nicotiana benthamiana* plants through a transient expression method. The infiltrated leaves were harvested five days later and homogenized. The expression levels of VP1, VP2, VP3, Rep78, and Rep52 were analyzed using western blot and Jess for stoichiometry and relative expression. The performance of the plant-based system was compared to the traditional HEK-293 cell-based method, where Rep and Cap were expressed from a single plasmid.

Capsid titer was measured using ELISA, and Dynamic Light Scattering (DLS) was performed on the purified material using Stunner.

Results:
The natural stoichiometry of AAV capsid proteins is 1:1:10 (VP1:VP2:VP3), but achieving this ratio from a single plasmid is challenging due to competing transcription and translation. By separating VP1, VP2, and VP3 onto different plasmids, their expression levels can be independently controlled, ensuring proper capsid assembly. We observed that fine-tuning the expression of VP1, VP2, VP3, Rep78, and Rep52 from separate plasmids optimized capsid formation, leading to higher AAV vector production efficiency. We consistently produced more than 1e15 AAV capsid particles from just 1kg of plant biomass (approximately 2 liters of plant homogenate for downstream processing).

Conclusion:
This work demonstrates for the first time that plant-based AAV production using a split-Cap and split-Rep plasmid system significantly enhances yield and scalability. This method preserves the natural stoichiometry of AAV vectors, prevents toxicity from overexpression, and reduces recombination issues, resulting in more consistent vector production. Moreover, the split-Cap system potentially allows for the creation of hybrid AAV vectors by mixing and matching VP1, VP2, and VP3 proteins from various serotypes, which could improve tropism and immune evasion in future applications.

499 AAV9 Neutralizing Antibody Seroconversion in Household Contacts Of Participants With Duchenne Muscular Dystrophy Receiving Fordadistrogene Movaparvovec

Doris Leung[1], Barry Byrne[2], Seth Perlman[3], Aravindhan Veerapandiyan[4], Russell Butterfield[5], Heliang Shi[6], **Nayra Gad**[7], Daniel Levy[8]
[1]Kennedy Krieger Institute, Baltimore, MD, [2]University of Florida, GAINESVILLE, FL, [3]University of Washington School of Medicine, Seattle, WA, [4]Arkansas Children's Hospital, Little Rock, AR, [5]University of Utah, Salt Lake City, UT, [6]Pfizer Inc Chesterfield BioTherapeutics Pharmaceutical Science, [7]Pfizer, Rutherford, NJ, [8]Pfizer Reaearch & Development, Merion Station, PA

Introduction:
Fordadistrogene movaparvovec was a candidate disease modifying AAV9 gene-replacement (mini-dystrophin) therapy for Duchenne muscular dystrophy (DMD). Viral vector shedding has been reported in trials of AAV-based gene therapies, but the risk of developing neutralizing antibodies (NAbs) to AAV9 for household contacts of clinical trial participants receiving fordadistrogene movaparvovec is unknown. This study aimed to determine the rate of AAV9 NAb seroconversion in previously seronegative household contacts of participants in phase 2 and 3 trials of fordadistrogene movaparvovec (NCT05429372 and NCT04281485, respectively).

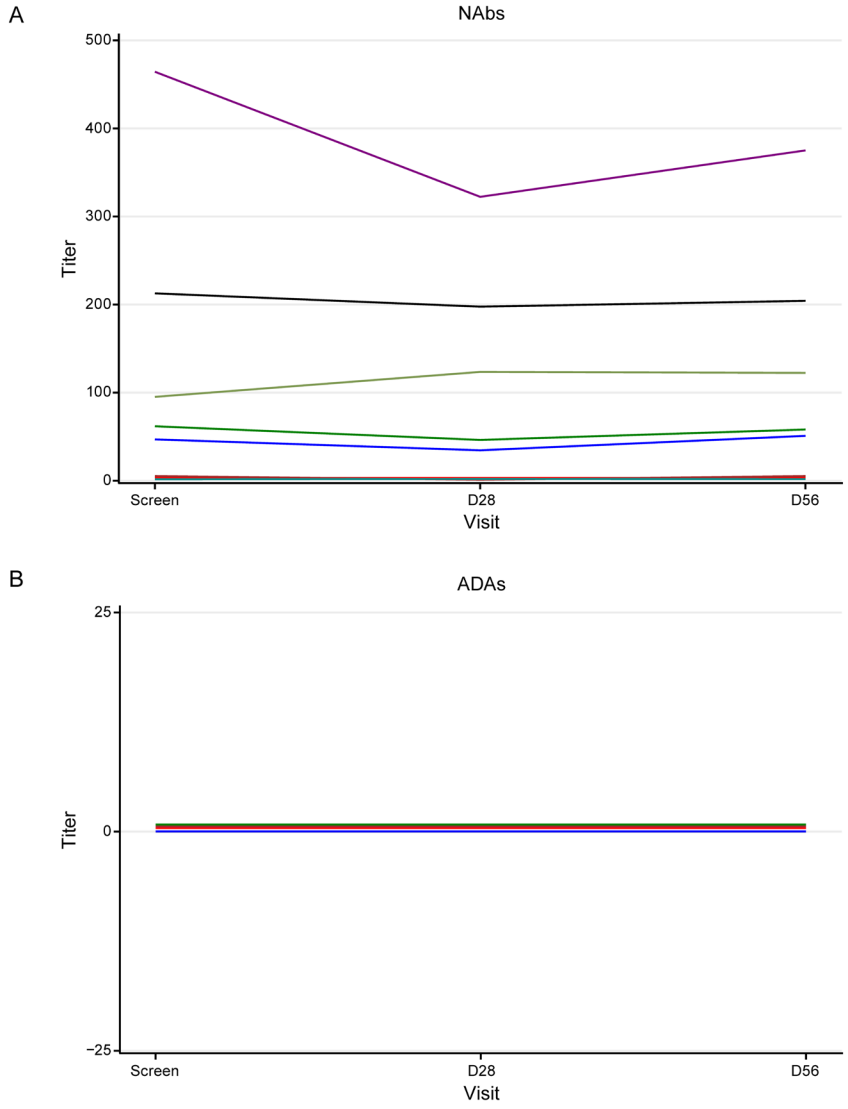
Methods:
The primary endpoint was the development of NAbs to AAV9 in household contacts defined by an increase ≥6-fold above baseline titer after a detectable but negative test (titer ≥1 to <4) at baseline, or development of a titer of ≥6 in those with an undetectable titer (<1) at baseline. The secondary endpoint was development of total binding antibodies (anti-drug antibodies; ADAs) to AAV9 in household contacts defined by a titer of ≥300 in those with a negative test (titer <50) at baseline. Blood samples from household contacts were collected at baseline and at 28 (±8) days and 56 (±10) days after fordadistrogene movaparvovec dosing (single intravenous dose of 2E14 vg/kg) in the clinical trial participant.

Results:
8 household contacts of 5 clinical trial participants receiving fordadistrogene movaparvovec were assessed. All household contacts (8 of 8) had direct contact with the fordadistrogene movaparvovec recipients for each of the first 14 days after infusion. 3 of 8 household contacts had negative NAb titers at baseline, and none of them seroconverted. None of the other 5 household contacts had ≥6-fold increases from their baseline NAb titers. Further, 7 of 8 household contacts had negative ADA titers at baseline and none of them seroconverted. The remaining household contact was unevaluable for ADAs due to a missing baseline sample. The rates of NAb and ADA

seroconversion were therefore 0% (0 of 3 and 0 of 7, respectively). Changes in NAb and ADA immunogenicity over time for household contacts are shown in Figure 1A and 1B, respectively.

Conclusions:
The results of this study indicate that the risk of developing NAbs and ADAs to AAV9 through contact appears to be low in a setting where household contacts have been advised to practice good hygiene. The study results should be interpreted with caution due to the small sample size of 8 household contacts. Specifically, the finding that 0% of household contacts displayed NAb seroconversion was based on results from only 3 individuals, since only 3 household contacts were negative for NAbs at baseline. This study was sponsored by Pfizer. ClinicalTrials.gov: NCT04543357.

Figure 1. Change in NAb and ADA immunogenicity over time.



Each line represents an individual household contact. (**A**) NAb titers below the limit of quantification were imputed as 0; the lower limit of quantification was 1. (**B**) ADA titers below the limit of quantification were imputed as 0; the lower limit of quantification was 50. Although all recorded values were below the lower limit of quantification and considered to be 0, the titer values plotted have been offset between 0 and 1 to allow for visual discrimination between household contacts. ADA, antidrug antibody; D, Day; NAb, neutralizing antibody

Inherited metabolic liver diseases (IMLDs) represent a diverse group of genetic disorders caused by enzyme deficiencies that disrupt essential metabolic pathways, resulting in systemic complications, including severe neurological manifestations. Although neonatal liver transplantation is used to treat certain IMLDs, it presents significant risks for patients, challenges in finding suitable donors, and does not fully address neurological impairment. These limitations highlight the urgent need for alternative therapies targeting both the liver and the brain.

Liver gene therapy holds significant promise; however, its efficacy is limited by risks such as DNA cargo depletion over time and potential insertional mutagenesis. To overcome these challenges, we developed the LTRX lentiviral vector, which improves safety by removing viral cis-regulatory elements. We tested LTRX in a mouse model of Maple Syrup Urine Disease (MSUD), an IMLD characterized by the absence of the mouse Dihydrolipoamide Branched Chain Transacylase (mDBT) gene, a critical subunit of the Branched-Chain Alpha-Keto Acid Dehydrogenase (BCKDH) Complex. This deficiency impairs the metabolism of branched-chain amino acids (BCAAs), leading to their toxic accumulation and resulting in neurological deficits.

Neonatal MSUD mice were treated with LTRX-mDBT at doses of 1.4×10^{11} and 1.0×10^{10} TU/kg, using a liver-specific promoter to restore BCKDH enzymatic activity in the liver. This intervention extended lifespan, improved body weight, and normalized plasma BCAA levels in a dose-dependent manner. Brain metabolomic analysis further demonstrated the correction of BCAA metabolism, including the normalization of neuroactive metabolites and sphingolipids.

In addition, we explored brain-targeted therapy by intracerebroventricular injection of an AAV-mDBT vector (PhP.eB serotype) at a dose of 7.5×10^{9} vg/pup. Unexpectedly, brain-targeted gene therapy alone led to prolonged survival and amelioration of specific CNS metabolites in MSUD mice, despite persistently elevated plasma BCAA levels. This approach also prevented delayed neuromotor development and mitigated the ataxic and hyperactive phenotypes characteristic of the MSUD model. Comparative analysis of brain metabolites from brain-targeted versus liver-targeted gene therapies, as well as untreated mice at different ages, revealed distinct effects of brain DBT expression on redox homeostasis, gamma-glutamyl amino acids, and lactoyl amino acid metabolites. These findings underscore the role of BCKDH in brain metabolism.

In conclusion, LTRX offers a promising approach for liver gene therapy in IMLDs, while brain-targeted interventions may hold promise in addressing neurological manifestations of MSUD. Together, these approaches hold the potential to pave the way for combinatorial therapies that target both hepatic and neurological dysfunctions.

501 Long-term correction of metabolic impairment in a mouse model of Glycogen Storage Disease type III after rAAV gene transfer reveals disease-specific host-vector interactions.

Glycogen Storage Disease type III (GSDIII) is a rare metabolic disorder caused by mutations in the *AGL* gene, leading to the accumulation of abnormally structured glycogen in the liver, heart, and muscles. The hepatic impairment associated with this disease is characterized by chronic liver damage, fasting hypoglycemia, hepatomegaly, elevated liver enzymes, and progressive fibrosis. Disease management is currently limited to dietary restrictions, underscoring the need for effective long-term treatments.

Adeno-associated virus (AAV) gene therapy has demonstrated promise in numerous metabolic disorders, including GSDIII. We recently reported the complete correction of muscle impairment in GSDIII mice and rats using a truncated transgene. However, correcting the metabolic impairment remains a challenge in GSDIII mice. While short-term, partial correction has been achieved, further development of gene transfer technologies is necessary for long-term disease correction.

This study supports the potential of recombinant adeno-associated virus (rAAV)-mediated gene therapy to correct the hepatic phenotype in GSDIII mice ($Agl^{-/-}$), a faithful model of the human liver disease. By tailoring the rAAV vector approach to the model's specific characteristics—such as capsid selection and transgene expression cassette optimization—we achieved sustained correction of hypoglycemia and glycogen accumulation.

Our data indicated that the short-term, complete correction achieved in $Agl^{-/-}$ mice with advanced liver disease was not maintained in the long term. However, an optimized transgene expression cassette, devoid of CpG dinucleotides in both the transgene and promoter sequences, resulted in prolonged transgene expression and metabolic correction at nine months post-injection. Interestingly, despite these advancements, a small subset of mice still exhibited a loss of transgene expression regardless of the optimization.

To investigate potential mechanisms contributing to this loss, we examined hepatocyte proliferation—an established disease manifestation in GSDIII livers—and identified a disease-specific immune response within liver-infiltrating immune cells. Notably, AAV-injected mice showed higher frequencies of immune cells infiltrating the liver including effector and memory lymphocytes, along with increased frequencies of activated CD69+ T cells. . Importantly, this heightened immune activation was observed exclusively in $Agl^{-/-}$ mice and only when the transgene was expressed, suggesting a previously uncharacterized immune activation mechanism in the GSDIII liver, likely influenced by its inflammatory background.

These findings highlight the importance of understanding host-vector interactions to enhance the durability of AAV gene therapy for liver diseases. The GSDIII mouse model serves as a valuable tool for studying these interactions. Furthermore, this research underscores the challenges of achieving stable correction in the presence of chronic liver disease and reinforces the need for continued optimization of gene therapy approaches to ensure lasting therapeutic benefits for patients with liver metabolic disorders.

502 mRNA therapy for Glycogen Storage Disease type 1b.

Genetics and Medicine, ITALY, [5]Moderna, Cambridge, MA, [6]Moderna Inc, Cambridge, MA, [7]Telethon Institute of Genetics & Medicine, Napoli, Italy

Glycogen storage disease type 1b (GSD1b) is an inherited metabolic disorder due to deficiency of glucose-6-phosphate transporter (G6PT) that result in recurrent episodes of life-threatening hypoglycemia, growth retardation, osteoporosis and long-term risk of renal failure and liver cancer. Current treatments focus on managing hypoglycemia by diet. In contrast to GSD1a, GSD1b patients also show neutropenia that causes recurrent infections and inflammatory bowel disease currently treated with Granulocyte colony stimulating factor (G-CSF) injections or sodium–glucose cotransporter 2 inhibitor (Empagliflozin). However, treatments for glucose metabolic defect remain unsatisfactory and more effective therapies are needed. mRNA encapsulated into lipid nanoparticles (LNP) has great potential for therapy of inherited metabolic liver diseases and several clinical trials for various disorders, including GSD1a, are ongoing. In a novel preclinical murine model of GSD1b knock-out for the gene encoding G6PT ($G6pt^{-/-}$ mice), we investigated the efficacy of mRNA replacement therapy. $G6pt^{-/-}$ mice showed a severe phenotype with high perinatal mortality and extensive liver glycogen storage. Glucose therapy by intraperitoneal injections only minimally improved neonatal survival whereas intravenous (IV) injections of mRNA encoding G6PT encapsulated into lipid nanoparticles (LNP-G6PT mRNA) significantly increased survival of $G6pt^{-/-}$ mice. Moreover, IV injections of LNP-G6PT mRNA rescued the fasting-tolerance of $G6pt^{-/-}$ adult mice. Normal blood glucose concentrations were achieved in mice injected with LNP-mRNA as early as at 6 hours post-dosing and the metabolic correction lasted for at least one week after the injection of the LNP-mRNA. In conclusion, our study provides for the first time LNP-G6PT mRNA as potential therapy for GSD1b and might pave the way for a clinical trial in GSD1b patients.

503 3D-printed Highly Porous PLG-based Scaffolds as a Platform for Therapeutic Cell Delivery

Matthew Remy[1], Carolina Bohorquez Fuentes[1], Kirstin Kebo[1], Xin Li[1], Jon Burke[1], Regeant Panday[1], Ramille Shah[2], Rafal Witek[1]

Introduction: Cell-based therapies have gained significant attention in treating several diseases, including Type I Diabetes (T1D) and liver disease. Therapeutic cells have traditionally been delivered via direct infusion or hydrogel encapsulation; however, these strategies have been hindered by the immunological rejection of injected cells, insufficient cell engraftment, and the use of biomaterials that limit cell attachment and nutrient and oxygen diffusion, each of which greatly impact cell viability and function. To address these limitations, scaffolds fabricated from highly porous biomaterials 3D-printed in open-architecture designs may provide a more effective method to deliver therapeutic cells and maintain their function long enough to restore organ function. In this approach, a 3D-printed PLG-based scaffold can be fabricated with an intrafiber porosity that promotes cell attachment, tissue infiltration, and vascularization within the scaffold macropores where cells are seeded. Here, we evaluated the ability of these scaffolds to support the viability and function of seeded therapeutic cells for the treatment of T1D and liver disease.

Materials: Tissue scaffolds were 3D-printed to produce open pore structures with printed fibers having ~80 vol% porosity and a total scaffold porosity of >95 vol%. Primary human islets (PHIs; Prodo Labs) or hepatocytes (PHHs; Thermo Fisher Scientific) were seeded onto scaffolds, evaluated for viability, and implanted into mice to assess the therapeutic function of the cell-seeded scaffolds. For T1D studies, scaffolds seeded with 2750 islet equivalents of PHIs were implanted into the epididymal fat pad of streptozotocin-induced diabetic nude mice. Glycemic control by the implant was assessed across 30 days via changes in blood glucose levels, body weight, and human c-peptide serum levels. For liver disease studies, PHH-seeded scaffolds were implanted into NOD SCID mice for 30 days. Blood was collected weekly to assess viability and synthetic function via quantification of human albumin. In both studies, implants were retrieved at study termination and processed for histology.

Results: For the T1D studies, all PHI-seeded implants showed functional responses to glucose challenge on Day 27, and human c-peptide was present across all timepoints. Furthermore, the PHI-seeded scaffolds reduced blood glucose to normoglycemic ranges for up to 30 days. Following histological processing, PHIs stained positively for

human insulin, indicating the implanted PHIs remain viable and functional within the scaffolds for at least 30 days. For the liver disease studies, hAlbumin was detected in mouse blood at levels equal to those of *in vitro* controls for at least 30 days. In addition, extensive vascular networks within scaffolds were identified ($CD31^+$ and presence of circulating red blood cells) suggesting significant graft vascularization.

Conclusion: The data from this study clearly demonstrate that both PHIs and PHHs can be successfully seeded into highly porous PLG open-scaffolds, maintaining viability and therapeutic functionality for at least 30 days *in vivo*. Notably, the scaffold's intrafiber porosity promotes vascular engraftment and tissue infiltration—critical factors for ensuring long-term cell viability and function. These compelling results pave the way for further exploration of this innovative delivery system and advance the treatment of Type 1 Diabetes (T1D), liver disease, and beyond.

504 Characterization of KRIYA-839, an AAV-based Gene Therapy Providing Insulin and Glucokinase, in Streptozotocin-induced Diabetic Mice

Brandon Burch[1], Pilar Prentiss[1], Uma Karadge[1], William Chappell[2], William Quinn[1], Peter Ross[3], Angela Ambakhutwala[3], Lihong Chen[1], Veronica Jimenez[4], Fatima Bosch[5], Michele Stone[6]
[1]Kriya Therapeutics, Morrisville, NC, [2]Kriya Therapeutics, Inc., Durham, NC, [3]Kriya Therapeutics, Durham, NC, [4]Universitat Autonoma de Barcelona (UAB) ESQ0818002H, Bellaterra, Spain, [5]Universitat Autonoma de Barcelona, Bellaterra - Barcelona, Spain, [6]NA, Morrisville, North Carolina

Type 1 diabetes (T1D) is a chronic, autoimmune disorder characterized by profound insulin deficiency resulting from destruction of insulin-producing β-cells in the pancreas. T1D results in persistent hyperglycemia and increases risks for severe, debilitating complications. Historically, life-long insulin therapy has been the only treatment for T1D. This approach requires multiple daily insulin injections and careful monitoring of blood glucose, which presents a significant patient burden. More recent approaches, including islet transplantation, have shown promise but face significant challenges and often require life-long immunosuppression, which increases risks for opportunistic infections and cancers.

KRIYA-839 is a novel AAV1-based gene therapy providing human insulin (AAV1.hINS) and glucokinase (AAV1.hGCK) that is administered via intramuscular injection and is being developed to treat T1D. Skeletal muscle is responsible for the disposal of around 70-80% of circulating glucose after meals but only around 20-25% during the fasted state (Petersen 2018). In muscle, glucose uptake is regulated by insulin-stimulated and concentration-dependent glucose transport through glucose transporter type 4 (GLUT4) and phosphorylation of glucose by hexokinase II (Printz 1993, Kahn 1996). In patients with T1D, GLUT4 translocation to the plasma membrane and glycolytic flux through hexokinase II activity are both suboptimal due to a lack of circulating insulin, which presents a therapeutic opportunity for KRIYA-839.

Prior investigations have demonstrated improved glycemic control in streptozotocin (STZ)-induced diabetic mice and dogs following intramuscular injection of AAV1-based vectors expressing insulin and glucokinase, with robust glycemic control durably maintained in dogs for up to 8 years (Mas 2006, Callejas 2013, Jaen 2017).

The constituent vectors of KRIYA-839 have been modified from these earlier constructs to optimize safety and efficacy. Injection of KRIYA-839 into skeletal muscle in STZ-induced diabetic mice resulted in improved glycemic control across multiple clinically relevant parameters. After 8 weeks of treatment, all KRIYA-839 treatment groups had significantly improved fasting blood glucose ($p<0.001$) and HbA1c levels (>2% reduction; $p<0.001$) and improved response to oral glucose challenge compared to the STZ-control group. Serum triglyceride levels were also significantly reduced in treated mice compared to STZ and non-STZ controls ($p<0.001$), suggesting potential secondary benefits of the therapy. Furthermore, symptomatic hypoglycemia was not observed in mice treated with KRIYA-839 at any dose or timepoint over the duration of the 8-week study. This study demonstrates the potential of KRIYA-839 for T1D and lays the foundation for future clinical studies.

505 Towards the Development of Adeno-Associated Viral Gene Therapy for the Treatment of Patients with Propionic Acidemia Resulting from a Deficiency of PCCB

Randy Chandler[1], Christian Kim[2], Charles Venditti[3]
[1]National Institutes of Health, Bethesda, Maryland, [2]National Institutes of Health, Bethesda, MD, [3]NIH, Bethesda, MD

Background: Propionic acidemia (PA) is rare autosomal recessive disorder of metabolism caused by defecits in the mitochondrial localized enzyme propionyl-CoA carboxylase (PCC). PCC is composed of six α- and six β-subunits with causative genetic variants occurring at equal frequencies in either the nuclear encoded *PCCA* or *PCCB* genes. Patients with PA can suffer from poor growth, lethal metabolic decompensations, and cardiomyopathy despite current medical management, which has led to the pursuit of gene therapy as a new therapuetic option for patients. Here, we create several new murine models of PA caused by PCCB deficiency and generate pre-clinical proof of concept data as part of the Accelerating Medicine Partnership (AMP®) Bespoke Gene Therapy Consortium (BGTC). Led by NCATS, the BGTC partnership relies upon the FDA, FNIH, 10 NIH Institutes and Centers (ICs), including NHGRI, several pharmaceutical companies, and nonprofit organizations. The BGTC is intended to bring together partners from the public, private, and non-profit sectors to foster development of gene therapies for the treatment of rare genetic diseases.

Results: To enable the testing of gene delivery as a treatment for PA, CRISPR-Cas9 gene editing of the murine *Pccb* gene and transgenesis were used to create several new murine models of PCCB deficiency and recapitulate the spectrum of clinical severity observed in PA. Neonatal lethal, juvenile lethal and hypomorphic PCCB PA mice, representative of the spectrum of genetic mutations and disease phenotypes reported in PA patients, were treated systemically via retroorbital injection of AAV9-hPCCB at doses ranging between $5x10^{12}$ to $1x10^{14}$ vg/kg. Based on disease severity, murine models of PA were treated as neonates, juveniles, or adults, which is reflective of the age range of the PA patient population.

AAV9-hPCCB treatment resulted in significantly increased survival (Figure 1), reduced disease related metabolites, improved growth and protection against metabolic stress in comparison to the respective untreated mutant mice. All the doses tested improved survival and reduced disease related biomarkers in comparison to untreated PA mice, but the response in $5x10^{12}$ vg/kg dose cohort was suboptimal and temporal in nature. AAV9-hPCCB gene therapy resulted in increased *PCCB* mRNA and PCCB protein expression in liver, heart, skeletal muscle, brain and the kidney, which are tissues impacted by PA.

Conclusions: The preclinical efficacy data presented here was used successfully to obtain both Orphan and Rare Pediatric Drug Designations from the FDA. PA patients experience early mortality and lethal metabolic decompensation in response to stressors, therefore the significant improvement in survival and biochemical parameters seen in all models treated with AAV9-hPCCB therapy strongly supports the active pursuit of an IND and advancement toward clinical translation.

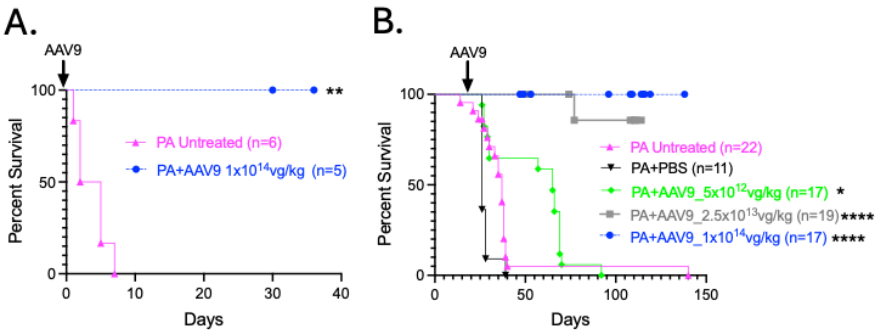

Figure 1. Survival Curve of Neonatal Lethal (A) and Juvenile Lethal (B) Models of PA Caused PCCB Deficiency. PBS=phosphate buffered saline

506 In Vivo Pooled Mosaic Screening for the Discovery of Drug Targets in Adipose Tissue

Linda Chio[1], Joanne Hsieh[2], Shengping Wang[3], Jingshu Chen[3], Vinay Kartha[2], Daniel Fuentes[2], Lianna Fung[2], Sam Hayward[3], Chris Towne[1], Francisco LePort[2], Martin Borch Jensen[4]*

Reducing obesity is an important clinical objective because it's a risk factor for many diseases, including diabetes, cardiovascular disease, and cancer. Adipose tissue is involved in many important aspects of human health from metabolic to immune. Recently, GLP-1 receptor agonists have shown dramatic effect in diseases such as obesity and diabetes, but indirectly regulate the adipose tissue that contributes to these diseases. Our in vivo pooled screening methodology, termed mosaic screening, is able to assay hundreds of genetic perturbations in a cell type specific manner. Using a pool of barcoded AAV interventions, we can deliver single gene therapy interventions to our cell type of interest in an animal model of clinical relevance. The tissue is then processed with 10x single-cell system and Illumina sequencing, and readouts are assessed using single-cell transcriptomics. Gene therapy candidates that show improvement of gene pathways associated with disease are nominated and further tested in vivo to confirm improvement of various physiological readouts. This technique has been applied to a variety of complex diseases such as osteoarthritis and heart failure to good effect and herein we show the ability to apply our method to the adipose tissue.

Several AAV serotypes were delivered to the adipose tissue to mice fed an obesogenic high fat, cholesterol and fructose diet, also known as the Gubra-Amylin (GAN) diet. We compared three methods of administration: intravenous injection (IV), intraperitoneal injection (IP), and intra-depot injection. Transduction was observed in all three routes with IP delivery chosen as the preferred method due to its higher adipose transduction than IV and ease of administration as compared to intra-depot. In order to prevent off-targeted transduction in the liver, we engineered short adipocyte-specific promoters, in contrast to existing adipocyte-specific promoters that are too large to fit into AAVs. These promoters expressing red fluorescent protein were barcoded and produced in a pool and injected in GAN mice at three different doses (n = 3 per dose). Transduced nuclei from white adipose tissue were isolated and the promoter with the highest expression as determined by sequenced barcodes was nominated for further use. With confirmation of feasibility of screening in adipocytes and preadipocytes, we further tested an AAV pool of barcoded therapeutic interventions in GAN diet-fed SpCas9-Tg or female C57BL6/J mice (n = 11 or 20 mice). Results of the screen were analyzed by single-nucleus RNA-sequencing and compared to non-targeting controls. With the ability to see cell-type specific transcriptomic perturbations in the adipose tissue, we hope to nominate further therapeutic targets tailored to adipose-associated diseases.

507 An Ultra-Low Dose of a Localized CNS Gene Therapy for Severe Pediatric Obesity

Brain-derived neurotrophic factor (BDNF) is a secreted growth factor that promotes neuronal health throughout the central nervous system and is a key signaling component of metabolic homeostasis. In the ventromedial hypothalamus (VmH), elevated leptin signals melanocortin 4 receptor (MC4R) expressing neurons to release BDNF, which then acts through tropomyosin receptor kinase B (TrkB) to signal fullness and reduce food intake. Patients with loss-of function mutations along this pathway develop severe early-onset obesity syndromes characterized by hyperphagia and food-related distress as young as six months old. Current therapeutic approaches such as bariatric surgery and glucagon-like peptide 1 (GLP1) agonists may be effective for generalized obesity, but do not result in significant, durable treatment for individuals with MC4R or BDNF deficiency. By directly delivering BDNF to the VmH through an adeno-associated virus (AAV)-based gene therapy, we aim to treat these individuals early in

childhood in a safe, effective, and lasting way. Treating these children early could significantly improve their physical and emotional well-being and prevent the development of irreversible sequelae such as cancer and diabetes.

To achieve this, we developed a more potent vector which could decrease the AAV gene therapy dose required to maintain effective weight loss, potentially mitigating adverse effects associated with high levels of AAV administration. Our optimized BDNF clinical construct, designed by altering various cis-regulatory components, expresses BDNF up to 143-fold greater than basal levels *in vivo*, significantly higher than the original academic construct. This is well in excess of the levels shown to prevent weight gain in the diet-induced obesity (DIO) wild-type mouse model. This highly potent AAV-BDNF vector showed efficacy in DIO mice with significant dose-dependent weight loss observed across a wide therapeutic window, with a 60-fold-dose range. Delivery of AAV-BDNF to a single hemisphere of obese mice on high-fat diet resulted in dramatic weight loss up to approximately 40%, which plateaued at the level of wild-type lean controls. In comparison, weight loss in DIO animals injected daily with a GLP-1 agonist, semaglutide, plateaued at approximately 12%. Weight loss in AAV-BDNF treated mice has been maintained for at least three months and continues to be monitored to further assess the durability of AAV-BDNF. In addition to lower body weight, AAV-BDNF-expressing mice showed significantly improved glucose tolerance compared to control AAV-GFP-expressing obese mice.

To assess the safety of AAV-BDNF gene therapy administered directly to the hypothalamus, we performed biodistribution, hematology, serum chemistry, and brain histology. Because the hypothalamus controls additional behaviors besides feeding, we also assessed animals using the open field, novelty-suppressed feeding, food intake measurements, and standard opponent tests to survey other behavioral attributes. As previously reported, locomotion increased in AAV-BDNF-treated animals. More importantly, animals did not display heightened aggression after AAV-BDNF treatment and exhibited normal pro-social behaviors. Furthermore, AAV-BDNF treatment did not ablate the ability of animals to feed. Overall, our data suggest that AAV-BDNF is an effective and safe therapeutic strategy for severe early-onset pediatric obesity syndromes.

508 A Novel Non-Viral DNA Gene Therapy Ameliorates Disease in a Mouse Model of Hypophosphatasia

Minh-Ha Do[1]*, Brian Truong[1], Ryan Agabani[2], Annika Holquist[1], Anthony Pham[1], Vahid Raessi[2], Lesley Padron[2], Joey Orpilla[2], Greg Evans[2], Neema Adhami[2], Jeffrey Bartlett[2]

**Corresponding Author*

Hypophosphatasia (HPP) is an inborn error of metabolism caused by mutations in the gene encoding tissue non-specific alkaline phosphatase (TNALP). Reduced expression of functional TNALP leads to defective bone mineralization, and depending on the age of onset, can result in a wide spectrum of skeletal abnormalities, respiratory failure, seizures, premature tooth loss, and musculoskeletal pain. In infantile-onset HPP, failure to thrive, delayed motor development, and 50% mortality are observed. Currently, the standard-of-care is enzyme replacement therapy with asfotase alfa (STRENSIQ®). While effective, asfotase alfa has a short half-life and requires almost daily subcutaneous injections leading to painful site reactions in most patients.

To overcome this requirement, we have assessed a novel gene therapy platform, HALO™, for the treatment of HPP. HALO is a circular DNA vector with unique structural DNA elements designed to mediate nuclear uptake, nuclear retention, and immunomodulation, which greatly increases efficiency, durability, and the ability to readminister the treatment *in vivo*. We constructed a HALO DNA vector encoding a secreted form of human TNALP fused to a human IgG Fc domain and a bone-targeting peptide (HALO TNALP). This DNA construct was formulated in an MC3-based lipid nanoparticle (HALO TNALP-LNP) for systemic administration and expression of TNALP from the liver. To evaluate its potential therapeutic application, we utilized an established mouse model of HPP (Akp2$^{-/-}$, *Alpl*^{tm1Jlm} on B6129S background, constitutive knock-out of the murine gene encoding TNALP, *ALPL*). This model is characterized by premature mortality (median survival of ~19 days), seizures, and impaired bone development, recapitulating major aspects of the infantile form of the human disease.

In Akp2$^{-/-}$ mice, a single intravenous dose of HALO TNALP-LNP shortly after birth on post-natal day (PND) 3 enabled complete rescue of mortality until scheduled study termination on PND 30. Untreated or PBS-treated Akp2$^{-/-}$ mice died prematurely, just prior to weaning, as expected. In treated Akp2$^{-/-}$ mice, skeletal development, as measured by long bone (femur and tibia) length via calipers, was the same as observed in Akp2$^{+/+}$ (wild-type littermates). Examination of vertebrae and metatarsal spacing in radiographic images further supported full phenotypic rescue in this model. Rescue was associated with marked and durable increases in plasma ALP activity compared to untreated Akp2$^{-/-}$. HALO DNA vector copies were detectable in the liver, as expected with MC3-based LNP delivery, with no concomitant indication of hepatoxicity through measurement of serum liver transaminase activity.

These data show that a HALO DNA vector encoding TNALP can be formulated within an LNP for systemic delivery to support full rescue of premature mortality and impaired skeletal development in Akp2$^{-/-}$ mice following a single dose. These data provide proof-of-concept for HALO as a viable and durable non-viral DNA platform for the next generation treatment for HPP.

509 Homology-Independent Targeted Integration-Based Strategy Restores Canine FVIII Activity from FVIII Intron 22 Inversion Mutation

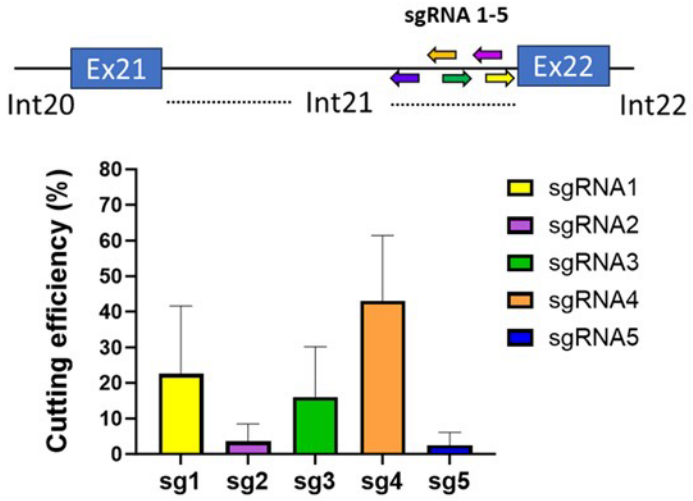
Chun-Yu Chen[1], Xiaohe Cai[2], Timothy Nichols[3], Carol Miao[4]
[1]Seattle Children's Research Institute, Seattle, WA, [2]Seattle Children's Research Institute, [3]The University of North Carolina at Chapel Hill, [4]Seattle Children's Research Institute, Seattle, WA

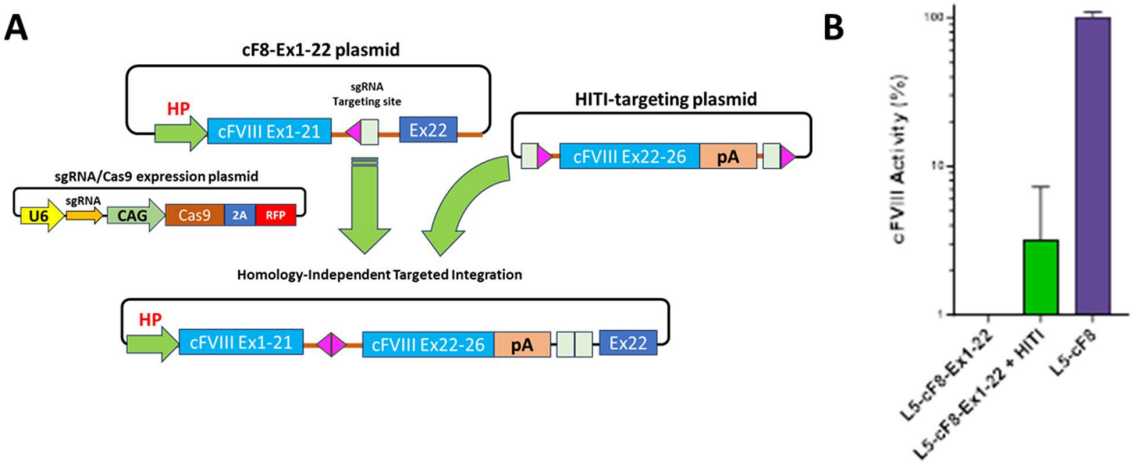
Over 50% of severe hemophilia A (HA) cases are caused by the intron 22 inversion (Int22inv) mutation in the factor VIII (FVIII) gene. This mutation disrupts the transcription downstream of exon 22, resulting in a truncated canine FVIII transcript. The Chapel Hill HA dog model carries the similar FVIII Int22inv mutation, making it a valuable model for developing therapeutic gene editing strategies for a long-term cure of this mutation. Homology-independent targeted integration (HITI) strategy is a CRISPR/Cas9-based strategy that enables DNA integration at sgRNA-targeting sites. In this study, we applied the HITI approach at the canine FVIII (cF8) gene locus, inserting exon 22-26 upstream of the inversion site to restore normal cF8 transcription.

To evaluate the efficiency of intron 21-targeting sgRNAs, we constructed a plasmid containing the cF8 exon 20-intron 22 sequence (cF8-ex20-in22). Plasmids encoding the Cas9 protein and cF8 intron 21-targeting sgRNA (**Cas9/cF8In21sg**) were co-transfected into 293T cells. The insertion and deletion (Indel) efficiency of sgRNA was assessed, with the selected cF8 intron 21-targeting sgRNA demonstrating an average gene editing efficiency of 43% *in vitro*.

To demonstrate HITI efficiency in *vivo*, we designed a truncated cF8 plasmid containing cF8 exon 1-22 and intron 21 (**cF8-ex1-in21**) and a HITI-targeting construct carrying cF8 exon22-26 (**HITI-cF8-ex22-26**). HA mice were hydrodynamically injected with a plasmid mixture, including Cas9/cF8In21sg, cF8-ex1-in21 and HITI-cF8-ex22-26. Rescue of the truncated cF8 protein expression was confirmed through activated partial thromboplastin time (aPTT) assay. After hydrodynamic injection of the plasmid mixture into HA mice, **cFVIII expression levels were restored to 3.2% on day 7 relative to the levels achieved from a wild-type cFVIII plasmid,** whereas mice injected with the cF8-ex1-in21 plasmid alone exhibited no detectable activity.

HITI Efficiency was further evaluated using NGS sequencing, confirming approximately 2.4% of successful integration of the exon 22-26 gene cassette into intron 21. This HITI strategy achieved successful integration of the exon 22-26 gene cassette into intron 21 and restored the truncated cFVIII transcripts, leading to functional cFVIII activity *in vivo*. This HITI approach will be evaluated to repair cFVIII Int22Inv mutation in HA dogs.





510 *A Novel Agent-based Computational Model for Liver-targeting, AAV-based Gene Therapies Could Predict Response Durability in Hemophilia B Patients Treated with Etranacogene Dezaparvovec*

Yuezhe Li[1], Partha Nandy[2], Eric Jordie[3], Karsten Peppel, Timothy Knab[4], Daniel Kirouac[5], Anna Wilkins[6], Silpa Nuthalapati[2]
[1]Metrum Research Group, Rockville Centre, NY, [2]CSL Behring, King of Prussia, PA, [3]Bill and Melinda Gates Foundation, Seattle, WA, [4]Metrum Research Group, Boston, MA, [5]Metrum Research Group, Boston, CT, [6]MetrumRG, Weston, MA

Many gene therapies use adeno-associated viral (AAV) vectors to deliver ITR-flanked therapeutic transgene cassettes that persist as non-integrated and non-replicating episomes in target cells. The liver, known to be self-renewing, is a common target organ for AAV based gene therapies, including etranacogene dezaparvovec, developed for the treatment of hemophilia B (congenital factor IX (FIX) deficiency).

The assumption of regular cellular turnover causing transgene loss has led to speculations that therapeutic protein expression could not be sustained in liver-targeting gene therapies. Differential equation-based models have previously been developed to describe AAV uptake and protein production. However, episomal transgene loss associated with target cell turnover has proved difficult to capture in these models. To overcome this shortcoming,

an agent-based model (ABM) was developed and described herein, enabling simulation-based analyses on the effects of several assumptions around hepatocyte cell biology and patient physiology on the long-term durability of etranacogene dezaparvovec.

In this ABM, each individual hepatocyte, diploid or polyploid, was represented by an agent, capable of cell division and death, changing ploidy, and of being transduced with one or several AAV particles. Upon transduction, the AAV genomes form stable episomes, enabling the expression of therapeutic protein by the host's transcriptional and translational machinery. During cell division, all episomes were passed from mother and equally shared among daughter cells. Episomes were only lost when transduced cells died. The agents' behavior over time was specified by kinetic parameters describing cell division, diploid to polyploid differentiation, death, and associated effects on FIX production. One ABM consisted of 1000 agents, with the initial proportion of diploid and polyploid hepatocytes depending on patient age. The initial fraction of transduced cells and the initial episome count per transduced cell were estimated from preclinical studies.

To understand the expected variability in treatment outcomes, a population of 160,000 virtual patients was set up. One anticipated source of variability was the impact of patient age - and its implications for cellular composition of the liver. Less quantifiable sources of potential inter-patient differences included the fraction of cells transduced immediately after treatment, the number of episomes per transduced cell, and the maximum number of actively expressed episomes per cell.

The ABM and virtual population were parameterized based on liver physiology, endogenous coagulation FIX biology reported in literature, and an early subset of FIX activity data (training data) following the first two years after treatment of hemophilia B patients with etranacogene dezaparvovec (CSL222; NCT03569891).

Virtual population ABM simulations of FIX activity in patients treated with this therapy were consistent with the range of clinical observations over three years (incl. validation data; Figure 1), capturing the median, population variation, and dynamics of FIX expression. Prospective virtual population simulations out to 20 years established confidence in long-term outcomes and highlighted the impact of target cell turnover rates.

While the model was applied here in the context of treating hemophilia B, the modeling and simulation-based framework should be adaptable to many other AAV-based gene therapies.

Thick light grey dashed line: median of training data.

Light blue triangles: validation data set individual observations.

Thick blue dash line: median of validation data.

Thin dashdot lines: outlining 95% CI of the observed FIX activity.

Yellow solid line: ABM-predicted median FIX activity, increasingly lighter shaded areas representing 50%, 80% and 95% CIs.

511 Identification of bioengineered AAV capsids with enhanced targeting of liver sinusoidal endothelial cells (LSECs)

Jonathan Lindgren[1], Yonghong Chen[1], Brian Lewandowski[1], Beverly Davidson[1], Denise Sabatino[2]
[1]Children's Hospital of Philadelphia, Philadelphia, PA, [2]The Children's Hospital of Philadelphia, Philadelphia, PA

Most coagulation factors (factor IX, factor V, etc.) are synthesized in hepatocytes within the liver. However, coagulation factor VIII (FVIII) is primarily synthesized in liver sinusoidal endothelial cells (LSECs). Deficiencies of FVIII cause the X-linked bleeding disorder, hemophilia A (HA). Current gene therapy approaches using AAV vectors to treat HA target hepatocytes for transgene expression by using AAV serotypes that efficiently target hepatocytes in combination with hepatocyte-specific promoter elements. While several naturally occurring AAV serotypes target LSECs, they do not target them efficiently. Through an in vivo screen of an AAV capsid library, we identified novel AAV capsids that efficiently transduce LSECs. To identify novel AAV capsid variants that efficiently target mouse LSECs, we used AAV capsid libraries based on AAV2. Previous studies in our laboratory have demonstrated that the parental AAV2 does not efficiently target LSECs. Random 7-mer peptides were inserted at a surface accessible region in the capsid VP3. Three rounds of screening were performed to identify capsids with improved LSEC-targeting. The top 2 capsid candidates (AAV^{LSEC1} and AAV^{LSEC2}) were selected for validation of improved targeting of LSECs. HA/CD4KO mice were intravenously administered $1x10^{11}$, $1x10^{10}$, or $1x10^{9}$ vector genomes/mouse of either AAV^{LSEC1}-CAG-eGFP, AAV^{LSEC2}-CAG-eGFP, or a positive control AAV8-CAG-eGFP. Four weeks after vector administration, mice were perfused using a modified two-stage collagenase perfusion to harvest hepatocytes and liver NPCs for FACS analysis of $CD31^{+}CD146^{+}CD45^{-}$ LSECs. At $1x10^{11}$ vg/mouse, FACS quantification of $CD31^{+}CD146^{+}CD45^{-}GFP^{+}$ LSECs showed 94 and 97% GFP^{+} LSECs, respectively, for AAV^{LSEC1} and AAV^{LSEC2} compared to AAV8 (89%), suggesting that at this dose the vector may be saturating the cellular receptors required for entry into the cell. At a 10-fold lower vector dose ($1x10^{10}$ vg/mouse), AAV^{LSEC1} transduced 64% and AAV^{LSEC2} transduced 48% of LSECs and compared to 11% with AAV8, demonstrating 4-6-fold enhanced targeting of AAV^{LSEC} compared with the AAV8 serotype. At the lowest vector dose ($1x10^{9}$ vg/mouse), AAV^{LSEC1} (7% GFP+ LSECs) and AAV^{LSEC2} (3% GFP+ LSECs) compared to 2.8% GFP+ LSECs with AAV8. Based on these data, we then compared AAV^{LSEC1} and AAV^{LSEC2} targeting of LSECs at the $1x10^{10}$ vg/mouse dose in another experiment to validate these findings. FACS quantification of $CD31^{+}CD146^{+}CD45^{-}GFP^{+}$ LSECs showed 58% and 63% GFP+ cells respectively, for AAV^{LSEC1} and AAV^{LSEC2}, confirming the improved LSEC targeting of these capsids. Thus, AAV^{LSEC} vectors significantly improved (~6-fold) targeting of LSECs compared to AAV8 at $1x10^{10}$ vg/mouse. Overall, these studies identify bioengineered AAV capsids that can target LSECs more efficiently than naturally occurring serotypes. These LSEC-targeted capsids provide an innovative strategy for a second-generation approach to hemophilia A gene therapy by targeting FVIII expression to the endogenous site of FVIII synthesis.

512 Superior Efficacy of AAV Gene Therapy for Hemophilia A Using Engineered Factor VIII Variants and Transient B Cell Depletion for Effective Vector Readministration

Kentaro Yamada[1], Zhouji Chen[2], Sandeep Kumar[3], Miguel Gonzalez[4], Maite Munoz[5], Calista Greenwood, Sreevani Arisa[6], Bridget Brian[7], Moanaro Biswas[4], Ype De Jong[8], Weidong Xiao[6], Randal Kaufman[9], Roland Herzog[10]
[1]Indiana University School of Medicine, Indianapolis, Indiana, [2]Sanford Burnham Prebys Medical Discovery Institute, [3]Indiana University School of Medicine, INDIANAPOLIS, IN, [4]Indiana University, Indianapolis, Indiana, [5]Gene and Cell Therapy Group IU School of Medicine Department of Pediatrics, Indianapolis, IN, [6]Indiana University, Indianapolis, IN, [7]Indianapolis, IN, [8]Weill Cornell Medicine, New York, NY, [9]Sanford-Burnham Medical Research Institute, [10]IU School of Medicine, Indianapolis, IN

Liver-directed adeno-associated viral (AAV) vector-based gene therapy drugs have recently received regulatory approvals for treatment of the X-linked bleeding disorder hemophilia. However, large vector doses are used to treat hemophilia A (deficiency in factor VIII, FVIII). Furthermore, FVIII is not normally expressed in hepatocytes, may induce cellular stress responses, and its expression has substantially declined over time in many patients. We developed a total of 16 FVIII vector cassettes expressing CpG-depleted, codon-optimized, B domain-deleted (BDD) human FVIII. These vectors include clinically tested liver-specific promoters (HLP and TTR) and 8 different FVIII

variants (WT, F309S for reduced aggregation and ER stress and improved secretion, X5 for improved secretion, R336Q/R562Q or "QQ" for improved stability in circulation, ΔSQ linker deletion, and combinations F309S-X5, QQ, X5-QQ, ΔSQ-X5). AAV8 vectors were administered IV into hemophilia A mice (C57BL6/129 F8e16-/-) at the dose of 1.0E+11 vg/mouse, and FVIII activity in plasma was measured at week 2 using a chromogenic assay. For most FVIII variants, TTR promoter constructs outperformed the HLP constructs by ~2 fold. Overall, the highest performers were HLP-X5-QQ (on average 539% of normal human FVIII plasma activity), TTR-X5-QQ (468%), and TTR-F309S-X5 (631%). These levels were >1 log better than those from the basal HLP-FVIII cassette. Biochemical assays using in vitro transduced primary human hepatocytes showed that superior variants not only exhibit improved secretion but also enhanced biosynthesis. Human FVIII is highly immunogenic in hemophilic mice. For example, hepatic gene transfer in the hemophilia A mouse strain BALB/c F8e16-/- induces inhibitory antibody and CD8+ T cell responses (Mol Ther 30:3552, 2022). We administered AAV8-TTR-FVIII vector (expressing WT BDD-FVIII) at 1.0E+11 vg/mouse to this strain in combination with our recently developed transient immune suppression protocol, which combines anti-CD20 and anti-BAFF treatments for effective transient B cell depletion (Mol Ther Methods Clin Dev 32:101216, 2024). With this combination therapy, we achieved sustained expression in the normal human FVIII range. FVIII expression reached a peak (383%) at week 4, decreased by 8 weeks, then remained within the normal range (45-133%) for the next 5 months, which is 4 months after B cells had reconstituted. Notably, after 6 months, we administered another AAV8 vector (expressing human FIX) at identical dose and achieved expression levels in the normal FIX range, similar to naïve control mice. Using this strain and B cell depletion, we tested our so far most promising variants at a 5-fold lower dose (2.0E+10 vg/mouse) in the same experimental condition as above. Surprisingly, X5 and X5-QQ variants expressed much lower than expected for a 5-fold reduction in vector dose. In contrast, F309S-X5 variant maintained efficacy and expressed within the normal range (~62-73%) during the first month (we are now following up for long-term expression). These results indicate: i) an unexpected threshold effect; and ii) the ability of the F309S mutation to enhance X5 secretion when FVIII expression is low. In totality, our experiments establish a benefit for a combination of FVIII variants. Inclusion of X5 yielded superior results, and F309S-X5 emerged as the most optimal combination, thus representing strong candidate for improved clinical AAV-FVIII gene therapy for hemophilia A.

513 Homology-Independent Targeted Integration in a Humanised Mouse Model of Haemophilia A

Paula Sureda Horrach[1], Federica Esposito[2], Mitra Torabi[3], Hristiana Lyubenova[4], Stefano Auricchio[1], Edoardo Nusco[5], Mina Yazdi[6], Eric Weidinger[7], Ester Borroni[8], Antonia Follenzi[9], Ernst Wagner[10], Alberto Auricchio[11]

Haemophilia A (HA) is the most common X-linked bleeding disorder caused by lack of factor VIII (FVIII), an essential cofactor of the coagulation cascade. Almost half of the severe HA cases are due to an inversion within intron 22 of the *F8* gene, which results in the inversion and translocation of the first 22 exons and consequent absence of FVIII expression and activity. In order to correct this common *F8* inversion by genome editing, we generated a humanised mouse model missing *F8* exons 23 to 26 and instead carrying the first 4 kilo bases of the human *F8* intron 22. We then used adeno-associated viral (AAV)-mediated homology-independent targeted integration (HITI) directed to liver to insert the last missing *F8* exons (23 to 26) downstream of the exon1-22 translocation, thus restoring FVIII expression. To do this, 2 different AAV8 vectors were used: one vector encodes *Staphylococcus pyogenes* CRISPR/Cas9 (*SpCas9*); another vector encodes the HITI donor containing the mouse *F8* exons 23 to 26 flanked by two inverted gRNA sites, and the U6 promoter expressing the gRNA specific for the human *F8* intron 22. We confirmed positive donor integration of all gRNA-treated animals by PCR amplification of DNA extracted from liver samples. In contrast, mice administered with tested constructs show undetectable FVIII activity levels and prolonged coagulation times at various time points post-injection, regardless of the promoter used to express SpCas9. These findings suggest that the donor integration at the target site is taking place but not at sufficient levels and/or in the correct liver cell type, particularly in liver sinusoidal endothelial cells (LSECs) which are the physiological producers of FVIII. We are currently setting up a platform to

deliver *SpCas9* mRNA with lipid nanoparticles with high tropism to LSECs. Restoration of FVIII expression in a relevant portion of the LSEC population could result in therapeutic efficacy in HA mice.

514 Enhancing the Potency of *In Vivo* Lentiviral Gene Therapy to Hepatocytes

Lentiviral vectors (LV) are attractive vehicles for *in vivo* liver-directed gene therapy, representing a complementary strategy to adeno-associated viral (AAV) vectors. In contrast to AAV, LV integrate into the genome of target cells, potentially ensuring transgene maintenance during liver growth. We have previously shown stable gene transfer to the liver in mice, dogs, and non-human primates by LV administration. However, high quantities of highly purified LV are required for clinical translation. Increasing the potency of gene transfer remains a crucial goal in gene therapy since lowering the dose required to achieve therapeutic efficacy would result in a reduction of dose-dependent toxicities and immunogenicity, besides reducing the costs associated with manufacturing. We focused on LV-mediated in vivo gene transfer to hepatocytes of coagulation factor VIII (FVIII) and coagulation factor IX (FIX), the genes mutated in hemophilia A and B, respectively. We tested strategies to increase the corrected liver mass *a posteriori* or *a priori*. To increase the potency *a posteriori*, we provided, together with the coagulation FIX or FVIII transgene, a short hairpin RNA downregulating Cypor, the redox partner of all microsomal cytochromes P450s (CYP450s), a previously shown strategy. Since paracetamol is partially metabolized by CYP450s generating a toxic metabolite, the transduced hepatocytes become resistant to toxic doses of the drug, replacing the damaged ones. We confirmed and expanded the feasibility of this strategy, applying it to hemophilia A and B. We achieved positive selection of transduced hepatocytes, turning FVIII and FIX transgenes amounts from sub-therapeutic to fully therapeutic. Notwithstanding the clonal expansions, we did not detect any enrichment of LV integrations near oncogenes in the mice that underwent the selection procedure, suggesting that hepatocyte expansions were not driven by LV integrations but due to the selective advantage of LV-transduced hepatocytes. To increase potency *a priori*, we evaluated several procedures (fasting, inhibition of interferon, IFN, or proteasome pathways) to implement before LV administration. Specifically, fasting mice or administering a single dose of an anti-IFNα receptor (IFNAR) antibody or of the proteasome inhibitor Bortezomib before LV increased the circulating amounts of coagulation FVIII or FIX ~5-fold, indicating their role as transduction enhancers. When testing these transduction enhancers in combination, we achieved up to 13-fold higher circulating FIX amounts compared to LV only, paralleled by an increase in LV copy number in hepatocytes. Finally, we assessed the possible effect of transduction enhancers on LV enriched, on their surface, with CD47, a phagocytosis inhibitor (CD47high LV). These LV have been shown to be more protected from macrophage uptake following intravenous administration to NOD mice, which can cross-recognize the human CD47. We administered CD47high LV to NOD mice, with or without pre-treatment with the combination of the previously identified enhancers. We observed >40-fold higher FIX circulating amounts in the combination group, suggesting a synergistic effect in maximizing hepatocyte transduction when phagocytosis-shielded LV are combined with transduction enhancers. Here, we successfully enhanced the potency of *in vivo* LV-mediated hepatocyte gene transfer, thus paving the way to expand its in vivo applicability and ease its clinical translation.

515 Liver-Humanized Mice Repopulated with Hepatocytes From a Hemophilia B Donor Exhibit Delayed Blood Clotting and Have a Physiologic Response to Gene Therapy Correction of Human FIX

Devo Goldman[1]*, Zoe Dimond[2], Riffat Ahmed[3], Rob Copenhaver[2]
[1]Yecuris, Portland, Oregon, [2]Yecuris, Portland, OR, [3]Yecuris Corporation, Tualatin, OR
Corresponding Author

Hemophilia B (HEMB), a single gene disorder affecting Factor IX, is an ideal target for gene therapies. In order to establish a relevant model for evaluating such therapeutics, primary hepatocytes from a patient with HEMB were evaluated for clotting defects and gene therapy correction in vivo in liver-humanized mice. For this, primary hepatocytes from a male HEMB donor were transplanted into male FRG® mice on the NOD background (FRGN). Primary hepatocytes from a non-hemophilic human male donor were transplanted into male FRGN mice as a control. Mice with human albumin levels of >4000 µg/mL, indicative of livers repopulated with >70% human hepatocytes, were compared. Humanized mice repopulated with control donor cells (n=4) had average circulating hFIX levels of 895 ±96.6 ng/mL, whereas mice repopulated with the HEMB donor (n=5) had 9-fold lower average circulating hFIX levels of 98.9±26.9 ng/mL. Measurement of partial thromboplastin time (PTT) in plasma samples from liver-humanized mice created with the control donor cells (n=9) revealed a mean PTT of 28.49 seconds. In HEMB liver-humanized mice (n=9), the average PTT was increased by 24% to 35.34 seconds. Thus, physiologically relevant defects in clotting could be modelled in liver-humanized mice reconstituted with a HEMB donor. To demonstrate that this model could be used to assess efficacy of gene therapies, HEMB mice were injected i.v with $2.5x10^{11}$ copies per mouse of liver-tropic AAV expressing hFIX (AAVDJ-CAG-hFIX). Two weeks after injection, increased expression of hFIX (343±66.6 ng/mL) and a significant decrease in PTT (30.25s, $p<0.005$) was observed compared to untreated HEMB liver-humanized mice. Even without significant optimization of AAV-mediated correction, there was no significant difference in clotting time between HEMB liver-humanized mice that received hFIX gene therapy and mice that were liver-humanized with hepatocytes from a control donor. Our findings demonstrate that primary human hepatocytes from donors with genetic disease such as hemophilia B can successfully repopulate FRG mice, recapitulate physiologic disease pathologies, and be used to evaluate relevant in vivo therapeutic approaches.

516 Gene therapy of hemophilia a: identification of the most efficient aav serotype vector for transduction of human liver sinusoidal endothelial cells

Jakob Shoti[1], Keyun Qing[1], Porkizhi Arjunan[2], Dhruv Champaneri[3], Geoffrey Keeler[3], Roland Herzog[4], Arun Srivastava[3]
[1]University of Florida, Gainesville, Florida, [2]Christian Medical College and Hospital Vellore, Vellore, Tamil Nadu, India, [3]University of Florida, Gainesville, FL, [4]IU School of Medicine, Indianapolis, IN

Gene therapy of hemophilia A has been performed with several AAV serotype vectors, but none has proven to be optimal. For example, although a BioMarin-sponsored clinical trial with AAV5 vectors at a high dose of $6x10^{13}$ vg/kg led to ~100-200% levels of expression of human clotting factor VIII (hFVIII), over a three-year follow up period, the hFVIII levels declined to ~8% (Pasi *et al*., *N Eng J Med*, 382: 29-40, 2020). Nontheless, given the overall improvement in disease severity (such as multi-year substantial deduction in annual bleeding rates), this drug was approved by the FDA in 2023 as Roctavian, priced at $2.9M/dose. In a Takeda-sponsored clinical trial with AAV8 vectors at a dose of $3x10^{13}$ vg/kg, all patients lost expression of hFVIII within 1 year (Chapin *et al*., *Haemophilia*, doi: 10.1111/hae.15121, 2024). More recently, despite encouraging results from two Phase I/II clinical trials, one with AAV-LK03 vectors (George *et al.*, *N Engl J Med.,* 385: 1961-1973, 2021) and one with AAV6 vectors (Leavitt *et al*., *Blood*, 143: 796-806, 2024), two Phase III hemophilia A clinical trials sponsored respectively by Spark-Roche with AAV-LK03 vectors, and Sangamo-Pfizer with AAV6 vectors, were halted. Although some patients treated with Roctavian or other vectors have maintained FVIII levels in the normal range, it has generally been difficult to achieve lasting high levels of FVIII expression (i.e. near or within the normal range). While all these vectors target hepatocytes for transgene expression, FVIII is normally made in liver sinusoidal endothelial cells (LSECs), which are able to efficiently secrete FVIII by co-expression of von Willebrand factor. None of the aforementioned AAV capsids have been shown to efficiently target human LSECs. In our present studies, we evaluated the transduction efficiencies of AAV5, AAV6, and AAV3 vectors in human hepatic cells as well as in human LSECs under identical conditions. These results, shown in **Figure 1A**, document that AAV6 vectors are ~623x more efficient than AAV5 vectors, and AAV3 vectors are ~2,600x more efficient than AAV5 vectors in human hepatic cells. Interesingly, AAV3 vectors also transduce human LSECs most efficientlty, ~7x more efficiently than AAV6 vectors, and ~51x more efficiently than AAV5 vectors (**Figure 1B**). Taken together, these results suggest that AAV3 vectors may prove to be efficacious as well as cost-effective in gene therapy for hemophilia A by directing FVIII expression to the natural site of synthesis, thereby improving secretion and avoiding mechanisms that downregulate expression as a result of intracellular FVIII accumulation.

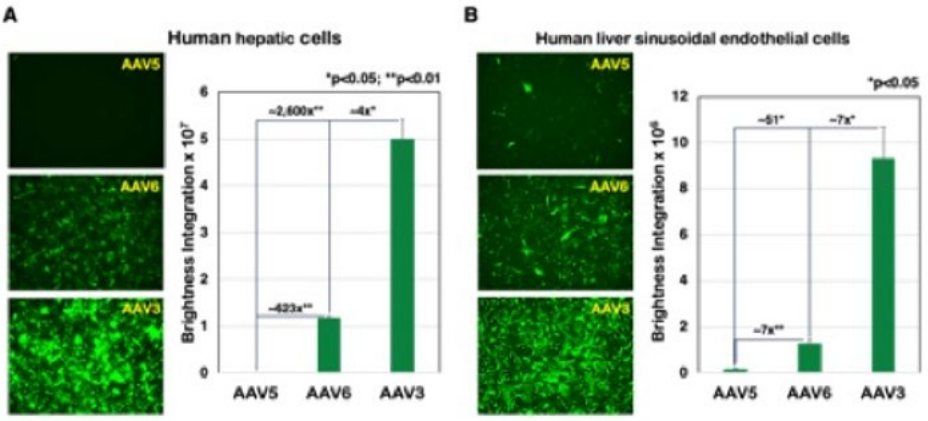

Figure 1: Transduction efficiencies of AAV5-, AAV6-, and AAV3-EGFP vectors in human hepatic **(A)** and human liver sinusoidal endothelial cells **(B)**. Cells were transduced in triplicates with each vector at $3x10^3$ vgs/cell. Transgene expression was determined 72 hrs post-transduction and quantitated using a Keyence microscope.

517 Gene therapy of hemophilia b: identification of the most efficient aav serotype vector for transduction of human hepatic cells

Arun Srivastava[1], Jakob Shoti[2], Keyun Qing[2], Porkizhi Arjunan[3], Geoffrey Keeler[1]
[1]University of Florida, Gainesville, FL, [2]University of Florida, Gainesville, Florida, [3]Christian Medical College and Hospital Vellore, Vellore, Tamil Nadu, India

In 2022, the United States Food and Drug Administration (USFDA) approved Hemgenix, an AAV5-based vector from uniQure for gene therapy of hemophilia B. A relative high dose of 2x1013 vgs/kg of this vector leads to up to ~12% expression of the human clotting factor IX (hFIX). In 2024, the USFDA also approved Beqvez, an AAVrh74-based vector from Pfizer for gene therapy of hemophilia B, which leads to up to 21% expression of hFIX at a dose of 5x1011 vgs/kg. Both Hemgenix and Beqvez are priced at $3.5M/dose. However, neither AAV5 nor AAVrh74 serotype vectors possess selective tropism for human liver. More than a decade and a half ago, we observed that of the 10 most commonly used AAV vectors, AAV3 is the most efficient in transducing primary human hepatocytes *in vitro* (*Molecular Genetics & Metabolism*, 98: 289-299, 2009). Subsequently, we reported AAV3 vectors to be 82x more efficient than AAV5 vectors in transducing primary human hepatocytes in humanized mice in vivo (*Molecular Therapy*, 24: 1042-1049, 2016) (**Figure 1A**). In our current studies, we compared the transduction efficiencies of AAV5, AAVrh74, and AAV3 vectors in human hepatic cells under identical conditions. As can be seen in **Figure 1B**, AAVrh74 vectors are ~6x more efficient than AAV5 vectors, whereas AAV3 vectors are ~1,100x more efficient than AAV5 vectors. AAV3 vectors are also ~6x more efficient than AAVrh74 vectors. We have previously reported the remarkable tropism of AAV3 vectors to be mediated by the human hepatocyte growth factor receptor (huHGFR), which AAV3 utilizes as a cellular co-receptor to gain entry into human hepatic cells (*Human Gene Therapy*, 21: 1741-1747, 2010). We have also reported that AAV3 vectors mediate therapeutic levels of hFIX expression in humanized mice (*Human Gene Therapy*, 31: 1114-1123, 2020) as well as in non-human primates (*Molecular Therapy Methods & Clinical Development*, 23: 98-107, 2021). All of these proof-of-concept studies make a compelling case for the use of AAV3 vectors with lower immunogenicity, improved safety, ensuring translation to the clinic with higher probability of success for gene therapy of hemophilia B. Furthermore, the reduced vector production costs as well as lower cost per patient should allow the eligible patient population worldwide to benefit from AAV3 vector-mediated gene therapy of hemophilia B in particular, and human liver diseases in general, in which other AAV serotype vectors have proven to be less than optimal.

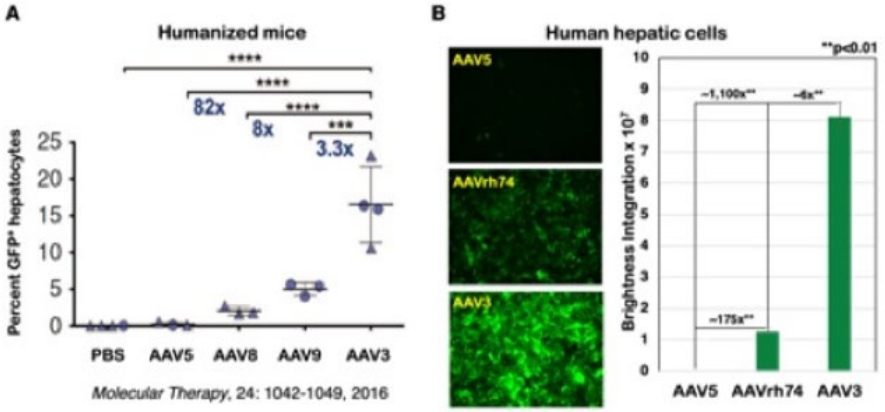

Figure 1: (A) Transduction efficiencies of AAV5, AAV8, AAV9, and AAV3 vectors in human hepatocytes in humanized mice *in vivo*. **(B)** Transduction efficiencies of AAV5, AAVrh74, and AAV3 vectors in human hepatic cell line, Huh7. Cells were transduced in triplicates with $3x10^3$ vgs/cell with each of the vectors expressing the EGFP reporter gene. Transgene expression was visualized and quantitated 72 hrs post-transduction using a Keyence microscope.

518 Novel intravenous AAV gene therapy for symptomatic mucopolysaccharidosis type IIIA in canine model of the pathology

Rafael ALONSO[1], Julien Lemaitre[2], Stephane Madec[3], Armelle Gaston[2], David Augereau[4], Marion Fusellier[5], Marie-Anne Colle[6], Jerome Ausseil[7], Françoise Roux[8], **Francoise Piguet[9]**

MPSIIIA is an autosomal recessive lysosomal storage disorder, caused by N-sulfoglucosamine sulfohydrolase (SGSH) enzymatic deficiency leading to accumulation of Heparan Sulfate Oligosaccharides (HSO) in tissues and notably in the central nervous system (CNS). Patients display progressive central nervous system degeneration that manifest as severe intellectual disability, developmental regression, and other neurologic manifestations including autism spectrum disorder (ASD), behavioural problems, and sleep disturbances. To date, there are no curative therapies for MPSIIIA. Several trials have been initiated with intracerebral or intravenous but with poor CNS targeting and thus no real clinical improvement.

Based on our strategy developed for MPS3B, we used a last generation AAV, a serotype able of large Blood brain barrier crossing after intravenous delivery notably in large animals. Here we described for the first time symptomatic delivery at 18M in the canine model of the pathology. In vivo monitoring demonstrates significant MRI improvement with regression of all brain abnormalities, prevention of cerebral loss, neurobehavior improvement as well as reduction of GAG accumulation. Efficacy and safety studies are ongoing and data of molecular and anatomopathological read outs will be disclaimed.

519 Dual site administration of AAV gene therapy for treatment of feline GM1 gangliosidosis

GM1 gangliosidosis is a fatal neurodegenerative disease caused by a deficiency of lysosomal β-galactosidase (βgal). There are currently two ongoing clinical trials for the treatment of GM1 gangliosidosis using adeno-associated viral (AAV) gene therapy administered either intravenously (IV) or in the cerebrospinal fluid (CSF) via the cisterna magna (CM). Preclinical trials of either administration route show that single site treatment significantly increases lifespans in a feline model of GM1 gangliosidosis. We hypothesize that deficiency in efficacy caused by either single site injection will be addressed by the additive effect of combinatorial administration. GM1 cats received $6.0x10^{13}$ vector genomes/kg of AAV9 split equally between IV and CM administration at approximately 2 months of age. Four animals will be followed to humane endpoint and four animals were evaluated 16 weeks following treatment. Untreated GM1 animals survive approximately 8.0 ± 0.6 months while treated animals have a significant increase in average lifespan to 19.9 ± 7.8 months, with 2 animals in the long term cohort still alive at 28.7 and 26.5 months of age (Figure 1A). Clinical assessments include neurological exams, CSF biomarkers, and 7T magnetic resonance imaging (MRI) and spectroscopy (MRS). Postmortem analysis included βgal and AAV distribution. Neurological deficits, which in untreated GM1 animals lead to an inability to stand and humane endpoint by 8 months of age, were attenuated in all treated animals (Figure 1B). Aspartate aminotransferase (AST) and lactate dehydrogenase (LDH), biomarkers of central nervous system damage when measured in the CSF, were both reduced in treated animals 16 weeks after treatment and maintained to 1 year in comparison to untreated animals. 7T magnetic resonance imaging (MRI, Figure 1C) revealed a delay in progression of neurodegeneration and preservation of brain architecture. While animals are ongoing we are unable to fully determine if CM+IV administration of AAV is better than either single administration route. Further analysis indicates that the combined treatment outperforms intravenous delivery using the same dose and AAV backbone.

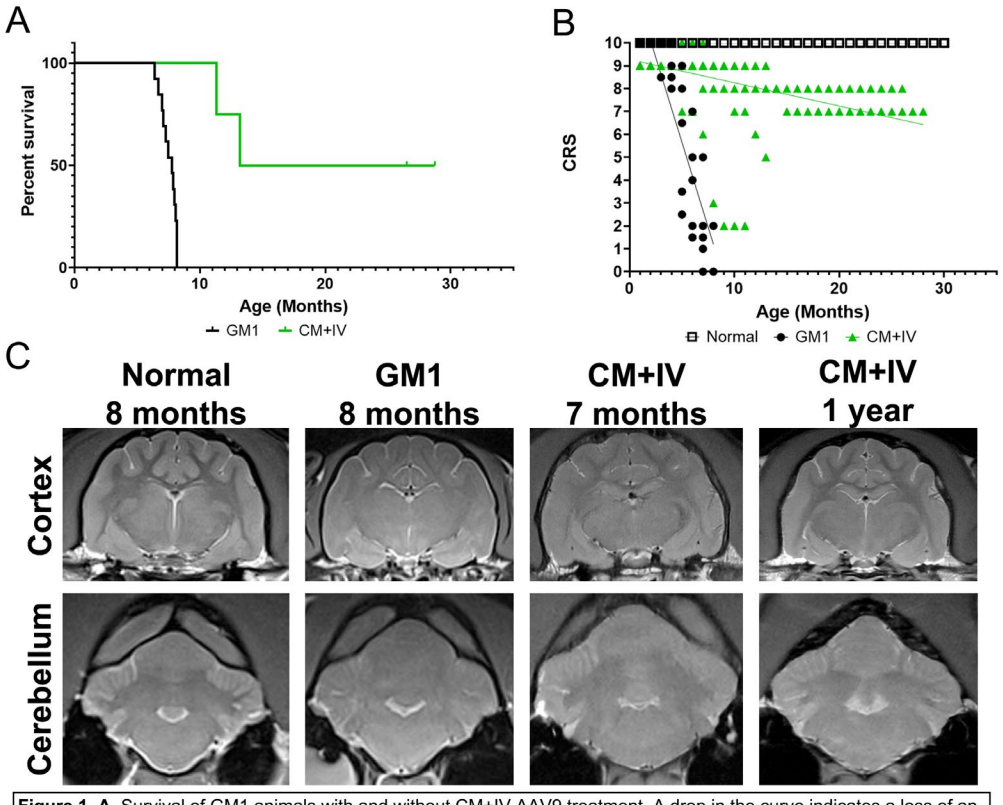

Figure 1. A. Survival of GM1 animals with and without CM+IV AAV9 treatment. A drop in the curve indicates a loss of an animal in the cohort. P=0.0018. **B.** Clinical rating score (CRS) of treated animals. A decrease in value designates progression of neurological disease. A line of best fit is graphed for each cohort. **C.** Magnetic Resonance Imaging (MRI) of cortex and cerebellum of treated animals.

520 Dosage Effects on Circulating GAA as a Pharmacodynamic Biomarker for systemically delivered rAAV9-coGAA Gene Therapy in Pompe Disease

**Corresponding Author*

Pompe disease (PD) is a lysosomal storage disorder caused by a deficiency in acid α-glucosidase (GAA), resulting in glycogen accumulation in cardiac, skeletal muscle, and central nervous system cells. The gene therapy product rAAV9-coGAA (GC301), a recombinant adeno-associated virus (rAAV) vector carrying the codon-optimized gene for GAA (coGAA), has demonstrated promising preclinical efficacy, including prolonged lifespan and significant reductions in tissue glycogen accumulation in Gaa-/- mice after a single intravenous administration. To advance the clinical development of GC301, it is crucial to identify reliable pharmacodynamic biomarkers to confirm the drug's efficacy and monitor its biological effects over time. In this study, we evaluated circulating GAA activity as a potential pharmacodynamic biomarker to assess the therapeutic effects of GC301. Wild type Balb/c mice were treated with 1.2E+14 vg/kg of GC301 and monitored for 60 weeks. During this period, animals were regularly sacrificed for sampling (Fig 1.A) to measure vector genomes, GAA expression and GAA activity. Plasma and hemocytes (prepared as dried blood spots, DBS) were separated to determine whether their contributions to circulating GAA differed. Mice treated with GC301 exhibited widespread biodistribution and efficient GAA expression. Compared to the GAA enzyme activity in each tissue of the control group, the fold increase results were presented in Figure 1.B. The heart showed the highest fold elevation, followed by the liver, diaphragm and quadriceps. Regarding circulating GAA activity, the maximal values in hemocytes and plasma peaked at week 6, reaching 4-6 times, and remained approximately twice that of the control mice for up to 60 weeks. Interestingly, while the GC301 vector genome became undetectable in the blood by 12 weeks, it persisted in other tissues, accompanied by sustained GAA expression (Fig 1.C). These findings suggest that the elevated GAA activity in plasma following GC301 administration primarily reflects a "spillover" from treated tissues, thus making it a promising pharmacodynamic biomarker for monitoring the ongoing efficacy of GC301. In Gaa-/- mice treated with GC301, efficient glycogen clearance was observed, along with a dose-dependent increase in GAA activity across multiple tissues and in the blood at dosages of 3E+13 and 6E+13 vg/kg. In the low-dose cohort (3E+13 vg/kg), GAA activity increased by 1.5- to 58-fold in various tissues compared to untreated wild-type mice. However, blood GAA activity in the low-dose cohort showed minimal elevation, remaining comparable to untreated Gaa-/- mice throughout the 16-week study period. (Fig. 2)

Our findings highlight that circulating GAA activity could serve as a potential non-invasive biomarker for monitoring the long-term pharmacodynamic or therapeutic effects of GC301 in Pompe disease, particularly in high-dose treatments. However, for individuals receiving low-dose treatment, blood GAA enzyme activity is unlikely to be a reliable biomarker, while muscle GAA enzyme activity appears to provide a more accurate indicator of pharmacodynamic. Early clinical trial results further support these findings, demonstrating that in IOPD patients treated with GC301, the increase in muscle GAA enzyme activity significantly exceeded that observed in the blood.

[1]Latus Bio, Inc, Philadelphia, PA, [2]Latus Bio, Philadelphia, PA, [3]Children's Hospital of Philadelphia, Philadelphia, PA, [4]Philadelphia, PA, [5]Latus Bio, Princeton, NJ, [6]Latus Bio, Boston, MA

Introduction:

Latus Bio, Inc. is developing LTS-101, a gene therapy for the treatment of neuronal ceroid lipofuscinosis Type 2 (CLN2), a form of Batten disease caused by deficiency in the tripeptidyl peptidase 1 (TPP1) protein, leading to lysosomal dysfunction and neurodegeneration. LTS-101 is an intracerebral ventricular (ICV)-delivered gene therapy utilizing a novel capsid, AAV-Ep+, packaging the *hTPP1* gene, which transduces the ependymal cells that line ventricles that can produce and secrete TPP1 protein into the CSF. AAV-Ep+ was identified by a capsid

screening campaign in multiple non-human primate (NHP) species as a potent transducer of ependymal cells and neurons. A non-GLP dose range finding (DRF) study in cynomolgus macaques was conducted to evaluate the biodistribution, and transgene expression, and safety of LTS-101 at three doses. This study demonstrated supraphysiological, potentially therapeutic, levels of TPP1 protein in the CSF at all three doses of LTS-101 and identified a maximum tolerated dose of LTS-101.

Results:
Juvenile macaques were administered a vehicle, or a low-, mid- or high-dose of LTS-101 via MRI-guided bilateral ICV administration for an in-life study duration of 6 weeks. Safety endpoints included in-life safety observations, neurological exams, clinical pathology, and histopathology. AAV biodistribution and expression were quantified by qPCR, RT-qPCR and ELISA. The low and mid doses of LTS-101 were well tolerated, with no significant in-life safety observations. However, animals treated with the high dose of LTS-101 developed motor deficits that spontaneously improved slightly before scheduled necropsy. Histopathology results supported that LTS-101 was well tolerated at all doses except for dose-dependent DRG inflammation and neurodegeneration. Based on these safety data, the mid dose of LTS-101 was identified as the maximum tolerated dose. Biodistribution of LTS-101 viral genomes in the brain was generally dose-dependent and was highest in ependyma. Very low levels of viral genomes were detected in peripheral organs, with the highest levels in the liver and spleen. Brain human *TPP1* mRNA expression was detected in all dosed groups. High concentrations of TPP1 protein were detected in the CSF at all doses, with no clear dose response. Finally, elevated levels of TPP1 enzyme activity were detected in brain parenchyma, indicating cross correction and mature processing of TPP1 protein within cells.

Conclusion:
In a dose-range finding study investigating three doses of LTS-101 in NHPs, bilateral ICV administration produced brain-wide TPP1 activity, high levels of TPP1 in the CSF, a favorable safety profile, and low systemic exposure at logs-fold lower doses that than the conventional capsids which have been used in clinical gene therapy programs. High levels of TPP1 protein in the CSF at the low dose suggest that even lower doses should be explored in future studies and underscore the potency of the novel AAV-Ep+ capsid. In conclusion, LTS-101 is a promising gene therapy candidate with the potential to treat CLN2 Batten disease patients with a one-time ICV administration providing stable, long-term expression of TPP1.

522 SPR301: Dose Dependent Reduction of Inflammation and Substrates in a Surrogate Model for GBA1-linked Neuroinflammation

Parkinson's disease (PD) is one of the most common neurodegenerative diseases, affecting nearly two million people across US and Europe. An association between Gaucher disease (GD), *GBA1* mutations which attenuate or abrogate the activity of the lysosomal enzyme glucocerebrosidase (GCase) and PD has been established, with approximately 5-15% of PD patients carrying a pathogenic or non-pathogenic *GBA1* mutation. There is also evidence for reduced GCase activity in PD patients *without* a known *GBA1* mutation (idiopathic PD, iPD), with factors impacting GCase stability, activity, lipid clearance and α-synuclein aggregation. Although most *GBA1*^{mut} patients do not develop PD, *GBA1* mutation status is still the most predictive genetic factor for the development of PD and is associated with early onset PD and rapid progression.

SPR301 is an AAV9 based gene therapy in development for GBA1-linked PD, containing an expression cassette encoding a novel engineered GCase variant (GCase85) with improved stability compared to GCase. Initial proof of principle was established in an SH-SY5Y *in vitro* model of dopaminergic neurons. Untreated or α-synuclein aggregate seeded cells were pre-treated with SPR301 or AAV9-GBA1 WT. SPR301 demonstrated a significant and

superior GCase activity in treated cell supernatants and a more efficient intracellular α-synuclein reduction when compared with AAV9-GBA1 WT treated cells.

In vivo proof of principle was established in a surrogate murine model for GBA1-linked neuroinflammation. Wildtype C57BL/6J mice treated daily for 16 days with conduritol-β-epoxide (CBE), a brain penetrant irreversible inhibitor of GCase, established a model of *GBA1* deficiency. AAV vectors were administered by unilateral stereotactic injection to the right caudate putamen, 24h post first CBE dose, at doses 5.2 x 10^8, 2.6 x 10^9, 1.3 x 10^{10} vg for SPR301, while positive (AAV9-GBA1 WT) and negative (AAV9-'stuffer') vector controls were at 1.3 x 10^{10} vg only. GCase activity and substrates glucosylceramide and glucosylsphingosine were analysed in the cerebrospinal fluid, treated and untreated hemispheres. Semi-quantitative immunohistochemistry for GBA, inflammation markers (e.g. IBA-1) and co-location of GBA to dopaminergic neurones (tyrosine hydroxylase) was also performed.

SPR301 was effectively distributed within the treated hemisphere from the striatum, the site of injection, to target dopaminergic neurones in the substantia nigra and other key areas of the brain associated with PD. A dose response was observed for SPR301 for GCase activity and substrate reduction. SPR301 at low to mid dose, ≥ 25-fold lower dose than that required for AAV9-GBA1 WT, successfully reduced CBE induced inflammation to near naïve levels in the thalamus, hypothalamus and substantia nigra and did not stimulate inflammation at the site of injection.

523 A Humanized *RBM20* Mouse Model Exhibits Dilated Cardiomyopathy Phenotypes and Enables Development of *In Vivo* Prime Editing for Treating Human *RBM20* Cardiomyopathy Patients

RNA-binding Motif Protein 20 (*RBM20*) encodes a splicing regulator and mutations in *RBM20* can cause dilated cardiomyopathy (DCM), displaying high penetrance and aggressive progression with high rates of heart failure, arrhythmias, and sudden cardiac death. The majority of *RBM20* disease-causing mutations cluster in a 5-amino-acid arginine/serine-rich region, which mediates nuclear localization of *RBM20* protein in cardiomyocytes. While no disease-specific therapy targeting the underlying genetic cause of *RBM20* cardiomyopathy is available, we have developed an in vivo cardiomyocyte prime editing (PE) strategy which may be suitable for correcting the mutations in many *RBM20* patients, as PE can mediate all 12 types of base-to-base conversions and various mutations in the *RBM20* hotspot may be addressed by the same PE therapeutic.

To model the disease and enable *in vivo* testing of human *RBM20* targeting PE therapeutics, we engineered a humanized *RBM20* mouse model with one allele carrying the human wildtype (WT) DNA sequence and one allele carrying the human R634Q (equivalent to R636Q with mouse numbering) mutant DNA sequence in the hotspot and flanking regions ($hRBM20^{R634Q}/hRBM20^{+}$). The total humanized region was designed to be large enough to accommodate binding of guide RNAs (prime editing guide RNA and nicking guide RNA) in potential human *RBM20* PE therapeutics, while being restricted to avoid deviating from the native mouse protein coding outcome. While echocardiogram monitoring detects no abnormal heart function in the control ($hRBM20^{+}/hRBM20^{+}$) mice, $hRBM20^{R634Q}/hRBM20^{+}$ mice display a DCM phenotype, mimicking the heart function defects in the corresponding mouse endogenous *Rbm20* R636Q heterozygous model and in human patients. Additionally, $hRBM20^{R634Q}/hRBM20^{+}$ mice show abnormal splicing of *RBM20* downstream target genes, consistent with findings in the corresponding mouse endogenous model and human patients. Finally, we developed PE therapeutics targeting the human *RBM20* hotspot region and screened them in the humanized *RBM20* mouse model for efficiency of correcting the pathogenic R634Q mutation *in vivo*. Together, we present a novel mouse DCM model with humanized *RBM20* sequences, exhibiting expected heart function and gene-splicing phenotypes of *RBM20* cardiomyopathy and enabling *in vivo* testing of human *RBM20* PE therapeutics. (WL and EE contributed equally to this work.)

524 Development of a Novel AAV Gene Therapy for the Treatment of Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is a complex cardiovascular disorder characterized by dilation and impaired contractility, leading to systolic dysfunction, reduced cardiac output, and congestive heart failure. DCM is the leading cause of heart failure and the most prevalent indication for heart transplantation. Therefore, novel therapeutic strategies are urgently needed to prevent and treat the cardiac dysfunction associated with DCM. Previously, we showed that small molecule-mediated induction of the activating transcription factor 4 (*ATF4*) rescued the contractile dysfunction in induced pluripotent stem cell-derived cardiomyocytes (iPSC-CM) carrying DCM-associated mutations[1]. In this study, we aimed to investigate the therapeutic potential of *ATF4* gene augmentation using novel AAV vectors. To optimize expression, enhance safety and specificity, human *ATF4* (h*ATF4*) was codon-optimized and several human cardiac-specific promoters were tested. The novel vectors were initially assessed for manufacturability and subsequently they were tested *in vitro* in human iPSC-CMs. The candidate that exhibited the highest mRNA and protein expression levels was selected for further investigation in a proof-of-concept gene therapy *in vivo* study using a preclinical model of DCM, the TM54 transgenic mouse. TM54 mice and wild type littermates were dosed at 6 weeks of age, when DCM is evident, with 3E+13 vg/Kg of the candidate AAV via tail vein injection. After dosing, cardiac function was assessed by echocardiography at different time points (2, 6, and 8 weeks) to evaluate heart function. At study termination (8 weeks post-dosing), molecular analysis was performed in relevant tissues (heart, liver, skeletal muscles) demonstrating selective expression of the codon-optimized h*ATF4* transcript in the heart. Importantly, biomarker analyses revealed no significant toxic effects in the liver or the kidneys. This study underscores ATF4 as a promising novel therapeutic target for DCM and supports the potential of *ATF4* gene augmentation as a viable therapeutic strategy for DCM. Further studies in larger species are warranted to evaluate the safety, efficacy, and potential for clinical translation.

Bcl2-associated athanogene 3 (BAG3) is a ubiquitously expressed molecular chaperone that regulates protein homeostasis. In cardiomyocytes, BAG3 modulates apoptosis, autophagy, sarcomere integrity, and contractility. Mutations in *BAG3* lead to haploinsufficiency and are associated with dilated cardiomyopathy (DCM). A gene therapy to augment BAG3 protein expression in cardiomyocytes can be a disease-modifying therapy for patients with *BAG3*-mutation-associated DCM. To model BAG3 deficiency and evaluate the potency of rAAV, BAG3 knocked-down human iPSC-derived cardiomyocytes were transduced with rAAV encoding transgenic BAG3 under a cardiac-specific promoter. Knockdown of endogenous BAG3 resulted in the depletion of BAG3 and its partner protein HSPB8, which was stabilized by AAV-mediated BAG3 expression. The impact of BAG3 on cardiac function *in vivo* was assessed using a cardiac-specific BAG3 knockout (*Bag3* cKO) mouse model. Homozygous *Bag3* cKO mice develop progressive LV systolic dysfunction and dilatation. rAAV expressing human BAG3 (ALXN2350) was administered intravenously after the onset of DCM. ALXN2350 demonstrated dose-dependent improvements in LV systolic function and dilation, halting disease progression at 3E13 vg/kg and above. By 12-weeks post-dosing, ALXN2350 progressively improved LV ejection fraction and significantly reduced *Nppa* and *Nppb* expression in the heart. Biodistribution and safety of ALXN2350 were assessed in cynomolgus macaques at 4E13 and 1.3E14 vg/kg for a 6-week period following intravenous administration and with daily methylprednisolone. ALXN2350 treatment was well tolerated and there were no test-article-related histopathology findings. ALXN2350 treatment resulted in dose-dependent increases in human BAG3 mRNA and protein expression in the NHP heart. Collectively, ALXN2350 demonstrated dose-dependent efficacy in the *Bag3* cKO mouse model of DCM and preclinical safety in non-human primates, supporting its potential as a treatment for patients with BAG3-associated DCM.

526 Ad-VEGF-B186R127S gene therapy induces angiogenesis in mouse heart by recruiting endothelial progenitor cells

Myocardial ischemia is the most common clinical consequence of cardiovascular disease, due to reduced blood supply to the affected region(s) of the heart. Subendocardial blood flow is frequently insufficient despite reperfusion therapies (traditional bypass surgery or catheter-mediated procedures). Hence, there is a strong need for new therapeutic approaches to encourage capillary and collateral artery formation. Vascular endothelial growth factor B186 (VEGF-B186) is known to promote coronary vascular development in both healthy and damaged myocardium. However, prior research also suggests that VEGF-B186 has a serious adverse effect that prevents its use in cardiac gene therapy, which may be caused by binding to neuropilin 1 (NRP1). We have designed adenoviral vector (Ad) based VEGF-B186 variant, VEGF-B186R127S, which is resistant to proteolytic processing and unable to bind to NRP1. Here, we investigated the mechanism of VEGF-B186-induced vascular development as well as its impact on cardiac function by studying its effects on the mouse heart. Without having any negative consequences, such as arrhythmias, the proteolytically resistant VEGF-B186R127S greatly stimulated vascular development in the mouse heart by recruiting endothelial progenitor cells.

527 Novel Combination Gene Therapy to Prevent Rejection after Solid Organ Transplantation

Krish Dewan[1], Jengwei Chen[2], Sarath Mandava[3], Jun Wang[4], Linda Cendales[4], Darion Rapoza[4], Carolyn Glass[4], Alejandro Alvarez-Lobo[4], Allan Kirk[4], Zachary Hartman[4], Carmelo Milano[4], Adam Cockrell[5], Dawn Bowles[4]
[1]Duke University Medical Center, Durham, NC, [2]Duke University, Durham, Taipei, Taiwan, [3]Solid Biosciences, Charlestown, MA, [4]Duke University, Durham, NC, [5]Solid Bioscience, Gainesville, FL

INTRODUCTION:
Administration of targeted gene therapy to allografts prior to transplantation has the potential to decrease morbidity associated with rejection and chronic systemic immunosuppression. We have previously demonstrated the ability of a modified programmed death ligand 1 (PDL1) single-gene therapy to prolong graft survival in a murine heart transplant rejection model when provided with a brief course of concomitant low-dose systemic co-stimulation

blockage (CTLA-4 Ig). A combination of multiple immunosuppressive transgenes into one construct is currently an untested alternate approach. We evaluated six novel combinatory transgene constructs in two distinct *in vivo* models.

METHODS:
Six novel constructs utilizing PDL1 in combination with other immunosuppressive genes were engineered (ASC-1 through ASC-6). We first engineered an immunogenic rejection model of ovalbumin (OVA)-expressing E0771 triple-negative breast cancer cells which are normally rejected in an adaptive immunity-dependent manner in immune-competent mice within three weeks of implantation. Cells were transduced with each of the six novel constructs. After confirmation of gene expression, 500,000 cells were then injected into the flanks and mammary fat pads of immune-competent mice. Tumor engraftment was monitored through biweekly caliper measurements. The best performing constructs from this model were then packaged into a proprietary Solid Biosciences AAV capsid (AAV-SLB101) and tested in an MHC-mismatched murine heterotopic heart transplant model. BALB/c mice were each injected with one of the viral vectors two weeks prior to transplant. Donor hearts were transplanted into the abdominal position of C57BL/6 recipients with and without concomitant CTLA-4 Ig. Grafts were assessed for function by abdominal palpation and echocardiography. Fulminant graft rejection, defined as complete cessation of allograft function on exam and by echocardiography, was the endpoint of the study.

RESULTS:
When implanted into the flanks of immune-competent mice, immunogenic cell lines with gene constructs 2 and 5 consistently outperformed all other constructs in tumor growth and engraftment. Anti-OVA response was intact when measured by quantification of OVA-specific IgG antibodies and in vitro T cell responses against the immunodominant OTI/II peptides. ASC-2, ASC-5, and an unmodified PDL1-only construct were tested in the murine heart transplant model. In the absence of concomitant immunosuppression, transplanted control and therapeutic grafts were fully rejected within a median of 7-9 days. With the addition of concomitant CTLA-4 Ig, all treated allografts demonstrated higher graft survival at 100 days compared to grafts with CTLA-4 Ig alone (ASC-2 and PDL-FL 66.7% vs ASC-5 50% vs CTLA-4 Ig alone 22%), though overall survival distributions between groups were not statistically different.

CONCLUSIONS:
Overexpression of PDL1 in combination with other key immunomodulatory pathways has the potential to prevent or delay acute cellular rejection locally without abrogation of systemic immune function. Further work is required to determine the optimal combination, transgene order, and dose to achieve therapeutic biodistribution.

528 Preclinical Efficacy and Safety Evaluation of FT-017: a Novel AAV-Based Gene Therapy for *MYBPC3*-associated Hypertrophic Cardiomyopathy

Chao Ren[1]*, Hongbin Xu[2], Amy Jiang[2], Hong Duan[3], Yogeshwar Sharma[2], **Zhong-Dong Shi[4]***, Xinyan Li[1]*
[1]Frontera Therapeutics, Shanghai, China, [2]Frontera Therapeutics, Bedford, MA, [3]Frontera Therapeutics, Lowell, MA, [4]Frontera Therapeutics, Belmont, MA

Background:
Hypertrophic cardiomyopathy (HCM) is a common inherited heart disease, primarily caused by mutations in the cardiac myosin-binding protein C (*MYBPC3*) sarcomere-associated gene, which encodes the cMyBP-C protein. Most pathogenic mutations in *MYBPC3* arise via frameshift, nonsense, or conserved RNA splice site mutations on a single allele, resulting in lower levels of total cMyBP-C (haploinsufficiency). Reduction of cMyBP-C protein in cardiac myocytes leads to sarcomeric dysfunction and deregulation of contraction and relaxation. Restoration of cMyBP-C haploinsufficiency offers a viable therapeutic approach for the treatment of HCM. We have designed an AAV gene therapy, FT-017, for *MYBPC3*-associated HCM. Here, we further investigated the preclinical efficacy and safety of FT-017 for its therapeutic use.

Results:
FT-017 is a novel and unique AAV9 vector expressing a codon-optimized human *MYBPC3* gene under the control of a cardiac-specific promoter. *In vitro*, FT-017 efficiently transduced C2C12 cells to express human cMyBP-C in a

dose-dependent manner. *In vivo*, the efficacy and biodistribution of FT-017 were evaluated in neonatal, juvenile, and adult *Mybpc3*-KO mice, respectively. Following a single intravenous injection of FT-017 at doses of 1×10^{13} to 3×10^{14} vg/kg, the vector effectively and specifically transduced cardiomyocytes in the hearts to express cMyBP-C protein, restoring its level to that of wild type. FT-017 significantly reduced myocardial fibrosis and the severity of myocardial pathology, improved left ventricular (LV) systolic function, and decreased the serum cardiac biomarker levels in *Mybpc3*-KO mice. The data suggest that FT-017 has the potential to delay or prevent the progression of *MYBPC3*-related HCM. In a GLP-compliant toxicology study in non-human primates (NHPs), FT-017 was well tolerated up to 1.2×10^{14} vg/kg. Apart from a transient elevation of ALT/AST levels in some individuals within two weeks post-injection, no test article-related systemic, immunological or histopathological abnormalities were observed during the 13-week observation period.

Conclusion:
Overall, these preclinical studies demonstrated the robust efficacy of FT-017 in non-symptomatic and symptomatic *Mybpc3*-KO HCM model mice, with a favorable safety profile showing no hepatotoxicity, thrombotic microangiopathy (TMA), cardiotoxicity, or neurotoxicity observed in NHPs. This provides strong support for the clinical translation of this approach in patients with *MYBPC3*-associated HCM.

529 *An Effective Viral Vector for Treatment of Myocardial Infarction.*

Nihay Laham-Karam[1], Isidore Mushimiyimana[2], Erika Gurzeler[1], Svetlana Laidinen[2], Maria Barbiera[2], Seppo Yla-Herttuala[2]
[1]University of Eastern Finland, Kuopio, Northern Savo, Finland, [2]University of Eastern Finland, Kuopio, Finland

Ischemic diseases, including myocardial infarction and ischemic stroke, are due to blocked arteries or compromised vasculature. In the last 15 years and despite advances in pharmacologic care, they have remained as the leading cause of global mortality necessitating further development of adjunct therapies. To this end gene therapy treatments utilizing viral vector delivery of angiogenic factors, intended to stimulate new blood vessels from existing ones and thereby rescue the remaining viable tissues, were developed. Some of these demonstrated efficacies in increasing the vasculature but were associated with problems such as oedema. These gene therapy treatments have yet to yield success in Phase III clinical trials. Our recent work with novel cell-specific viral vectors and transgene supports a unique therapeutic strategy. We first developed a lentiviral vector (LV) to activate transgene expression specifically in the vessel-forming endothelial cells (ECs), and which was regulated by hypoxia, a low oxygen condition occurring in ischemia. This development was based on a screen of enhancers derived from endothelial specific super-enhancers, from which one enhancer, named E2 was selected due to its superior endothelial activation and specificity. We then combined this vector with a modified vascular endothelial growth factor receptor 2 (VEGFR2mod) which is the main signaling molecule for the potent VEGFA. Once activated VEGFR2 can stimulate endothelial cell proliferation, migration and permeability and is absolutely required for vascular formation. The modification of VEGFR2, abrogates a particular phosphorylation site in VEGFR2 that was previously shown to control adherence junctions and subsequently endothelial permeability but maintains all other functions, therefore we expected that this transgene would facilitate new blood vessel formation with reduced oedema. We tested this novel vector in treatment of ischemic disease by direct delivery into mouse myocardium following induced infarction. We observed survival of all the mice in LV-E2-VEGFR2mod group in contrast to control groups, where mortality was observed. Specifically, as opposed to 100% survival of the mice in LV-E2-VEGFR2mod group (n=5/5), in wild-type VEGF-R2 (LV-E2-VEGFR2) treated mice only 39% (n=7/18) of the mice survived. Likewise, in mice treated with control vector incorporating stuffer DNA in place of E2 (LV-SD-VEGFR2) only 64% (n=7/11) of the mice survived. Consistent with the poor survival of wild-type VEGFR2-treated mice we also observed significantly reduced left ventricular ejection fraction (EF) in this group. Our ongoing studies of the mechanisms of this vector are focused on assessment of capillaries, oedema, inflammation and fibrosis to determine its precise activity. Overall, our studies to date indicate that this vector may provide a breakthrough in angiogenic and regenerative gene therapy for myocardial infarction.

530 Investigating the Mechanisms of Acute Preservation of Cardiac Function Post-Myocardial Infarction Following Angiotensin-(1-9) Gene Therapy

Iain Black[1], Lisa McArthur[2], Lorena Zentilin[3], Mauro Giacca[4], Gillian Lappin[2], Josie Fullerton[5], Martin McBride[2], Christopher Loughrey[2], Stuart Nicklin[2]*

**Corresponding Author*

Introduction
Adeno-associated viral vector serotype 9 (AAV9)-mediated gene therapy expressing Angiotensin-(1-9) (Ang-(1-9)), a peptide of the counter-regulatory renin angiotensin system axis, preserved left ventricular systolic function in mice 8 weeks post-myocardial infarction (MI)[1]. We now demonstrate preservation of systolic function as early as 24h post-MI with AAV9-Ang-(1-9) gene therapy.

Aim
Investigate molecular mechanisms underlying preservation of cardiac function 24h post-MI following Ang-(1-9) gene transfer *in vivo* and *in vitro*.

Methods
AAV9 and adenoviral vectors encoding Ang-(1-9) with mCherry or mCherry alone (control) were constructed. Wild-type (*At2r*$^{+/+}$) and angiotensin type 2 receptor (AT_2R) knockout (*At2r*$^{-/-}$) male mice underwent coronary artery ligation and were intravenously administered AAV9-Ang-(1-9) or AAV9-Control at MI onset. Cardiac fractional shortening was measured at 24h and 14 days post-MI via echocardiography. Bulk RNA-Sequencing of infarct border zone tissue was performed 24h post-MI in wild-type C57BL/6J mice to compare sham + AAV9-Control, MI + AAV9-Control, and MI + AAV9-Ang-(1-9) groups. Ingenuity Pathway Analysis was conducted on differentially expressed genes. Isolated neonatal rat cardiomyocytes (NRCMs) and fibroblasts (NRCFs) were transduced with adenoviral vectors encoding Ang-(1-9) and mCherry (AdAng-(1-9)) or mCherry alone (AdControl) 24h before pathological stimuli treatment. NRCFs were stimulated with 100nM Angiotensin II (Ang II) and 20ng/mL Transforming Growth Factor Beta-1 (TGF-β1), with proliferation measured by MTT assay at 48h. NRCM hypertrophy was induced with 500nM Ang II for 48h and measured via immunofluorescence microscopy. Ang-(1-9) peptide served as a positive control.

Results
Fractional shortening decreased post-MI in wild-type mice without (Sham vs MI: 24h, $P<0.01$; 14 days, $P<0.01$) or with AAV9-Control (Sham vs MI + AAV9-Control: 24h, $P<0.05$; 14 days, $P<0.05$). AAV9-Ang-(1-9) preserved fractional shortening 14 days post-MI (Sham vs MI + AAV9-Ang-(1-9): 42.2%±1.5 vs 39.8%±2.3, $P>0.05$) and as early as 24h post-MI (Sham vs MI + AAV9-Ang-(1-9): 42.1%±2.80 vs 38.4%±3.79, $P>0.05$). Fractional shortening also decreased in *At2r*$^{-/-}$ mice post-MI without (Sham vs MI: 24h, $P<0.05$; 14 days, $P<0.05$) or with AAV9-Control (Sham vs MI + AAV9-Control: 24h, $P<0.05$; 14 days, $P<0.05$). Unlike wild-type mice, *At2r*$^{-/-}$ mice transduced with AAV9-Ang-(1-9) had reduced fractional shortening 14 days post-MI (Sham vs MI + AAV9-Ang-(1-9): 44.0%±1.9 vs 32.0%±3.1, $P<0.05$) and at 24h post-MI, albeit non-significant (Sham vs MI + AAV9-Ang-(1-9): 46.1%±1.6 vs 34.4%±2.4, $P=0.088$). RNA-Sequencing of border zone tissue at 24h post-MI detected transgene expression in AAV9-administered mice. Differentially expressed genes and pathways were identified for further analysis. *In vitro*, adenoviral-mediated Ang-(1-9) gene transfer abolished Ang II-induced NRCF proliferation ($P<0.01$) and reduced TGF-β1-induced proliferation by 20.1% ($P<0.05$). Ang II-induced NRCM hypertrophy (60.1% cell area increase, $P<0.05$) was prevented by AdAng-(1-9).

Conclusions
AAV9-mediated Ang-(1-9) gene therapy preserves cardiac function 24h post-MI in mice, with RNA-Sequencing revealing accompanied border zone transcriptome changes. *In vitro* Ang-(1-9) gene transfer mitigated pathological fibroblast proliferation and cardiomyocyte hypertrophy, underscoring its therapeutic potential for cardiac disease.

531 Gene Therapy for Cardiac Conduction Disorders and Muscular Dystrophy in POPDC2 Null Mice by Systemic MyoAAV4A.POPDC2 Delivery

Shuang Li[1], Renzhi Han[1]
[1]*Indiana University School of Medicine, Indianapolis, IN*

POPDC2 is a member of the Popeye domain-containing gene family, predominantly expressed in skeletal muscle and the heart, particularly in the sinoatrial and atrioventricular nodes. It plays a crucial role in cardiac pacemaking and conduction. A recent study identified a heterozygous nonsense mutation in the POPDC2 gene (POPDC2W188∗) in patients with familial atrioventricular block (AVB), causing a loss-of-function and impaired modulation of the TREK-1 channel. This mutation highlights POPDC2 as a novel susceptibility gene for cardiac conduction disorders.

Here we developed a new POPDC2 null mouse model that exhibits sinus bradycardia, sinus pauses, and tachybradycardia. These mice also show decreased body weight as early as three months of age, vocal sounds, and reduced muscle weight. Histological analysis reveals muscular dystrophy, elevated creatine kinase levels indicating muscle injury, and decreased contractile strength. These findings underscore the multifaceted impact of POPDC2 mutations on both cardiac and skeletal muscle function.

Currently, no therapeutic treatments exist for POPDC2 mutant patients. Our work explores the potential of gene therapy to address this gap. We are evaluating the efficacy and safety of MyoAAV4A-mediated systemic delivery of human POPDC2, driven by a muscle-specific promoter MHCK7, in POPDC2 null mice. Previous studies have shown that this delivery system can efficiently transduce cardiac and skeletal muscle tissues when intravenously injected. Our ongoing experiments aim to develop the first systemic MyoAAV4A.POPDC2 delivery that ameliorates both cardiac conduction disorders and muscular dystrophy in mouse models of POPDC2 mutants. This work holds significant promise for advancing therapeutic strategies for patients with POPDC2-related disorders.

532 FT-018, a Novel AAV Gene Therapy for ARVC, Improves Heart Function and Rescues Survival of Cardiac Pkp2-Deficient Mice

Hong Duan[1], Hongbin Xu[2], Deepthi Yedlapudi[2], Amy Jiang[2], Yogeshwar Sharma[2], Chao Ren[3], Xinyan Li[3]*, Zhong-Dong Shi[4]*

**Corresponding Author*

Introduction: Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a hereditary cardiac disorder characterized by early electrical disturbances in the right ventricle, followed by fibrofatty replacement of myocardial tissue. These pathological changes often lead to ventricular arrhythmias and sudden cardiac death. ARVC affects approximately 1 in 1,000 to 5,000 individuals globally. Most cases of ARVC are linked to mutations in desmosomal genes, with mutations in plakophilin 2 (PKP2) accounting for nearly 45% of cases (>750K worldwide). Current treatment options for ARVC are mainly palliative, focusing on symptom management and arrhythmia prevention but failing to address the underlying genetic cause. Given the haploinsufficiency associated with mutations in the PKP2 gene, which has a small coding sequence, AAV-mediated gene therapy emerges as a promising therapeutic approach.

Methods: Utilizing the tailored recombinant AAV capsid and transgene for optimal response (TRACTOR) vector engineering platform, we designed various human cardiac PKP2 expression cassettes aiming for optimal and durable expression specifically in cardiomyocytes. The transduction and effectiveness of these AAV-PKP2 vectors were evaluated in a cardiac Pkp2 conditional knockout (cKO) mouse model, which recapitulates major clinical features of ARVC in human patients. Survival, cardiac function, myocardial fibrosis, and transgene and biomarker expression

were assessed to identify the best design as the lead development candidate. The safety of the lead candidate was evaluated in WT mice.

Results: All vehicle-treated Pkp2-cKO model mice died between 5 and 9 weeks after induction of Pkp2 knockout. All AAV-PKP2 vectors could significantly improve survival and cardiac function while reducing myocardial fibrosis in the Pkp2-cKO mice. Five of the 9 AAV-PKP2 vectors achieved 100% survival rescue at 13 weeks post-knockout induction (study termination). Among which, PA271, a vector containing a unique payload, showed superior performance in terms of left ventricular ejection fraction (LVEF) and cardiac output (CO) and significantly reduced expression of biomarkers of fibrosis (Col1a1), tissue remodeling (Mmp2), and heart failure (Nppa), while maintained human PKP2 high expression specifically in the heart. Immunohistochemistry confirmed efficient cardiomyocyte transduction and proper human PKP2 localization to the junction of the cardiomyocytes. Based on its novel design and best performance, AAV-PA271 was selected as the lead development candidate (FT-018). In vitro pharmacology testing of FT-018 revealed a dose-dependent expression of PKP2 in C2C12 myocytes. Preliminary toxicity studies in wild-type mice treated with 3E13 vg/kg and 1E14 vg/kg of FT-018 showed dose-dependent on-target PKP2 expression in the heart and no detectable expression in the liver and skeletal muscle. Serum clinical chemistry panel and tissue pathology results showed no overt liver toxicity.

Conclusions: FT-018 containing a unique and sophisticated payload demonstrated robust cardiac PKP2 expression, restored cardiac function, reduced myocardial fibrosis, and significantly improved survival of Pkp2-cKO mice. The innovative vector design of FT-018 offers the potential for optimal efficacy and great therapeutic durability and safety. Further preclinical studies are warranted to advance FT-018 towards clinical development and address the unmet medical needs of patients with PKP2-associated ARVC.

533 Gene Therapy Targeting Atrial Fibrillation Using Mouse Models: A Novel Approach to Cardiac Rhythm Regulation

Sofia De La Serna Buzon[1], Vassilios Bezzerides[1], William Pu[1], Mason Sweat[1]
[1]*Boston Children's Hospital, Boston, MA*

Background: Atrial fibrillation (AF) is the most prevalent cardiac arrhythmia, characterized by rapid and irregular atrial contractions, significantly increasing the risk of stroke and heart failure. Current therapeutic options, including pharmacological agents and catheter ablation, exhibit limited efficacy and significant adverse effects. Gene therapy represents a unique approach, offering the potential to correct molecular aberrations underlying AF. A common hallmark in AF progression is the hyperactivation of CaMKII, a serine/threonine kinase that phosphorylates multiple ion channels and intracellular calcium regulators, leading to calcium overload, increased afterdepolarizations, and atrial arrhythmogenesis. Elevated CaMKII activity has been directly linked to electrical and structural remodeling in AF, making it a promising target for therapeutic intervention. Here, we investigate the efficacy of adeno-associated virus (AAV)-mediated gene therapy targeting CaMKII activity in two mouse models of AF.

Methods:

1. **Gene Therapy Vector:** A multimerization of a CaMKII peptide inhibitor was developed through serial optimization to attenuate calcium dysregulation associated with atrial cardiomyocyte hyper-excitability.
2. **Model Development:** Two models of spontaneous AF were utilized: mice with atrial specific deletion of liver kinase B1 (LKB1) or T-box protein 5 (TBX5). Cre recombinase expression in LKB1flox/flox or TBX5flox/flox mice, driven by an atrial-specific promoter and delivered via AAV9 at postnatal day 3 (P3), resulted in nearly 100% penetrant spontaneous AF with atrial enlargement and fibrosis, mimicking human disease progression.
3. **In Vivo Administration:** To mimic a clinically relevant scenario, the effectiveness of gene therapy was tested after AF onset. An inducible AAV system was employed to overcome adaptive immune responses to multiple AAV doses. Mice were injected with AAV-Cre alongside a Tet-inducible AAV-TRE-AIPx5-mNeonGreen vector at P3. The Tet-on system restricted CaMKII inhibitor expression to atrial tissue upon doxycycline administration, ensuring targeted therapy.

4. **Electrophysiological Analysis:** AF was assessed using in vivo electrocardiography. Variability in the n-to-n interval was measured, with higher variability indicating dysregulated atrial activity consistent with AF.
5. **Molecular Characterization:** Ion channel phosphorylation changes were evaluated via western blot. Viral transduction and therapy expression were confirmed using immunohistochemistry (IHC).

Results:

- AAV-mediated CaMKII inhibition resulted in a significant reduction in atrial CaMKII activation, confirmed by western blot. Expression of the CaMKII inhibitor was localized to the atria, preventing systemic off-target effects.
- AF inducibility was markedly decreased in both treated models of AF. LKB1-knock out mice saw a 15.4% reduction in beat-to-beat variability while TBX5 knock out mice saw a 24.13% reduction just one month after induction of therapy.

Conclusion: This study demonstrates that AAV-mediated gene therapy targeting atrial CaMKII remodeling effectively reduces AF burden in mouse models. By addressing CaMKII-driven calcium dysregulation and electrical remodeling, this approach presents a promising, minimally invasive therapeutic strategy for AF. These findings emphasize the potential of gene therapy as a precise, impactful treatment, warranting further preclinical development and translation to human studies.

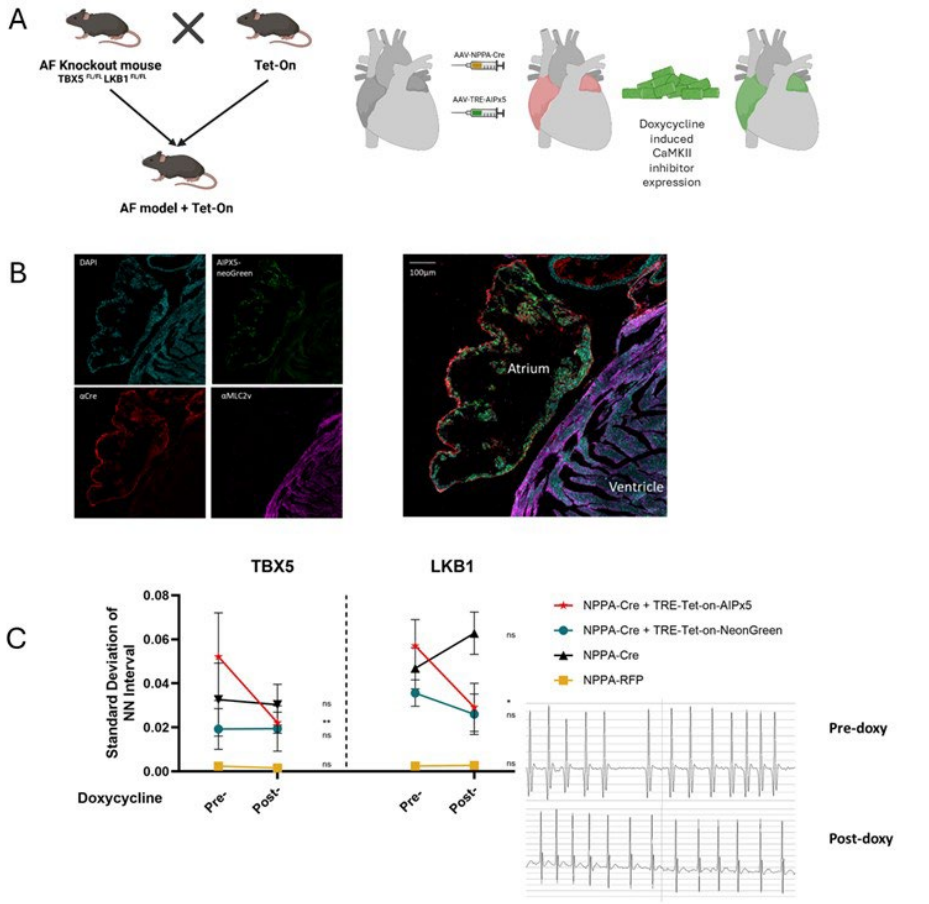

Figure 1. (A) Study design. TBX5 fl/fl and LKB1 fl/fl mice were crossed with a tet-on inducible mouse. The progeny were injected with NPPA-Cre and TRE-CaMKII inhibitor at P3, limiting expression to the atria only. After mice had developed AF (confirmed via EKG), mice were administered a diet with doxycycline, thus activating the therapy. (B) Histology confirming the presence of Cre and CaMKII-inhibitor only in the atria. (C) Results show a significant decrease in the beat-to beat variability in EKG recordings. TBX5 showed a reduction of 24.13% while LKB11 saw a reduction of 15.4%.

534 Engineered Epicardial Hydrogels for Cardiac-Specific Gene Therapy

Gabriella Kabboul[1], Luiza DaMotta[2], Lanfang Wang[3], Christopher Doering[3], Andrés García[2], Rebecca Levit[4]
[1]Georgia Institute of Technology & Emory University, Atlanta, GA, [2]Georgia Institute of Technology, Atlanta, GA, [3]Emory University, Atlanta, GA, [4]Emory University School of Medicine, Atlanta, GA

Introduction: Gene therapy is a promising approach to treat cardiovascular disease. However, clinical trials using adeno-associated virus (AAV) are challenged by immune-mediated responses to AAV and poor transduction of cardiomyocytes. The field has relied on increasing vector doses, but this has led to the discovery of dose-limiting toxicities. Local delivery provides a plausible solution. Here we investigate an epicardial hydrogel delivery of AAV as a potential approach to overcome limitations to cardiac gene transfer. We hypothesize that hydrogels delivered to the epicardium will increase cardiac gene uptake, minimize off-target effects, and circumvent immune-mediated neutralization, while supporting reduced doses needed for efficacy.

Methods: AAV9-CMV-mCherry-luciferase at a dose of 1E12 vector genomes (vg) was delivered to male Sprague-Dawley rats by epicardial hydrogels, intravenous (IV) injection, intramyocardial (IM) injection, and intrapericardial (no gel) delivery (N=5-9/group). Another cohort received AAV at a dose of 1E11 vg via epicardial hydrogels (N=5). All animals were randomized to receive a single AAV dose. Hydrogels were synthesized with 4-arm poly(ethylene glycol) maleimide-terminated (PEG-4MAL) macromer reacted with a crosslinker. Bioluminescence imaging was performed after 28 days. Cardiac and hepatic AAV expression was quantified with regions of interest drawn around the heart and liver from *in vivo* images. Total anti-AAV9 antibody titers were measured by ELISA. Histology evaluated mCherry expression in cardiac tissue.

Results: Epicardial hydrogel delivery displayed local cardiac expression with minimal off-target transduction, whereas the other routes led to systemic vector distribution. In the high dose groups, epicardial hydrogels resulted in 8.9-fold higher cardiac expression compared to IV rats ($p<0.0001$) without significantly differing to IM injections. Epicardial hydrogels showed 2.6- and 3.4-fold lower hepatic expression with respect to IV and IM groups, respectively. Delivery to the pericardial space (with or without gel) efficiently targeted the heart; however, hydrogels generated 12-fold lower hepatic expression compared to no gel delivery ($p<0.05$). Epicardial hydrogels blunted immune responses to AAV with 2.4- and 2.6-fold lower anti-AAV9 antibody titers compared to IV and IM injections ($p<0.05$), respectively, but was not significantly different from intrapericardial delivery. Epicardial hydrogels supported a 10-fold dose reduction with cardiac expression comparable to high dose systemic delivery. Low dose epicardial hydrogels resulted in 49- and 63-fold lower hepatic expression ($p<0.0001$) as well as 3.4-fold reduced anti-AAV9 antibody titers compared to high dose IV and IM groups ($p<0.01$), respectively. High dose epicardial hydrogels localized mCherry expression to the epicardium and myocardium with an average 2.7-fold higher fluorescent intensity across the thickness of the heart compared to IV groups which showed diffused transmural transduction. IM injections resulted in mCherry expression limited to the needle track.

Conclusion: These results suggest epicardial hydrogels are a promising delivery platform to effectively localize vector cargo to the heart, while minimizing systemic circulation, attenuating AAV immune responses, and reducing the dose required for efficient cardiac transduction. Future directions will focus on optimizing epicardial AAV hydrogels for cardiac therapeutic applications.

535 HG204 CRISPR-Cas13 RNA-Editing Therapy for *MECP2* Duplication Syndrome: Preclinical Success to First-in-Human Study

Dong Yang[1], Yiqun Yuan[1], Xin Zhang[2], Alvin Luk[3], Hui Yang[4], Linyu Shi[1]
[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China, Shanghai, Shanghai, China, [2]HuidaGene Therapeutics Co., Ltd., Shanghai, China; HuidaGene Therapeutics, Clinton, NJ, USA, Shanghai, Shanghai, China, [3]Huidagene Therapeutics Inc, Clinton, NJ, [4]HuidaGene Therapeutics Co., Ltd., Shanghai, China; Shanghai Institute of Meteria Medica, Chinese Academy of Sciences, Shanghai, China, Shanghai, Shanghai, China

Background: Methyl-CpG binding protein 2 (*MECP2*) is an X-linked, dosage-sensitive gene critical for neurodevelopment. Its gain-of-function leads to *MECP2* duplication syndrome (MDS), a severe fatal

neurodevelopmental disorder. To address this, we developed HG204, a CRISPR-Cas13-based RNA-editing therapy utilizing high-fidelity Cas13Y (hfCas13Y) and *MECP2*-targeting gRNAs (g*MECP2*) packaged into a single AAV vector (AAVhfCas13Y-g*MECP2*). Preclinical studies in MECP2 transgenic mice demonstrated the long-term safety and efficacy of HG204 in reducing MeCP2 protein levels and reversing disease phenotypes. These findings laid the foundation of clinical translation, and HG204 is now being evaluated in the HERO clinical trial to assess its safety, tolerability, and therapeutic potential in MDS patients.

Methods: Preclinical studies evaluated the editing efficiency of HG204 in reducing *MECP2* mRNA in the brain and the MeCP2 and GDF11 levels in the cerebral spinal fluid (CSF) of the adult wild-type (WT) non-human primates (NHPs) following intracerebroventricular (ICV) injection. Safety assessments included histopathology, MRI, serum biochemistry, CSF analysis, and immunological indicators.
HG204's clinical evaluation is ongoing in the **HERO** (a first-in-**H**uman clinical trial to **E**valuate the safety, tolerability, and efficacy of a single ICV injection of HG204 **R**NA-editing therapy in MDS, a rare **O**rphan disease) study in six boys aged 2 to 18 years with genetically confirmed MDS and stable pattern of seizures within 8 weeks before screening. The primary objectives are the safety and tolerability of HG204 at different doses. Secondary objectives include change from baseline in motor behavior, adaptive behavior, seizure frequency, and other assessment scales within 52 weeks post-injection.

Results: In preclinical studies, HG204 effectively edited *MECP2* mRNA and significantly reduced MeCP2 protein levels in the brains of WT NHPs at low and high doses, with sustained effects observed at 13 and 26 weeks post-ICV injection. High-dose HG204 also reduced CSF's MeCP2 and GDF11 protein levels from D29 to D203 post-ICV injection. MRI scans at D92 or D203 showed no brain injuries in treated NHPs. Minimal histopathological changes were observed in the brain across all dose groups and in the dorsal root ganglion (DRG) and spinal cord of the high-dose group, with no microscopic findings in the liver, kidney, and other tissues. Other safety evaluations, including functional observation battery (FOB), serum biochemistry, CSF cytology/biochemistry, and immunological assessments, confirmed the safety of both low- and high-dose HG204 in adult WT NHPs.
In the HERO trial (Outlined in **Figure 2**), the first subject with MDS was successfully dosed with HG204, demonstrating favorable safety and tolerability. No elevations in liver enzymes or bilirubin were observed, and there were no signs of thrombotic microangiopathy or abnormalities on the brain MRI or electroencephalogram. Early clinical data from the low-dose cohort suggested potential improvements in certain adaptive behaviors.

Conclusions: Our preclinical and early clinical findings support the safety and efficacy of HG204 as a novel CRISPR-Cas13 RNA-editing therapeutic strategy for MDS. The U.S. FDA and the EMA's Committee for Orphan Medicinal Products (COMP) have designated HG204 as an orphan drug and rare pediatric disease (a total of 3 designations), underscoring its potential as a transformative treatment for MDS.

**Corresponding Author*

Dravet syndrome (DS) is a severe, early-onset genetic epilepsy, caused by *de novo* loss-of-function mutations of *SCN1A*, resulting in haploinsufficiency of Nav1.1, a voltage-gated sodium ion channel expressed throughout the brain and at low levels in the heart. Patients exhibit symptoms at approximately 6 months of age, including tonic-clonic and febrile seizures, ataxia and sudden unexpected death in epilepsy (SUDEP) in 15% of cases. Importantly, symptoms are often refractory to pharmacological intervention and no therapies targeting the genetic cause have been licensed.

Here, we describe the first use of a novel, humanised RNA editing technology known as CRISPR-Cas-inspired RNA targeting system (CIRTS) in a therapeutic setting for DS. We designed 21 guide RNAs (gRNAs) targeting a long non-coding RNA within the natural antisense transcript of *Scn1a* (*Scn1anat*) to inhibit its function, thereby reducing negative regulation of *Scn1a* and increasing levels of the endogenous *Scn1a* transcript. *In vitro,* 4 gRNA constructs resulted in a significant upregulation of endogenous *Scn1a*. gRNA9 and 21 led to 1.9- and 2.6-fold increases in *Scn1a*, respectively, restoring approximate wild-type expression levels, whilst also exhibiting high homology (>90%) to human *SCN1ANAT.* As such, these gRNAs were chosen as candidates for the *in vivo* study. Using the highly efficient, CNS-tropic AAV-F capsid, we produced AAV-F-CIRTS-gRNA vectors. We delivered AAV-F-CIRTS-gRNA9 to a clinically relevant heterozygous DS mouse model via neonatal intracerebroventricular and intravenous administration to target the brain and heart. Results revealed an increase in survival, reduced spontaneous seizure frequency, reduced severity of febrile seizures and increased endogenous *Scn1a* mRNA in the brain and heart. Neuropathology and RNAseq were also used to assess the safety of this technology.

Overall, in our proof-of-concept preclinical study, we show that our novel AAV-F mediated RNA editing treatment has promise as a potential therapy for DS.

537 Long-term expression of transgene in targeted cortical neurons following inoculation in the mouse striatum of a non-replicative HSV-1 vector.

Julien Ratelade[1], Justine Basset[2], Teddy Jégu[3], Samuel Salot[3], Alberto Epstein
[1]EG427, Paris, France, [2]EG 427, PARIS, Paris, France, [3]EG 427, PARIS, France

Efficient targeting of cortical neurons in central nervous system (CNS) remains a significant challenge for gene therapies. While direct intracerebral injection efficiently targets focal cell populations, this approach is unsuitable for covering broad structures like the cortex. Administration in the cerebrospinal fluid offers broader coverage but is often hampered by poor penetration of viral vectors in deep cortical structures. Systemic administration in the blood stream has been used to overcome these limitations. However, it requires high vector doses that often impact non-CNS tissues like the liver and DRG neurons. This can elicit immune responses, compromising safety and efficacy of the therapeutic product.

Herpes simplex virus type 1 (HSV-1) is a human neurotropic virus that establishes productive infections in epithelial cells and latent infections in neurons. Non replicative (nr) HSV-1 based vectors have been developed to exploit their therapeutic potential by leveraging their neurotropism, safety, and long-term transgene expression abilities. In contrast to AAVs, nrHSV-1 vectors can efficiently transduce neurons of the CNS at very low doses and can be efficiently transported retrogradely to connected brain regions. Here we administrated a nrHSV-1 vector in the striatum to broadly target, by retrograde transport, cortical neurons projecting in this area. This vector (EG143A) contains deletions in ICP4 and ICP27 genes and expresses the mGreenLantern reporter gene under the control of the CAG promoter. When stereotactically injected into the striatum of mice with no more than 4E+06 PFU (Plaque Forming Unit), EG143A demonstrated high-level transgene expression in layer V cortical neurons. Transgene expression was seen in many cortical areas such as the anterior cingulate, orbital, somatomotor, somatosensory and entorhinal cortex. Co-staining with neuronal marker NeuN showed that cells expressing mGreenLantern were exclusively neurons. Transgene expression kinetics were assessed at one week and six weeks post-administration using fluorescence microscopy and digital-droplet PCR. Both methods demonstrated stable transgene expression levels over time (Figure 1A). Digital PCR on isolated cortices showed stable levels of vector episome (on DNA) and levels of mGreenLantern transcripts (on RNAs after reverse transcription) (Figure 1, B and C).

Our results suggest that intra-striatal administration of low amount of EG143A broadly targets cortical neurons by retrograde transport achieving stable long-term transgene expression for at least 6 weeks. This vector is a promising tool for gene therapies targeting cortical neurons for the treatment of diseases of the CNS (such as Parkinson's disease, Huntington's disease, or other neurodegenerative diseases with cognitive impairment).

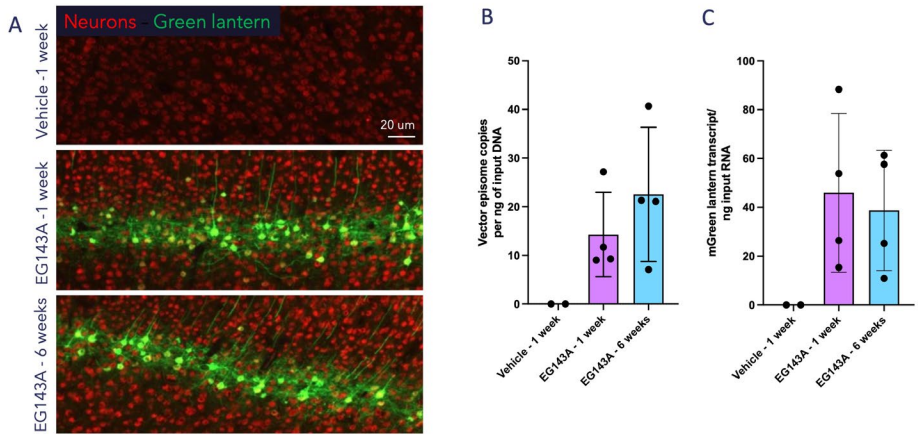

Figure 1. Long-term transgene expression after intrastriatal injection of EG143A in mouse. A. Fluorescence microscopy showing cortex of vehicle-injected animal at one week and EG143A-injected animal at one and 6 weeks. Sections were stained for mGreen lantern (green) and the neuronal marker NeuN (red). B. ddPCR showing quantification of number of vector episomes in the cortex. C. Reverse transcription ddPCR showing quantification of number of mGreen lantern transcripts in the cortex. Mean +/- SD. Each dot represents one injected hemisphere.

538 Successful RNA Therapy for Schinzel-Giedion Syndrome Demonstrated in Patient-Derived Stem Cell Models and a Clinically Relevant Mouse Disease Model

Carl Ernst[1], Alessandro Sessa[2]
[1]McGill University, Montreal, QC, [2]San Raffaele Scientific Institute, Milan, Lombardy, Italy

Schinzel-Giedion Syndrome (SGS) is a devastating neurodevelopmental disorder causing premature death. SGS is caused by increased SETBP1 protein due to heterozygous missense mutations in a degron motif of SETBP1 required for protein degradation. To lower SETBP1 protein levels characteristic of SGS, we developed antisense oligonucleotides (ASOs) to reduce SETBP1 mRNA and so lower SETBP1 protein levels. ASOs are able to downregulate SETBP1 in four independent SGS patient iPSC models with different disease-causing mutations at two neurodevelopmental stages. We calculate an IC50 of approximately 70nM suggesting that ASOs are efficient, with no evidence of off-target effects based on whole transcriptomic studies. These anti-SETBP1 ASOs behave similarly when assessed in SGS neuroepithelial primary tumor cells, SGS engineered cell lines, or healthy primate iPSC-derived neurons. We developed a brain-specific SGS mouse model that recapitulates disease, showing failure to thrive with hydrocephalus and death within 8 months. Intracerebral ventricular injection of anti-SETBP1 ASOs in brain of SGS mice all survive long term, gain weight normally, and have significantly reduced hydrocephalus. ASOs reduce SETBP1 protein in vivo, reverse clinically relevant pathological phenotypes, and show no major adverse events. This work highlights a novel RNA therapeutic for the treatment of Schinzel-Giedion Syndrome.

539 Convection-enhanced delivery of gene therapies to the pons – a novel method of achieving transgene expression throughout the Central Nervous System

Neil Barua[1], Ali Bienemann[2], Sharon Kane[3], **Steven Gill**[4]
[1]Neurochase Limited, Bristol, Bristol, City of, United Kingdom, [2]University of Bristol, Bristol, United Kingdom, [3]Neurochase, Glasgow, United Kingdom, [4]Neurochase Ltd, BRISTOL, Bristol, City of, United Kingdom

Introduction
Convection-enhanced delivery describes the direct delivery of drugs to the brain through intraparenchymal microcannulas, thus bypassing the blood-brain barrier. CED facilitates safe and targeted drug distribution through clinically-relevant brain structures. This method is particularly relevant to the delivery of gene therapies which cannot effectively cross the blood-brain and CSF-brain barriers, and where systemic administration can be associated with dose limiting toxicity. To date, the majority of gene therapy CED trials have aimed to treat disorders with a localised structural target such as the putamen in Parkinson's Disease or caudate and putamen in Huntington's disease. However, many CNS disorders are characterised by widespread neurodegeneration including Amyotrophic Lateral Sclerosis, Alzheimer's Disease, enzyme deficiencies and metabolic disorders. We hypothesised that due to the unique and extensive connectivity of nuclei and tracts within the pons and cerebellum, infusion of a retrogradely and anterogradely transported viral vector into this relatively small CNS volume, has the potential to transduce all the major neuronal circuits participating in sensory-motor processing including the pyramidal and extrapyramidal motor pathways as well as the limbic, somatosensory, visual and auditory circuits that modulate motor activity.

Methods
Bilateral trans-middle cerebellar peduncle cannula trajectories were used to deliver 250uL of AAV9-mCherry into the right hemipons, whilst 250uL of AAV5-mCherry was delivered into the left hemipons in a large animal (ovine model). Both vectors were infused at a concentration of 1E12vg/mL. In a second test subject, a unilateral pons infusion of 300uL of AAV9-mCherry was delivered at an infused concentration of 5E12vg/mL. GFP and mCherry expression throughout the brain and spinal cord was analysed using ELISA, fluorescence and DAB immunohistochemistry.

Results
GFP and mCherry expression measured by ELISA confirmed expression in the ipsilateral and contralateral motor cortex and spinal cord at 1 month post unilateral pontine infusion. At this early timepoint, GFP and mCherry was detected at 25cm along the spinal cord. Comprehensive analysis following unilateral AAV9-mCherry infusion

demonstrated mCherry expression measured by ELISA throughout all components of the motor and sensory subsystems of the brain and spinal cord, the limbic system and throughout the spinal cord. Fluorescence and DAB immunohistochemistry confirmed mCherry expression through widespread areas of the cerebral and cerebellar cortex, brainstem nuclei (including hypoglossal and inferior olive) and anterior horn cells of the spinal cord.

Conclusions
These data demonstrate that a single CED infusion of an antero- and retro-gradely transported adeno-associated viral vector to the pons through a transcerebellar trajectory results in gene expression in multiple components of the cerebral cortex, motor system and sensory and limbic systems – the motor cortex, basal ganglia, sensory, auditory, visual and visual association cortex, hippocampus and amygdala, spinal cord, cranial nerve nuclei, inferior olivary nucleus, thalamus, cerebellum including dentate nucleus, as well as the anterior horn cells of the spinal cord. This novel gene therapy method opens the door to the treatment of disorders characterised by widespread degeneration of multiple subsystems of the CNS with a single, low volume infusion.

540 AAV mediated APOE4 Silence and Replace Therapy to Treat Homozygous APOE4-associated Alzheimer's Disease

Kalpita Karan[1], Neil Hackett[1], Ronald Crystal[2]
[1]Weill Cornell Medical College, New York, NY, [2]Weill Cornell Medical College, New York

Variants of APOE, a 299 amino acid lipid transport protein that functions as a major carrier of cholesterol in the CNS, are the major genetic risk factors for sporadic late-onset Alzheimer's disease (AD). APOE has 3 common variants: APOE3 (C112/R158), APOE4 (R112/R158) and APOE2 (C112/C158). Epidemiologic, clinical and experimental evidence demonstrate that APOE3 is associated with an average risk for AD, APOE4 is pathogenic, conveying a high risk and APOE2 is protective, reducing risk. Inheritance of the APOE4 allele is linked to dysfunction in cholesterol efflux, cerebral hypometabolism, synaptic defects, mitochondrial dysfunction, blood-brain barrier dysfunction, enhanced neuroinflammation, cognitive impairment, increased Aβ production and aggregation, decreased Aβ clearance and deposition, neurotoxicity, increased tau phosphorylation and oligomerization and tau-related neurofibril tangles. In the context that APOE4 is toxic while APOE2 is protective, the ideal therapy for APOE4 homozygotes is to reduce CNS levels of APOE4 and to substitute APOE4 by addition of APOE2. To accomplish this goal, we have developed a "silence and replace" therapy, where suppression of CNS APOE4 is achieved using adeno-associated virus (AAV) expression of microRNAs (miRNA) designed to hybridize to and "silence" the endogenous human APOE4 mRNA, together with simultaneous "replacement" with an APOE2 gene resistant to the miRNAs. The endogenous APOE4 suppression was achieved by identification of miRNAs that suppress human APOE4 expression in TRE4 mice with humanized APOE4 gene when delivered with AAV.S2, a novel neurotropic AAVrh.10 variant that has broad CNS distribution following intraparenchymal CNS administration. By combining 2 different APOE-directed miRNAs, over 70% suppression of endogenous APOE4 mRNA level could be obtained (Karan KR et al Hum Gene Ther 2024; 35:904). We then engineered a silencing resistant (SR) APOE2 gene (APOE2-SR) that was expressed at high levels even in the presence of the 2 miRNAs that suppress endogenous APOE4 expression. AAV.S2 vectors expressing APOE2-SR with and without the miRNAs were administered to the hippocampus of human APOE4 (TRE4) mice and APOE protein levels assessed 2 weeks later by ELISA in coronal sections of the brain. Relative to endogenous APOE4 levels in TRE4 mice PBS control, both APOE2-SR vectors increased total APOE protein by 2.0±1.1 fold for APOE-SR and 2.3±1.0 fold for APOE-SR with miRNAs ($p<0.05$ compared to PBS control, $p>0.5$ comparing APOE2-SR with or without the miRNAs). TaqMan allelic discrimination assay was used to assess APOE2 to APOE4 ratio. As expected, both vectors with APOE2-SR increased the E2/E4 ratio relative to controls by 3.5±0.6 fold for APOE2-SR and 6.3±0.4 fold for APOE2-SR+miRNAs ($p<0.05$ comparing APOE2-SR with and without miRNA). We conclude that a single AAV vector can deliver a cassette that has the dual functions of suppressing expression of the toxic APOE4 variant while also delivering the protective APOE2 variant. This dual approach may provide a more potent gene therapy for APOE4-dependent Alzheimer's disease than either alone.

541 One-Time Delivery of a Vectorized Anti-Amyloid Antibody for Increased and Sustained CNS Expression and Target Engagement

Cassandra Retzlaff[1], Nivanthika Wimalasena[2], Roberto Calitri[3], Dave Rappoli[3], Alexandra Tsolias[1], Xiaoqin Ren[4], Ishan Shah[4], Jordan Routhier[1], Jeron Chen[5], Mathieu Nonnenmacher[3], Charlotte Chung[2], Rajeev Sivasankaran[1]
[1]Voyager Therapeutics, Inc., Lexington, MA, [2]Voyager Therapeutics, Inc., Cambridge, MA, [3]Voyager Therapeutics, Lexington, MA, [4]Voyager Therapeutics, Cambridge, MA, [5]Voyager Therapeutics, Inc., Houston, TX

Alzheimer's disease (AD) is characterized by the accumulation of amyloid plaques, leading to cognitive decline. Clinically, passive administration of anti-amyloid antibodies has shown promise in reducing amyloid plaque burden and improving cognitive function in patients with mild cognitive impairment. However, these therapies are limited by poor blood-brain barrier (BBB) penetration and require frequent administration, which can be burdensome for patients and care partners. Alternatively, the use of an adeno-associated viral (AAV) vector to deliver a transgene encoding an anti-amyloid antibody could enable sustained expression of the antibody in the brain after a single injection, especially if the vector is delivered via a BBB-penetrant capsid.

Here, we show that in wildtype mice a vectorized anti-amyloid antibody packaged in a BBB penetrant capsid has over 15-fold greater brain:plasma ratios as compared to a passively administered antibody over 4 weeks. In a transgenic mouse model of AD, we observe broad biodistribution of vector genomes and sustained antibody expression in the brain over a 2-month period. Immunohistochemical and immunofluorescence analysis of the cortex and hippocampus reveal that the vectorized antibody co-localizes with human amyloid-beta plaques, indicating successful target engagement.

Together, these results demonstrate that vectorization of an anti-amyloid antibody using a BBB penetrant capsid offers a promising strategy for sustained and enhanced, brain-wide antibody expression, overcoming the limitations of passive antibody therapies in AD.

542 Retargeting of AAV to CNS Using Anti-AAV X TFR1 Bispecific Antibodies

Adeno-associated virus (AAV) vectors are widely used in gene therapy due to their safety, efficiency, and ability to deliver therapeutic genes into target cells. However, most naturally occurring AAV serotypes are inefficient at crossing the blood brain barrier (BBB), making them suboptimal for delivering therapeutic cargo to the central nervous system (CNS) when administered systemically.

At Regeneron, we have developed platforms to target AAV to specific tissues using antibodies, which can bridge AAVs to target receptors specifically expressed on tissues of interest. Previously, we demonstrated enhanced AAV targeting to the CNS in both mice and non-human primates using a protein tagging system to covalently attach anti-Transferrin receptor 1 (TFR1) antibodies to the viral capsid. Here, we demonstrated that efficient TFR1-based BBB crossing can also be achieved using anti-AAV x TFR1 bispecific antibodies, thereby further expanding the applications of the antibody retargeted AAV platform.

By conducting extensive screening of antibodies and creating innovative antibody formats, we have developed bispecific antibodies that can effectively target AAV to the entire brain, achieving over a 10-fold increase in on-target transduction compared to AAV alone, measured by reporter mRNA expression level. Furthermore, the bispecific platform is shown to be highly modular, flexible, and adaptable. For instance, AAV and bispecific antibodies can be combined and administered using various dosing strategies while maintaining comparable efficacy. Also, by utilizing a broad serotype binding anti-AAV arm, we demonstrate that the same bispecific

antibody can improve CNS transduction of multiple different serotypes. In addition to CNS delivery, we have previously demonstrated that our bispecific platform can enhance AAV retargeting to skeletal muscle in mouse models, this highlights the potential to utilize bispecific antibodies to enhance transduction for a wide range of target tissues. Moving forward, bispecific antibodies can serve as a "plug and play" system that can combine with existing AAV programs to improve on-target transduction efficacy.

543 Investigating Focused Ultrasound Enhancement of CSF-Delivered AAV to the Brain

Nicholas Slimmon[1], Deepshikha Bhardwaj[1], Irvin Garza[1], Karina Alvarado[1], Bhavya Shah[1], Rachel Bailey[2]
[1]UT Southwestern Medical Center, Dallas, TX, [2]University of Texas Southwestern medical Center, Dallas, TX

Gene therapy with recombinant adeno-associated virus (rAAV) is used across a variety of disorders to achieve long-term expression of delivered DNA in postmitotic cells. For neurological disorders, AAV9 is commonly used due to its high neuronal and glial tropism, as well as its ability to cross the blood-brain barrier (BBB). While AAV9 can be targeted to the brain intravenously, this approach includes risks of hepatotoxicity and immune responses. Intrathecal CSF administration largely avoids these concerns and has improved CNS transduction, although it is limited by poor distribution to deeper brain and forebrain areas, especially in aged animals. Transcranial low-intensity focused ultrasound (FUS) can be used for transient BBB opening and more efficient targeting of AAV to deep brain structures. Previously, our group showed that FUS can enhance transduction of CSF-injected AAV to deep brain structures, such as the hippocampus and striatum. However, it remains unclear whether FUS enhances CSF-delivered virus by redirecting AAV that escapes to the blood back into the targeted brain or via other mechanisms, such as CSF-brain diffusion under FUS-stimulated glymphatic flux.

As part of the optimization of CSF-FUS delivery, we first established the timing of AAV9 CSF-blood escape in mice. Adult (6 months old) and aged (18 months old) C57Bl/6 mice were intrathecal intra-cisterna magna (ICM) injected with $1x10^{11}$ vg of AAV9-GFP and then blood was collected at a series of time points. Plasma DNA was tested for AAV genomes by qPCR. Virus concentrations rose in the blood within 30 minutes of injection, peaking at stable levels 1-4 hours post-injection and mostly clearing after 3 days. No significant differences in circulation kinetics were seen between age groups. These results indicate early post-injection FUS-BBB opening may be optimal for AAV brain entry. Since CSF-delivered virus peaked in the blood in 1-4 hours of injection, we hypothesized that FUS at 1 or 4 hours after AAV injection results in the highest transduction of targeted regions. To investigate optimal CSF-FUS delivery, we compared adult C57Bl/6 mice treated with FUS 1 hour before, or 1, 4, or 24 hours after ICM injection of $1x10^{11}$ vg AAV9-GFP. A microbubble-free control group was included to test the necessity of BBB opening. Mice received systemic infusion of Definity microbubbles and FUS-BBB opening of 3 targets in the left hippocampus. Systemically infused gadolinium was used to confirm BBB opening by T1-weighted MRI. Three weeks post-injection, brain transduction was assessed by GFP IHC and analysis is ongoing. If higher transduction is seen with BBB opening 1- or 4-hours post-injection this could indicate that blood circulation of CSF-delivered AAV contributes to its enhancement via FUS. Overall, these findings suggest CSF-delivered virus escapes to blood within 30 minutes of injection, with peak levels 1-4 hours post-injection and that FUS-BBB opening in this time frame should allow for maximal AAV transduction. The results of this work could enable improvements in AAV-mediated therapeutic delivery to the brain.

544 Targeted Bacteriophage Gene Delivery to Astrocytes Using Intelligent Phagemid-Assembled Gene Expression (iPhAGE) Technology for Neuronal Regeneration

Roderick Slavcev[1], Anna Ivanova[2]
[1]University of Waterloo, Waterloo, ON, [2]University of Waterloo, Waterloo

Neurodegenerative diseases are the leading cause of disability and remain largely incurable as current treatments focus on symptom management rather than slowing disease progression. As part of the iNeuron project, this research develops Intelligent Phagemid-Assembled Gene Expression (iPhAGE), a novel platform utilizing M13 bacteriophage-derived miniphagemids to deliver Neurogenic Differentiation Factor 1 (NeuroD1) to astrocytes, reprogramming them into neurons. This system addresses key limitations of traditional gene delivery methods, such as restricted cargo capacity, high immunogenicity, and inability to cross the blood-brain barrier.

M13 bacteriophages offer unique advantages, including their rod-shaped structure that facilitates blood-brain barrier penetration, large DNA cargo capacity, and lack of mammalian cell tropism, enhancing safety. The bacterial host, *Escherichia coli* JM109, packages NeuroD1 into miniphagemids lacking bacterial backbone elements, significantly reducing immunogenicity. The highest bacterial backbone contamination in the produced miniphagemids was detected to be $1x10^{-8}$. Miniphagemid production was optimized using a specialized helper plasmid, SW8, which ensures precise excision and circularization of the transgene cassette.

Targeting specificity can be enhanced through the incorporation of IRL1620 and EGF ligands into the M13 system. IRL1620, an endothelin B receptor agonist, selectively binds reactive astrocytes, while EGF targets the epidermal growth factor receptor, facilitating efficient gene delivery. To validate this approach, miniphagemids encoding NeuroD1 were transfected into A7 astrocyte cells. Transfection efficiency was assessed using a luciferase reporter gene, and neuronal differentiation was confirmed via PSA-NCAM1 immunostaining. At day 7 post-transfection transfected A7 cells showed close to half the level of expression compared to positive control – a neuronal cell line, HT22.

This research demonstrates a safe, efficient gene therapy approach that enables precise astrocyte targeting and reprogramming, providing a promising strategy to regenerate neurons and treat neurodegenerative diseases. Future directions include developing a test to mimic hypertrophic astrocytes. One key milestone will be to establish a protocol for 'activating' resting astrocytes via proinflammatory cytokines, oxygen deprivation, or LPS treatment to resemble hypertrophic astrocytes following a stroke event. The iPhAGE system's versatility suggests potential applications in other neurological and regenerative medicine contexts, marking a significant advancement in gene therapy technology.

545 Gene replacement therapy reverses behavioral and molecular phenotypes in succinic semialdehyde dehydrogenase deficiency (SSADHD) mice

Henry Lee[1], Zijie Jin[2], Yongho Choe[2], Gabrielle McGinty[2], Amanda Liebhardt[2], Guangping Gao[3], Alexander Rotenberg[4]
[1]Boston Children's Hospital, Boston, MA, [2]Boston Children's Hospital, Boston, [3]UMass Chan Medical School, Worcester, MA, [4]Boston Children's Hospital

Introduction: Succinic semialdehyde dehydrogenase deficiency (SSADHD) is a rare autosomal recessive neurodevelopmental disorder due to loss of function mutations of *ALDH5A1* gene essential for degradation of the inhibitory neurotransmitter g-aminobutyric acid (GABA). In SSADHD, pathologic GABA and g-hydroxybutyrate (GHB) accumulation results in early life encephalopathy, refractory epilepsy, and high mortality. Emerging evidence also suggested that elevated GABA/GHB levels underlie late-life disease risks in heterozygous SSADHD carriers (~0.3% of the population). Targeted drug treatments for patients with SSADHD and carriers are absent. Gene replacement therapy for SSADHD has not been developed.

We recently demonstrated in a Cre-dependent SSADH mouse model, *Aldh5a1*$^{lox\text{-}STOP}$, that SSADHD symptoms and mortality are reversible. As a step toward clinical translation of SSADH gene replacement, we developed a novel vector encompassing a human *ALDH5A1* full length native promoter (FLnP) tethered with a human *ALDH5A1* coding sequence, namely AAV-FLnP-hALDH5A1, and observed complete phenotype reversal when packaged in the blood-brain barrier (BBB)-penetrating capsid AAV-PHP.eB.

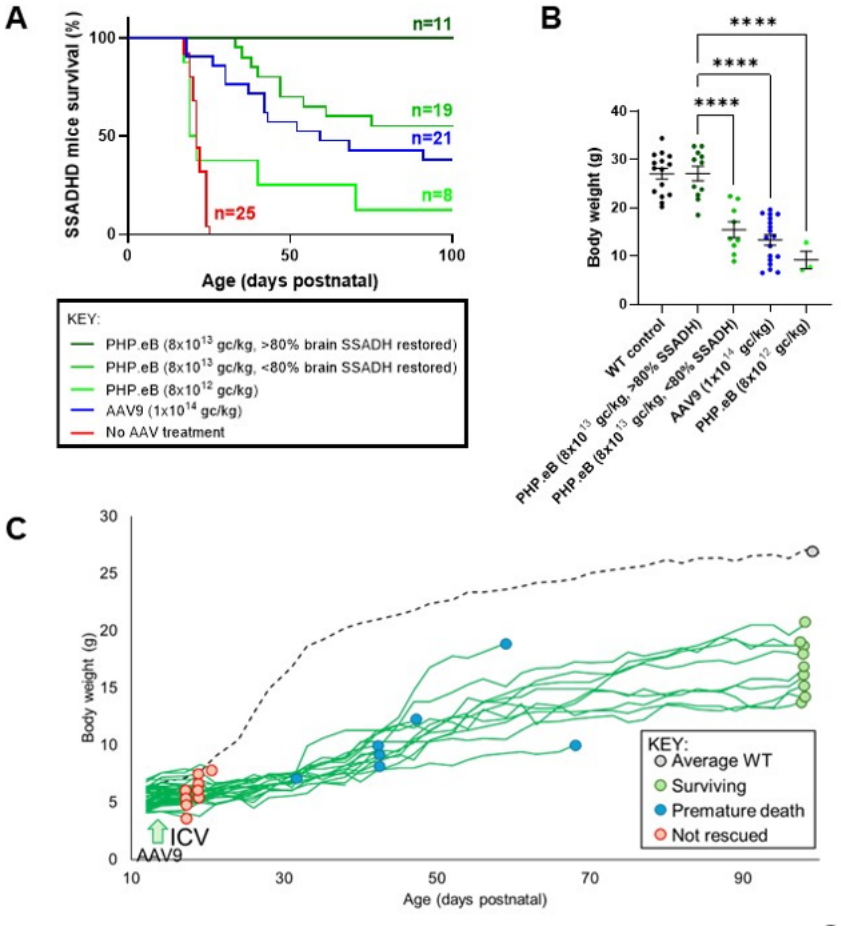
Since AAV-PHP.eB is not clinically translatable, we now test AAV-FLnP-hALDH5A1 encapsulated in AAV serotype 9 (AAV9). As an exploration of gene replacement in SSADHD carriers, we also treated AAV-PHP.eB-FLnP-hALDH5A1 in heterozygous SSADHD mice and measured SSADH content and GABA/GHB levels.

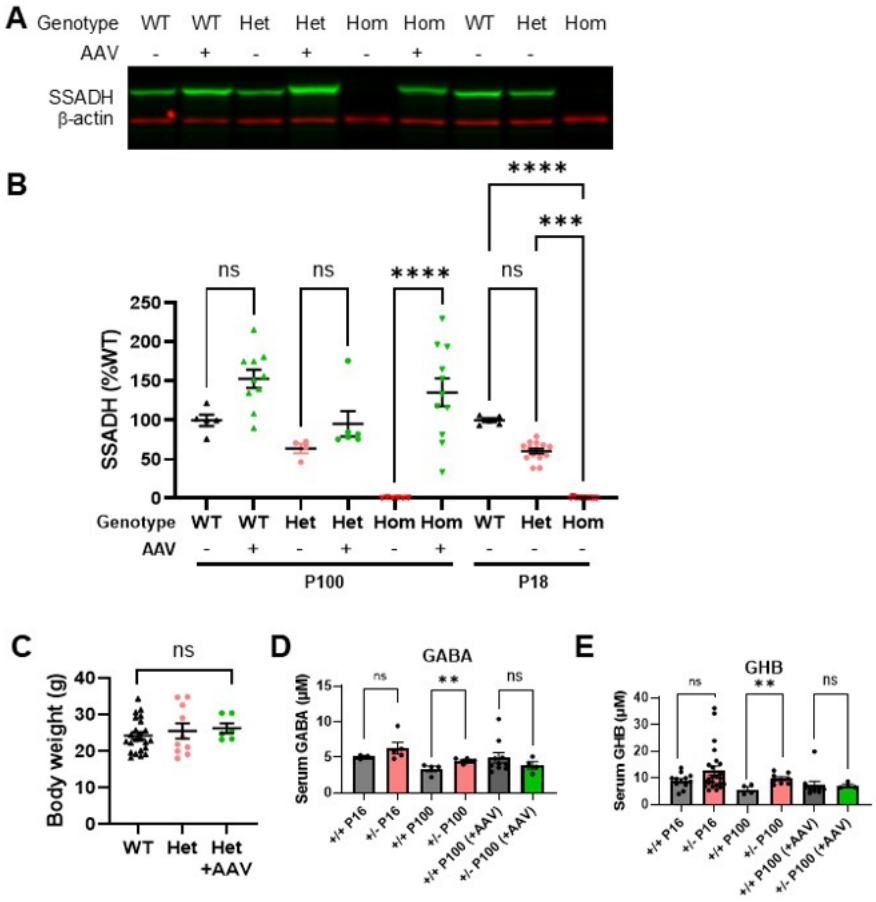
Methods: We packaged AAV-FLnP-hALDH5A1 into AAV9 and injected into homozygous mutant (Hom) *Aldh5a1*$^{lox\text{-}STOP}$ mice via retro-orbital (RO), intracerebroventricular (ICV), and intraperitoneal (IP) injection through a dose de-escalation paradigm at a symptomatic stage P14. Body weight and survival were tracked until P100, when blood and brain tissues were collected for metabolites and protein analyses. We also injected AAV-PHP.eB-FLnP-

hALDH5A1 into heterozygous (Het) mice and check for cortical SSADH expression and blood GABA/GHB content at P100.

Results: Relative to AAV-PHP.eB treatment, AAV9 resulted in incomplete rescue among injection routes (IP:1x10^{14} gc/kg; RO:1x10^{14} gc/kg; ICV:2x10^{13} gc/kg). At P100, the survival rate of AAV9-treated mice was 38%, comparable to a de-escalated dose of PHP.eB (54% survival in 8x10^{13} gc/kg, 13% survival in 8x10^{12} gc/kg) (Fig. 1A). AAV9 treatment also resulted in sub-optimal body weight restoration (WT:27±4g; Hom+AAV-PHP.eB (8x10^{12} gc/kg):9±3g; Hom+AAV9 (1x10^{14} gc/kg):13±5g) (Fig. 1B) and impaired growth trajectory (Figure 1C). AAV-PHP.eB-FLnP-hALDH5A1 resulted in SSADH overexpression in the cortex of WT (153±12% of un-injected WT), Het (un-injected:64±6% WT; injected:95±16%), and Hom (un-injected:1±0.2% WT; injected:136±18%) (Fig. 2A-B). AAV-PHP.eB did not affect body weight of Het mice (un-injected:26±2g, injected:26±1g) (Fig. 2C). AAV-PHP.eB reduced blood GABA (WT:3±0.4µM; Het:5±0.1µM; Het+AAV-PHP.eB:4±0.5µM) and GHB (WT:6±0.9µM; Het:10±0.7µM; Het+AAV-PHP.eB:7±0.5µM) in Het mice (Fig. 2D-E).

Conclusions: We found that SSADHD mice are partially rescued with AAV9-FLnP-hALDH5A1. AAV9 therapeutic effects are slightly better than a sub-optimal dose of AAV-PHP.eB, suggesting room for optimization and testing next-gen capsids with higher BBB penetrance. AAV-FLnP-hALDH5A1 is well-tolerated in Het mice, with reduced blood GABA/GHB content suggesting target engagement, paving the way for experimental SSADH-targeted gene therapy for SSADH carriers.





546 Translational Devices for Simultaneous Neural Recordings and Drug Delivery in the Brain: From Small to Large Animals

Maria Porto Cruz[1], Guadalupe Zepeda[2], Maria Vomero[3], Su-youne Chang[4], Jiwon Kim[4], Inyong Kim[4], Alfonso Chavez[2], Mary McNeil[2], Nidhi Kalia[2], Camilo Diaz-Botia[2], Dave Rosa[5], Gregory Worrell[4], Aura Kullmann[1]
[1]NeuroOne, Eden Prairie, MN, [2]NeuroOne Medical Technologies Corporation, Los Gatos, CA, [3]NeuroOne Medical Technologies Corporation, Los Gatos, [4]Mayo Clinic Rochester, Rochester, MN, [5]NeuroOne Medical Technologies Corporation, Eden Prairie, MN

The evaluation of drug effects on neural activity is essential for the development of brain-targeted therapies. Real-time neural recordings are useful in assessing drug efficacy, dosing, mechanism of action, and potential toxicity. Typically, drug effects on neural activity are assessed using in vitro systems (e.g. cell cultures, brain slices) or small animal models (mice, rats), with less frequent testing in large animals or humans. This gap in continuity between small and large species often contributes to drug failure in late developmental stages. This disparity may arise from a mismatch in technological capabilities between devices used in small versus large species and, specifically, the lack of a device able to simultaneously record neural activity and deliver drugs.

We are developing a drug delivery (DD) system with integrated neural recordings, utilizing an FDA-cleared stereoencephalography (sEEG) electrode. This system is intended for convection enhanced delivery (CED) in large brains (human and large animals) and has successfully been tested in swine. Here, we introduce a miniaturized version of the device tailored for use in small rodents. A first prototype consisting of a modified human-size sEEG with 0.8 mm outer diameter and an inner silica infusion cannula (320 µm inner diameter) inserted through the sEEG lumen, was tested in the rat brain. The device was implanted stereotactically into the hippocampus, and recordings were made prior to and following the administration of a drug that modulates neural activity (penicillin, 5000

units/µl; 5 µl; 0.5 µl/min). Histological analysis of the brain tissue using hematoxylin and eosin staining enabled the estimation of the diffusion volume.

While the modified human-size prototype demonstrated effective CED along with the ability to record neural activity in rats, its size and design limit its suitability to acute experiments only. Our most recent prototype is scaled down to better match the brain size of rodents and accommodate the small space available in headstages typically used for survival/chronic studies. The sEEG length is shortened by a factor of 10, its diameter reduced to 0.6 mm and the recording contacts shortened to 0.5 mm, a quarter of the length used in the human-sized version. The inner diameter of the infusion cannula is reduced by a factor of 3 to minimize the dead volume of the infusion line, a crucial aspect to cut drug expenses at early stages of drug development.

The integration of drug delivery and real-time neural recording into a single device, suitable for both small and large species, ensures consistency across species and streamlines the drug discovery process from rodents to humans. This approach enables more precise assessments of drug efficacy, dosing, toxicity, and mechanisms of action across species, potentially reducing the failure rate of drugs in later development stages and improving clinical outcomes.

547 ETX201: An AAV9-based Vectorized miRNA Therapeutic Candidate for Angelman Syndrome

Sirika Pillay[1], Winnie Lin[2], Elizabeth Hallam[1], Peter Neumann[1], Veda Tatavarty[1], Raghavendra Hosur[1], Maureen Haines[3], Pingping Jia[1], Charles Cao[1], Szu-Ying Chen[4], Cody McDermott[1], Sawyer Randles[4], Ron Chen[1], Greg Lucey[1], John McLaughlin[4], Nathan Moerke[1], Sheila Sears[1], Serena Liu[1], Alex Weber[1], Annie Tanenhaus[1], Archana Belle[2], SURESH PODA[5], Stephanie Tagliatela[2]
[1]Encoded Therapeutics, South San Francisco, CA, [2]Encoded Therapeutics, South San Francisco, California, [3]Raleigh, NC, [4]Encoded Therapeutics, South San Francisco, [5]Encoded Therapeutics, Tracy, CA

Angelman syndrome (AS) is a severe, neurodevelopmental disorder caused by loss of neuronal ubiquitin E3 ligase, *UBE3A*. Currently available treatments may address certain symptoms, but there are no approved disease-modifying therapies. Adeno-associated virus (AAV)-based vectorized knockdown of the paternal long non-coding RNA, UBE3A anti-sense transcript (UBE3A-ATS), has the potential to target the underlying cause of AS by increasing *UBE3A* expression specifically in neurons, with a single administration. Moreover, given UBE3A's involvement in the duplication disorder dup15q, an unsilencing approach mitigates the potential toxicity risk associated with UBE3A overexpression by limiting maximum expression to the capacity of the paternal allele. We previously showed that a mouse-specific miRNA candidate targeting Ube3a-ATS was capable of upregulating Ube3a RNA and protein. We also established that partial *Ube3a* reinstatement can rescue multiple disease phenotypes in an AS mouse model. We then developed an AAV9-based vectorized miRNA to knockdown human UBE3A-ATS and durably unsilence paternal *UBE3A* for potential long-term genetic correction. Screening of >120 human miRNA sequences identified top candidates capable of near-complete paternal *UBE3A* unsilencing in human iPSC neurons, with lead candidate, ETX201, emerging as the most potent human candidate. Here, we evaluate safety, biodistribution, and *UBE3A* target engagement for ETX201 at two doses in wild-type (WT) non-human primates (NHPs) following unilateral intracerebroventricular (ICV) administration. In this study, we observe broad vector distribution and miRNA transcript expression in the brain, particularly in disease-relevant forebrain regions important for learning, memory, and cognitive functioning. The miRNA product is also detected in CSF and serum, with expression stabilizing by day 8 post-administration and remaining sustained throughout the 60-day study. ETX201 is well-tolerated in NHPs, with significant UBE3A-ATS knockdown and dose-dependent paternal *UBE3A* upregulation of 15–29% across multiple cortical and hippocampal brain regions post ICV delivery. These paternal *UBE3A* levels are within the efficacy range induced in our prior in vivo studies in an AS mouse model. In addition, ETX201 significantly increases total UBE3A RNA and protein in multiple cortical regions, surpassing the normal background levels in WT NHPs. Collectively, these data establish the feasibility of a one-time, AAV9-based approach for the treatment of AS and support further development of ETX201.

548 AAV-delivered *GRIN1* gene improves synaptic NMDA receptor function in mouse models of *GRIN* disorder
